1 HISTORY

1.1 Definition

The series of 14 elements from thorium (atomic number 90) through lawrencium (atomic number 103) are commonly referred to as the actinides. In the current periodic table, the f-block elements, actinides (5f) and lanthanides (4f) are separated from the other elements. This modern placement as well as their name is attributed to Prof. Glenn T. Seaborg, who in the 1930s proposed the actinide theory. As a result of this concept, the actinides were removed from their original placement in the Hubbard Periodic Chart of the Elements and joined in a new period with their rare earth analogs, the lanthanides. This arrangement allowed for the transactinide elements ($Z > 103$) to be properly placed within the d-block elements. While other machinations of the periodic table have been derived, for example, three dimensional with the f-block extending behind the main table, there remains one fundamental classification issue. The debate revolves around which element starts and ends the actinides. Traditionally, actinium has been considered a group III element and thorium, the first f-block; however, it has been postulated that lawrencium should occupy the position as the first group III element. This has led to a number of different graphical representations; however, the chemistry tends to be such that all 15 elements, actinium through lawrencium, may be considered and discussed together, as will be the case in this chapter.

1.2 Discovery and Production

The actinides are all radioactive elements. Actinium, thorium, protactinium, and uranium are the only four actinides that have been found in the environment; the others are artificial, being produced through various nuclear reactions. It should be noted that at the creation of the universe some amount of ^{244}Pu could have been formed; however, with an 80 million year half-life, it would have fully decayed during the past 10 billion years.

Uranium was the first actinide element to be identified. In 1789, M. H. Klaproth discovered the presence of a new element in a sample of pitchblende (impure, mineralized form of UO_2). Klaproth named the element uranite after the recently discovered planet Uranus. Nearly 100 years later, Becquerel made the initial discovery of the radioactive behavior of uranium through experiments with uranium minerals and photographic plates.

Thorium was discovered in 1828 by J. J. Berzelius in a Norwegian mineral. As a result of its Norwegian legacy, thorium was named after Thor, a mythological Scandinavian god. In addition to having a natural long-lived isotope, thorium is constantly produced in nature through the decay of ^{235}U and ^{238}U.

The earliest discovery of actinium is attributed to A. Debierne in 1899, with F. Giesel also identifying and isolating the element in 1902. The name actinium is derived from the Greek word for ray, ‘aktinos’, which acknowledges the radioactive behavior of the element.

Protactinium was the last of the naturally occurring actinides to be identified. The original name for the element, brevium (latin for ‘brief’), was suggested by K. Fajans and O. H. Göhring, who first identified the radioactive element in 1913. However, after ^{231}Pa was isolated by groups in Germany (O. Hahn and L. Meitner) and the United Kingdom (F. Soddy and J. Cranston), it was ultimately named after the Greek word ‘protos’, meaning first. It is the rarest and most expensive of the naturally occurring actinide elements.

As previously stated, the remainder of the actinides are artificial, produced either through neutron irradiation or heavy-ion bombardment followed by various nuclear decay paths. Table 1 provides the details of the original synthesis, including date, discovering group, and nuclear process.

1.3 Radioactivity

All of the actinide elements have unstable nuclei and therefore are radioactive. The types of radiation that can be encountered are alpha, beta, neutron, and gamma. This ionizing radiation provides both advantages and disadvantages when studying the chemistry of the actinides.

Table 1 Identification and synthesis of the actinide elements

Element	Date	Discovering group(s)	Synthesis	Available quantities
Actinium (89) Ac derived from Greek word for ray (*akinos*)	1899	A. Debierne	Naturally occurring	kg
Thorium (90) Th named after Thor, mythological Norse god	1828	J. J. Berzelius	Naturally occurring	kg
Protactinium (91) Pa derived from Greek word for first (*protos*)	1913	K. Fajans, O. Gorhing O. Hanh, L. Meitner F. Soddy, J. Cranston	Naturally occurring	kg
Uranium (92) U named after the planet uranus	1789	M. H. Klaproth	Naturally occurring	kg
Neptunium (93) Np named after the planet neptune	1940	E. M. McMillian, P. H. Abelson	Bombardment of $^{238}_{92}$U with $^{1}_{0}$n	kg
Plutonium (94) Pu named after the planet pluto	1940	G. T. Seaborg, E. M. McMillian, A. C. Wahl, J. Kennedy	Bombardment of $^{238}_{92}$U with $^{2}_{1}$H	kg
Americium (95) Am named after America	1944	G. T. Seaborg, R. A. James, L. O. Morgan	Bombardment of $^{239}_{94}$Pu with $^{1}_{0}$n	kg
Curium (96) Cm named after P. and M. Curie	1944	G. T. Seaborg, R. A. James, L. O. Morgan, A. Ghiorso	Bombardment of $^{239}_{94}$Pu with $^{4}_{2}$He	g
Berkelium (97) Bk named after University of California, Berkeley	1949	S. G. Thompson, A. Ghiorso, G. T. Seaborg	Bombardment of $^{241}_{95}$Am with $^{4}_{2}$He	mg
Californium (98) Cf named after the State and University of California	1950	S. G. Thompson, K. Street, A. Ghiorso, G. T. Seaborg	Bombardment of $^{242}_{96}$Cm with $^{4}_{2}$He	µg
Einsteinium (99) Es named after A. Einstein	1952	Argonne Nat'l Lab, Los Alamos Nat'l Lab, University of California	Multiple neutron capture by $^{235}_{92}$U in a thermonuclear explosion	µg
Fermium (100) Fm named after E. Fermi	1953	Argonne Nat'l Lab, Los Alamos Nat'l Lab, University of California	Multiple neutron capture by $^{235}_{92}$U in a thermonuclear explosion	µg
Mendelevium (101) Md named after D. Mendeleev	1955	A. Ghiorso, B. G. Harvey, G. R. Choppin, S. G. Thompson, G. T. Seaborg.	Bombardment of $^{253}_{99}$Es with $^{4}_{2}$He	atoms
Nobelium (102) No named after A. Nobel	1957–1963	A. Ghiorso, T. Sikkeland, J. R. Walton, G. T. Seaborg	Bombardment of $^{243}_{95}$Am with $^{15}_{7}$He	atoms
Lawrencium (103) Lr named after E. Lawrence	1961–1965	A. Ghiorso, T. Sikkeland, A. E. Larsh, R. M. Latimer	Bombardment of $^{249-252}_{98}$Cf with $^{10}_{5}$B and $^{11}_{5}$B or $^{243}_{95}$Am with $^{18}_{8}$O	atoms

One of the most common topics asked of those who work with the actinides relates to handling procedures. The radioactive nature of these elements does require the use of special facilities, processes, and precautions. However, working with radioactive elements in subcritical quantities is as safe, if not safer, than handling many of the toxic chemicals found in a typical synthetic laboratory. The primary advantage in handling radioactive material is the ease with which these elements can be detected. Unlike other toxic chemicals, for example, lead, thallium, arsenic, and so on, a simple survey (seconds) with a radiation detector will show if containment of the material has been lost, where it is, and approximately how much is present. With appropriate monitoring, virtually no uptake of radioactive material occurs, and if any personnel contamination does occur, it is quickly detected and treated. It is interesting to note that with proper planning and limiting the quantity of material that is handled in an experiment, the overall annual radiation exposure for people working in a synthetic or analytical radiological laboratory is less than that found for aircraft crew. In order to fully mitigate the risks of handling radioactive material and maintain a minimum radiation fields, it is important to have an understanding of the nuclear processes that are typically involved or could occur.

An example of a common situation that leads to greater radiation exposure levels than would be expected occurs with some uranium compounds. Depleted uranium ^{238}U is an α-emitting isotope with an extremely long half-life, 4 billion years. As a result of this long half-life, ^{238}U is generally not considered to present a significant radiation hazard. However, uranium fluorides, a typical synthetic starting material, can

undergo an αn reaction in which a neutron is released from the fluorine nucleus upon reaction with the uranium-emitted α-particle.

The interaction of radiation with matter can have profound effects. Whether in solid, solution, or gaseous states, radioactivity can impact the environment and therefore change the molecular speciation of the actinides. To put this into perspective, three examples are discussed below: plutonium metal, americium crystals, and an aqueous solution of plutonium.

The most commonly used isotope of plutonium is ^{239}Pu, which has a half-life of 2.41×10^4 years. When the ^{239}Pu atom decays, an α-particle with an energy of 5 MeV and an ^{235}U atom with an energy of 86 keV are emitted. For Pu metal, this emitted α-particle or He nucleus travels approximately 10 µm, while the heavier α-recoil atom, ^{235}U, travels 12 nm. As these fragments travel through the metallic structure, Pu atoms are displaced off their lattice positions, forming Frenkel Pairs. For each disintegration, approximately 2600 Frenkel Pairs are formed, and over the course of 20 years, every atom in a piece of Pu metal has switched positions. This property becomes critical when trying to predict the long-term behavior of Pu materials.

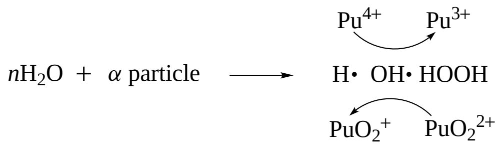
While metallic structures can do a significant degree of self-annealing, single crystals of molecular complexes can suffer irreversible damage in a relatively short time. The best example of this can be found in crystals of Am compounds. ^{241}Am has a half-life of 432.7 years. When a single crystal containing this highly radioactive material is isolated and analyzed by X-ray analysis, the intensity of the diffraction from the crystal has been observed to decrease with time, presumably as the crystal lattice is damaged. In the extreme, a visible change can occur where an originally clear crystal can become opaque in less than a day. These issues can partially be alleviated by using ^{243}Am, which has a half-life of 7.38×10^3 years. However, the radiation clearly provides a certain level of difficulty in obtaining crystal structures of molecular Am compounds.

In aqueous solutions of ^{239}Pu, the emission of α-particles has an entirely different effect. Scheme 1 shows the reactions that can occur in acidic solutions of Pu. The highly energetic α-particle causes the radiolysis of water, producing H and OH radicals as well as hydrogen peroxide. In acidic conditions, these species reduce Pu^{4+} and $PuO_2{}^{2+}$ ions to give Pu^{3+} and $PuO_2{}^{+}$, respectively. The radiolysis along with the disproportionation and reproportionation reactions shown in Scheme 2 results in oxidation state changes for ^{239}Pu solutions. An example of this instability is represented by an acidic solution of $PuO_2{}^{2+}$, which degrades by being reduced to Pu^{4+} at a rate of approximately 1.5% per day.

The effect of radiation on actinide containing materials and solutions can be altered by careful selection of the isotopes. For uranium, plutonium, americium, and curium, there are a number of different isotopes with varying half-lifes that can be used. In Table 2, the commonly available isotopes of the

$$2Pu^{4+} + 2H_2O \rightleftharpoons Pu^{3+} + PuO_2{}^{+} + H^{+}$$
$$Pu^{4+} + PuO_2{}^{+} \rightleftharpoons Pu^{3+} + PuO_2{}^{2+}$$
$$2PuO_2{}^{+} + H^{+} \rightleftharpoons Pu^{4+} + PuO_2{}^{2+} + 2H_2O$$

Scheme 1



Scheme 2

light actinides are listed along with the production methods and decay mechanisms. In the case of the plutonium example given above, by using the ^{242}Pu isotope, which has a half-life an order of magnitude greater than ^{239}Pu, solutions that show much lower radiation effects, for example longer oxidation state stability, can be made.

2 USES

This section is not intended to be an inclusive list of the uses of the actinides. The uses highlighted were selected on the basis of how widespread the use is or where inorganic and/or coordination chemistry of the actinides play a central role.

2.1 Nuclear Fuel Cycle

There are more than 400 operating nuclear reactors throughout the world. These reactors supply nearly 17% of the world's total electricity production capacity. The dependence on nuclear power varies significantly from country to country with some like Lithuania and France, which derive approximately 80% of their electricity from nuclear power to the United States, which while having the largest number of reactors at 104, only pulls 20% of its electricity from nuclear sources.

In order to address the needs for nuclear fuel, many countries have gone to a closed fuel cycle, which entails multiple steps, including mining, conversion, enrichment, fuel fabrication, fuel burning, spent fuel storage, reprocessing, stabilization, and disposal. Owing to the many transformations and separations required during these steps, inorganic coordination chemistry plays vital roles throughout the entire nuclear fuel cycle. As such, the fuel cycle is a prime example of the juncture of fundamental, applied, and environmental actinide chemistry.

Table 2 Half-lifes, mode of production, and decay mechanisms for the most widely used isotopes of the light actinides

Element	Isotope	Half-life (year)	Route of production	Decay
89 Ac	227	21.8	Natural	β
90 Th	232	1.40×10^{10}	Natural	α
91 Pa	231	3.25×10^4	Natural	α
92 U	235	7.04×10^8	Natural	α
	238	4.47×10^9	Natural	α
93 Np	237	2.14×10^6	${}^{235}_{92}U \xrightarrow{{}^1_0n} {}^{236}_{92}U \xrightarrow{{}^1_0n} {}^{237}_{92}U \longrightarrow {}^{237}_{93}Np + \beta^-$	α
94 Pu	238	86.4	${}^{237}_{93}Np \xrightarrow{{}^1_0n} {}^{238}_{93}Np \xrightarrow{{}^1_0n} {}^{238}_{94}Pu + \beta^-$	α
	239	2.41×10^4	${}^{238}_{92}U \xrightarrow{{}^1_0n} {}^{239}_{92}U \xrightarrow{{}^1_0n} {}^{239}_{93}Np + \beta^- \longrightarrow {}^{239}_{94}Pu + \beta^-$	α
	242	3.76×10^5	${}^{239}_{94}Pu \xrightarrow{3{}^1_0n} {}^{242}_{94}Pu$	α
	244	8.26×10^7	${}^{242}_{94}Pu \xrightarrow{2{}^1_0n} {}^{244}_{94}Pu$	α
95 Am	241	432.7	${}^{239}_{94}Pu \xrightarrow{2{}^1_0n} {}^{241}_{94}Pu \xrightarrow{{}^1_0n} {}^{241}_{95}Am + \beta^-$	α
	243	7.38×10^3	${}^{241}_{95}Am \xrightarrow{2{}^1_0n} {}^{243}_{95}Am$	α
96 Cm	248	3.40×10^5		α

Uranium ore is typically mined or leached *in situ*. For the mined ore, the raw material is milled to produce a high surface area slurry, which is then treated with H_2SO_4. The sulfuric acid oxidizes the uranium to the soluble hexavalent state. The addition of base to the solution precipitates an oxide of uranium known as ‘yellowcake’, U_3O_8. A similar process is used for the in situ leaching of uranium ore except that the initial treatment is performed on bores with a slightly acidic and high oxygenated aqueous solution that is raised to the surface and allowed to go through an extraction process to remove the uranium.

No matter which mining process is used, the final U_3O_8 is converted to UF_6 through a multistep process that takes the uranium through multiple species and oxidation states. In the first step of the conversion process, the uranium is purified by dissolving the yellowcake in nitric acid to produce the soluble uranyl ion, $UO_2{}^{2+}$, and purifying the aqueous stream through a solvent extraction process. The purified uranyl nitrate, $UO_2(NO_3)_2{\cdot}6H_2O$, is heated to produce uranium trioxide, UO_3. The conversion of UO_3 to UF_6 is not an efficient process, so the oxide is reduced at high temperatures by H_2. The resulting UO_2 is treated with HF to give UF_4, commonly known as ‘green salt’. A reaction between UF_4 and gaseous F_2 is the final step in the conversion process and yields nearly quantitatively gaseous UF_6.

The purpose of going through the entire conversion process is to obtain a uranium compound that can be run through a separations process to produce a product that is enriched in ^{235}U. Natural uranium is about 0.7% ^{235}U; however, electricity producing light water nuclear reactors require 3 to 5% ^{235}U. The gaseous UF_6 allows for multiple enrichment techniques to be used, including gaseous diffusion, gaseous centrifugation, and laser techniques. The first two techniques rely on the mass differences between ^{235}U and ^{238}U to effect the separation. By far the most commonly used physical method for enrichment is gaseous diffusion.

Once enriched, the UF_6 needs to be reduced to either uranium metal or UO_2 to be formed into fuel pins. A variety of methods can be used to accomplish the conversion to the oxide; however, the predominately used technique involves reduction of the UF_6 to U metal fully, using Ca at high temperatures, followed by burning in oxygen. Once formed, the UO_2 is pressed into pellets, which are then fed into fuel rods.

The burning of the uranium-based nuclear fuel causes a cavalcade of chemical and physical transformations. Nuclear reactions lead to the formation of a variety of actinide elements, for example, Np, Pu, Am, and Cm, as radioactive fission products. As a result of the production of these highly radioactive elements, burnt nuclear fuel must be allowed to ‘cool’ until the short-lived isotopes decay away and reduce the thermal generation. The cooling typically takes place in either water ponds or engineered dry casks/facilities.

Once ‘cooled’, the fuel can be manipulated within hot cell facilities for fuel reprocessing. In the United States, the reprocessing of spent nuclear fuel has not been embraced. The primary basis for this decision is the reduction of the threat of nuclear proliferation by avoiding the production of pure streams of plutonium. Some of the other concerns for reprocessing are based in economics. Through the Advanced Fuel Cycle Initiative within the U.S. Department of Energy, the technical feasibility of an economically, politically, and environmentally viable fuel cycle that includes recycling is being investigated. Despite the US efforts, most of countries that have nuclear production capabilities use reprocessing.

The chemistry of reprocessing is quite complex, but it embodies nearly every common aspect of inorganic chemistry: coordination, reduction/oxidation reactions, hard–soft

acid–base theory, and so on. The primary purpose of reprocessing is to separate uranium and plutonium from the rest of the actinides and fission products that are present in the spent nuclear fuel. The method of choice to perform these separations is liquid–liquid extraction, for example PUREX process. To effect the primary separation, the spent fuel is dissolved in 7 M HNO_3. The resulting solution contains the uranyl ion, $UO_2{}^{2+}$, and tetravalent plutonium cation, Pu^{4+}. This aqueous solution is contacted with an organic solvent, for example kerosene, which contains tributylphosphate, $OP(OBu_n)_3$ (TBP). The TBP molecule coordinates uranium and plutonium nitrate complexes and makes them soluble in the organic phase. The molecules predominately attributed to this extraction are $UO_2(NO_3)_2(TBP)_2$ and $Pu(NO_3)_4(TBP)_2$; however, research continues to show that these simple formulations may not accurately represent the speciation or the chemical environment during the extraction. In order to separate the uranium and plutonium, a reducing agent, for example $Fe(SO_3NH_2)_2$, in an aqueous phase is contacted with the actinide-laden organic phase. The Pu^{VI} is reduced to Pu^{III}, which does not form a strong complex and therefore selectively partitions to the aqueous phase. The uranium and plutonium can be purified further and the respective oxides produced. The oxides are then combined to produce a new nuclear fuel called *mixed oxide fuel* (*MOX*).

The remaining actinides and fission products must be stabilized for interim storage, long-term storage or final disposal. In order to optimize the storage facilities, some additional separations of the remaining actinides and fission products are required. The European Union has been leading the course in the implementation of advanced separation schemes, including diamide extraction (DIAMEX), selective actinides extraction (SANEX) and SESAME. In DIAMEX, a diamide is used to separate the actinides and the lanthanides from the fission products. In SANEX, a dithiophosphinic acid is proposed to separate the actinides from the lanthanides. The reason this process works is the slightly higher degree of covalency that occurs in the bonding of the actinides versus the lanthanides. In the SESAME process, americium and curium are separated using heteropolyanions, for example phosphotungstate $P_2W_{17}O_{61}{}^{10-}$, that coordinate Am(IV) but not Cm(III).

The stabilization of the nuclear waste products is usually performed by immobilizing the oxides of the radioactive material in glass. This process is known as vitrification. The environmental aspects of storing large quantities of radioactive glass logs are related to the leachability of the elements from the glass structure.[1,2]

2.2 Nuclear Weapons

Outside of nuclear energy, the most well-known utilization of the actinides is in nuclear weapons. The fissile nature of ^{235}U and ^{239}Pu has been exploited in the creation of nuclear arsenals throughout the world. Primarily found in the metallic state within the weapons, the isotopic and chemical purifications of these elements require complex separation chemistry and physics that are dependent on inorganic and coordination compounds.

2.3 Depleted Uranium Armor and Projectiles

Another military use of the actinide metals is in tank armor and armor piercing projectiles. Depleted uranium metal is an extremely dense material, for example, density of α-phase U is $\sim$19 g cm^{-3}, and is only mildly radioactive, half-life of ^{238}U is 4.5×10^9 years. When this metal is incorporated into a projectile, the density and metallic properties allow it to penetrate deeply into heavily armored vehicles.

2.4 Heat Sources

The portable generation or storage of power is essential to space exploration. In addition, maintaining working parts in the cold vacuum of space requires constant generation of heat. The electrical and heat requirements for a typical space mission, for example, landing a rover on the surface of Mars, drive the need for extremely dense power sources. One of the densest sources of energy is stored within the nucleus of radioactive materials. In order to tap into this energy source, space agencies have relied on plutonium in the form of the α-emitting ^{238}Pu isotope. The half-life for ^{238}Pu is 87 years, and when the dioxide is formed into pellets, it self-heats, producing an orange glow. The following example can be used to emphasize the energy density of these materials: a 250-g (3 cm in diameter) $^{238}PuO_2$ ball acts as a 100-W heat source. The publicity of using these heat sources peaked in 1997 with the launch of the Cassini–Huygens Mission to Saturn and Titan. The Cassini spacecraft was equipped with more than 200 $^{238}PuO_2$ pellets (150 g each) within three radioisotope thermoelectric generators (RTGs). Each one of these RTGs put out 4400 W of thermal energy at 1200 to 1300 °C. Thermocouples are able to convert this thermal energy into 285 W of electricity. As for pure heat generation, the Cassini spacecraft and the Huygens probe use radioisotope heating units (RHUs). The RHUs are constructed with 2.7-g pellets of $^{238}PuO_2$ and maintain a temperature of 35 to 40 °C.

2.5 Smoke Detectors

Americium plays a vital role in maintaining the safety of homes across the world. The α-emitting ^{241}Am isotope can be found in most smoke detectors in the form of the dioxide, AmO_2. The α-particle emission causes the air to ionize between two electrodes. The ionization of the oxygen and nitrogen allows a steady current to flow between the electrodes. However, when smoke enters the detector, the α-particles are absorbed by the smoke and therefore ionize less of the air, which causes the current to drop and the alarm to signal.

2.6 Lantern Mantles

One of the primary uses of thorium was in the production of lantern mantles. (Note: new materials have replaced Th, but older Th-based lantern mantles can still be found.) The mixture of 99% ThO_2 and 1% CeO_2 particles were impregnated into the mantle fabric. The burning of the ThO_2 produces a fairly bright light. However, the addition of the CeO_2 increases the thermal conductivity and catalyzes the combustion of the gas, allowing the flame to be brighter than would be possible with a thorium-only system.

2.7 Catalysis

Thorium and uranium are used in commercial catalytic systems. Industrially, thorium is used in the catalytic production of hydrocarbons for motor fuel. The direct conversion of synthetic gas to liquid fuel is accomplished by a Ni-ThO_2/Al_2O_3 catalyst that oxidatively cracks hydrocarbons with steam. The primary benefit to the incorporation of thorium is the increased resistance to coke deactivation. Industrially, U_3O_8 also has been shown to be active in the decomposition of organics, including benzene and butanes and as supports for methane steam reforming catalysts. Uranium nitrides have also been used as a catalyst for the cracking of NH_3 at 550 °C, which results in high yields of H_2.

3 OVERVIEW OF GENERAL TRENDS

Discussions of the chemistry and physical properties of the actinide elements are based typically around the nature of the 5f-electrons. Comparisons are routinely made between the actinides and their 4f-bretheren, the lanthanides. For true comparisons, it is convenient to separate the actinides into two distinct groups, the light or early actinides (Ac–Am) and the heavy or late actinides (Cm–Lr). The chemistry of the light actinides is intermediate between that of the transition metals, for example, the ability to access multiple oxidation states and engage covalent bonding, and that of the lanthanides, for example, significant degree of ionic bonding. Conversely, the chemistry of the late actinides is very reminiscent of their lanthanide analogs. The most common and stable oxidation state for the heavy actinides is the trivalent state, and the bonding is almost entirely ionic in nature.

3.1 Oxidation States

The chart of oxidation state and f-electron configuration between the actinides and the lanthanides is provided in Figure 1. The light actinides exhibit significant oxidation state variability with valences from II to VII. The boxes with question marks indicate oxidation states that have been reported in the literature once but are questionable and have not

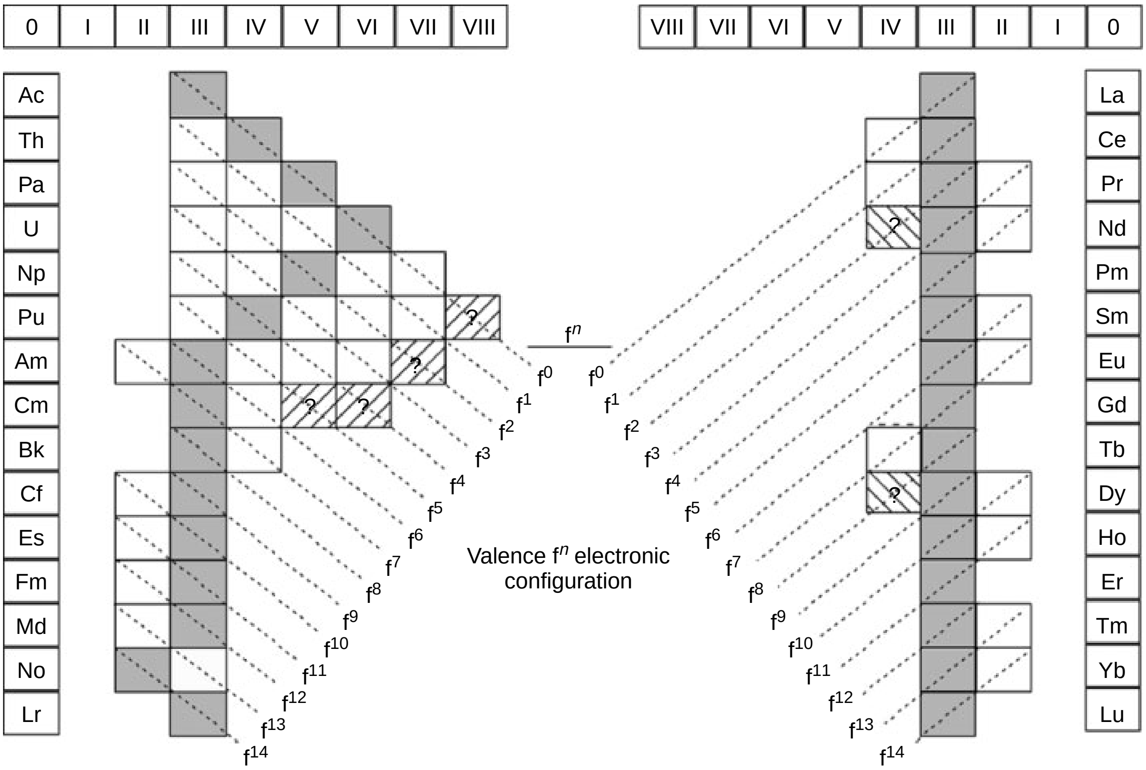


Figure 1 Classification of actinides and lanthanides

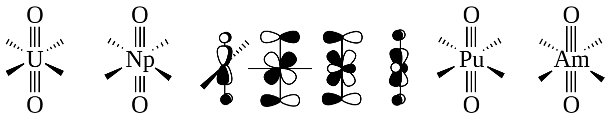
been verified by a secondary source. The maximum possible oxidation state can be reached for the elements from Ac through Np. There has been a single report for the synthesis of a Pu^{VIII} complex; however, this result has not been confirmed. In addition to being able to reach the maximum possible oxidation state to get to a f^0 system, the most stable oxidation state increases from Ac to U, Ac^{III}, Th^{IV}, Pa^{V}, and U^{VI}. After U, the most persistent oxidation state declines, for example, Np^{V}, Pu^{IV}, Am^{III}, until Cm, in which the trivalent ion continues to be the stable species. The only exception to this is No, where the divalent state predominates.

3.2 Chemical Characteristics

The majority of the chemistry that has been investigated for the actinide elements has been in aqueous solutions. For the light actinides in acidic solutions, four types of cations persist: trivalent, tetravalent, pentavalent, and hexavalent. The later two ions are always found to have trans oxo ligands, making up a linear dioxo unit. Actinide ions of this type are typically referred to 'yls' and have the names, uranyl (**1**, $UO_2^{+/2+}$), neptunyl (**2**, $NpO_2^{+/2+}$), plutonyl (**3**, $PuO_2^{+/2+}$), (**4**, $AmO_2^{+/2+}$) and so on.



(**1**) (**2**) (**3**) (**4**)

The metal ion affinity to form complexes is dependent on the oxidation state and the actinide element. For the cations stable in acidic solutions, the ligand-binding constants are generally greatest for the tetravalent state, followed by the trivalent and hexavalent states, which tend to be similar, and least for the pentavalent state. It should be noted that the lack of binding affinity of the pentavalent state for the light actinides, for example, Np and Pu, leads to some of the primary issues in the environmental migration of the ions. This general trend can be attributed to changes in the charge to size ratio of the ion as well as the electronic repulsion of the oxo ligands on the penta- and hexavalent ions. The charge to size ratio can also change for a given oxidation state on going across the actinide series. The increase in this ratio across the series is due to the decreasing ionic radii of the actinide ions through a phenomenon called the *actinide contraction*. The actinide contraction is discussed in the next section but is equivalent to the lanthanide contraction that leads to similar ionic radii being observed between second- and third-row transition metals.

The electrochemistry of the light actinides is impacted by the stability of the linear dioxo unit. The redox reactions in which there is no making or breaking of an An=O bond are fast and reversible, for example, reducing the tetravalent to the trivalent. However, when the making or a breaking of the An=O bond is required, for example, oxidizing the tetravalent to the pentavalent, the electrochemistry tends to be slow and irreversible.

The structure and bonding within coordination complexes of the light actinides will be discussed in the following section. However, the general trend between the actinides and the lanthanides is a larger degree of covalency in An–L bonds versus Ln–L bonds. In aqueous solutions, the predominant bonding interaction with ligands is ionic in character, and, therefore, the number and geometry of the ligands is mainly determined by pure steric and electrostatic considerations. For example, a wide range of coordination numbers (6–14) has been found for the actinide ions.

4 STRUCTURE AND BONDING WITH f ORBITALS

As was noted in the previous section, the structure and bonding of the actinides is partly driven by the nature of the 5f orbitals. For the lanthanides, the 4f orbitals are deeply buried and do not penetrate the core. Being almost completely screened by the 5s- and 5p-electrons, 4f orbitals have little to no chemical significance. This is one of the reasons that the trivalent state of the lanthanides are the most stable, formed through the ionization of the two 5s- and one 5p-electrons. Conversely, the 5f orbitals have a greater spatial expansion and also penetrate the core. Owing to the relatively small energy differences between the 5f, 6d, 7s, and 7p orbitals, multiple oxidation states can be obtained and covalent bonding can be engaged.

4.1 Electronic Configuration

The electronic configurations of the gas-phase actinide ions are given in Table 3. In order to determine these configurations, electronic spectra are taken. These spectra tend to be very complicated and, thus, make absolute determination of the configuration difficult. As a result, a number of configurations have question marks appended, indicating that either disagreement or doubt in the assignment exists. Despite these controversies, a general trend in the sequential filling of the f orbitals does exist.

4.2 Coordination Numbers and Stereochemistry

The coordination chemistry of the actinides in aqueous environments can be segregated along two lines, low valency (di-, tri- and tetravalent) and high valency (penta- and hexavalent). For actinide ions with a low valency, the coordination chemistry is dominated by ionic bonding. As a result, the coordination number and geometry of these aqueous complexes is dictated by the steric bulk and electronic

Table 3 Valence level electronic configuration of the actinides in the gas phase

Actinide	Ac	Th	Pa	U	Np	Pu	Am	Cm	Bk	Cf	Es	Fm
Z	89	90	91	92	93	94	95	96	97	98	99	100

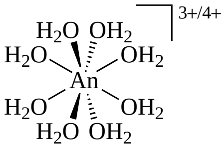
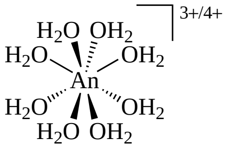
M^{4+} (g)			5f	$5f^2$	$5f^3$	$5f^4$	$5f^5$	$5f^6$	$5f^7$	$5f^8$	$5f^9$	$5f^{10}$

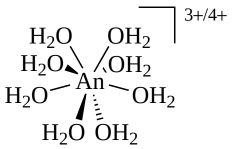
repulsion of the ligands. The actinide ions are relatively large with the ionic radii for the An^{3+} and An^{4+} ions being 1.12 to 0.95 Å and 0.94 to 0.82 Å, respectively. As a result of their size, the actinides are found to have large coordination numbers, 6 to 14. Some examples of the typical coordination geometries for the tri- and tetravalent actinide ions are shown in structures (**5–10**). Structure (**5–8**) are the potential geometries for the aquo ions, $An(H_2O)_{8/9}{}^{3+/4+}$. Structures (**5–7**) are eight-coordinate with a cubic, square antiprism, and a bicapped trigonal prism arrangement of the ligands, respectively. The coordination number in Structure (**8**) is nine with a tricapped trigonal prismatic geometry. The higher coordination numbers are observed with multidentate ligands, for example, $CO_3{}^{2-}$ and $NO_3{}^-$. Structure (**9**) represents the $An(CO_3)_5{}^{6-}$ anion that has a coordination number of 10, resulting from five bidentate carbonate ligands in an irregular geometry. The structure can almost be compared with the high-valent linear dioxo compounds with two trans carbonate ligands occupying the axial sites and three nearly planar carbonate ligands occupying a pseudo-equatorial plane. The $An(NO_3)_6{}^{2-}$ anion is extremely important in the purification and processing of actinides, for example plutonium. Structure (**10**) represents the coordination geometry for this anion, which has six bidentate nitrate ligands, giving the ion a coordination number of 12. The symmetry for Structure (**10**) is T_h with three sets of trans nitrato groups, each making a plane in the Cartesian coordinate system.



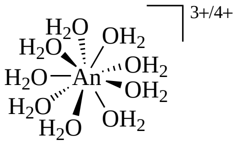
(**5**)



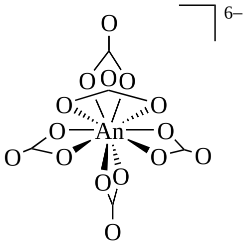
(**6**)



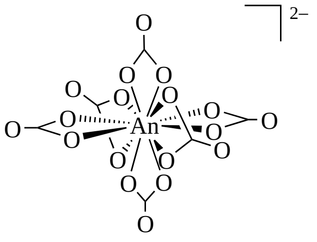
(**7**)



(**8**)

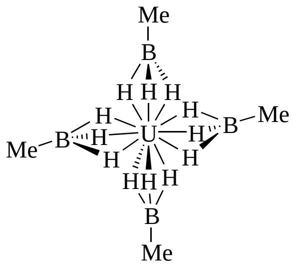


(**9**)

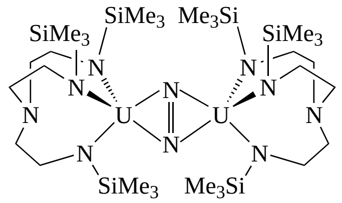


(**10**)

The nonaqueous chemistry of the tri- and tetravalent ions follows similar trends as the aqueous complexes. Coordination numbers are dictated by the steric bulk and electronic properties of the ligands; two structures, $U(MeBH_3)_4$ (**11**) and $[\{U(N(CH_2CH_2NSiMe_3)_3)\}_2(\mu^2\text{-}\eta^2 : \eta^2\text{-}N_2)]$ (**12**), are shown. Direct comparisons of the latter species can be made to the behavior of transition metals in both coordination and reactivity.



(**11**)



(**12**)

For the high-valent aqueous actinide species, the predominant linear dioxo unit, $AnO_2{}^{+/2+}$, drives all of the coordination variability into the equatorial plane. It is interesting to note that the bonding for these ions have significant covalency with the axial An–O ligands. However, for the majority of the ligands residing in the equatorial plane ('belly-band'), the bonding is primarily ionic. This shows the dual behavior (strong covalency and ionicity) of the trans dioxo ions. As a result of this behavior, the linear dioxo unit is unperturbed (with the exception of bond distance changes) throughout all of the aqueous-based complexes and the coordination numbers are dictated by the equatorial ligands' size and electronic properties. The structures of a variety of aqueous-based coordination complexes have been observed. Compounds with a D_{4h} symmetry are represented by the complexes, $AnO_2Cl_4{}^{2-}$ (**13**) and $NpO_4(OH)_2{}^{3-}$ (**14**). Seven-coordinate structures are also prevalent in actinide chemistry and are the highest coordination numbers achievable with all monodentate ligands. The

aquo ion (**15**) and pentafluoro (**16**) complex for the hexavalent actinides are represented below. Coordination complexes under aqueous conditions with eight atoms bound to the actinide are achievable.

(**16**)

4.3 Ionic Radii and the Actinide Contraction – A Partial Relativistic Effect

The ionic radii of the actinides is shown graphically in Figure 2. The ionic radii for a given oxidation state gradually decreases with increasing atomic number. This phenomenon is known as the actinide contraction. Similar to the lanthanide contraction, the cause of the contraction is an increase in the effective nuclear charge experienced by the valence shell electrons. The increase in the effective nuclear charge is a result of the additional protons and the poor shielding ability of the f-electrons due to their diffuse angular radial function. Relativistic effects also contribute to the lanthanide and actinide contractions. With heavy atoms, the core electrons approach speeds that are close to the speed of light. When these fast rates are obtained, the mass of the electron increases as described by the special theory of relativity. The mass of the electron has an inverse relationship with the Bohr radius, meaning as the mass increases the electron radius decreases. There are two different relativistic effects, direct and indirect. In general, direct relativistic effects are found for the s and p orbitals, which contract owing to an increase in the mass of these electrons. Indirect relativistic effects are predominantly found for the d and f orbitals, which generally have increased radii resulting from the enhanced shielding of the nuclear charge by the contracted s- and p-electrons. Understanding the difference between direct and indirect relativistic effects is actually a function of analyzing the angular wavefunctions of the s, p, d, and f orbitals. The s- and p-electrons have a greater probability of being found at the nucleus (minimal angular nodality) and, thus, greater probability of approaching the speed of light. The diffuse nature of the d and f orbitals reduces the lifetime of the electrons close to the nucleus and, therefore, the probability of being accelerated. Relativistic effects increase as a function of the atomic number, Z^n ($n > 1$), and, therefore, actinides have greater relativistic effects compared to the lanthanides. The effect can be recognized easily by looking at the calculated radial distribution functions of Sm^{3+} and Pu^{3+} with and without relativistic effects. In both ions, the s and p orbitals contract and the d and f orbitals expand; however, the magnitude of the effect is clearly greater in the case of the Pu^{3+} ion.

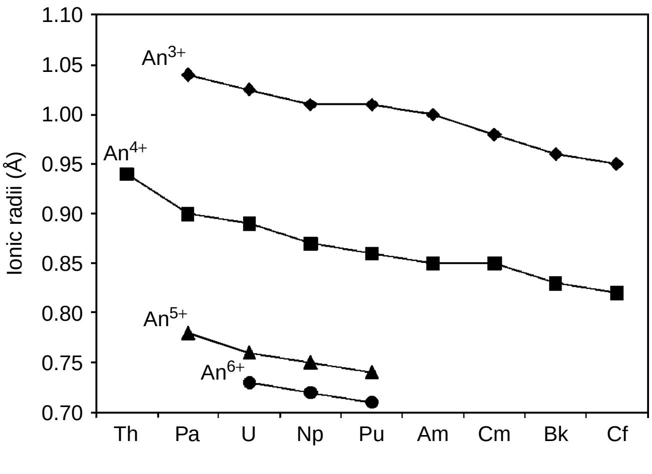

Figure 2 Ionic radii of actinide ions

4.4 Molecular Orbital Descriptions – The Linear Dioxo Diagram

Actinide complexes rarely follow the conventional rules, for example, 18-electron rule, typically found in inorganic and coordination chemistry of the transition metals. A prime example of the difference in actinide chemistry is the pervasiveness of the linear dioxo unit, which is unmatched in transition metal chemistry. For the actinides, the trans dioxo structure is maintained through different metal ions, oxidation states, and valence electron counts, for example, $UO_2^{2+/+}$ (f^0/f^1), $NpO_2^{2+/+}$ (f^1/f^2), $PuO_2^{2+/+}$ (f^2/f^3) and $AmO_2^{2+/+}$ (f^3/f^4). In transition metal dioxo complexes, MO_2L_x, the oxo ligand geometry (cis or trans) is almost entirely dependent on the electron count. For $ReO_2(CH_3)_3$ (d^0 system) (**17**), the oxo ligands are cis in order to maximize the π-bonding, while the oxo ligands in $ReO_2(py)_4$ (d^2 system) (**18**) are found in a trans geometry to minimize electronic repulsions with the unpaired metal-based electrons residing in the equatorial dx^2-y^2 orbital.

As a result of this disparity, many questions on the structure and bonding of the actinides center on the role of the 5f-electrons. The molecular orbital descriptions for the bonding of the actinide elements continue to evolve. One of the first general models used to describe the chemical bonding in d- and f-electron complexes is the 'FEUDAL' model. FEUDAL is an acronym for 'f *orbitals* essentially unaffected **d** orbitals accommodate ligands'. This model is represented in Figure 3, which depicts the molecular orbital

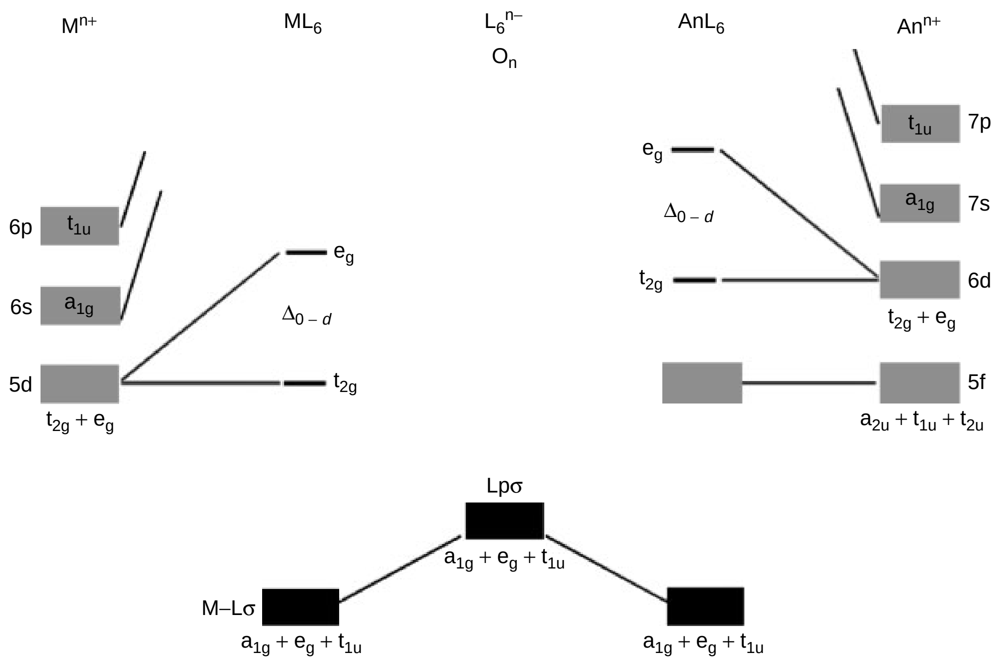

Figure 3 Bonding in actinide complexes

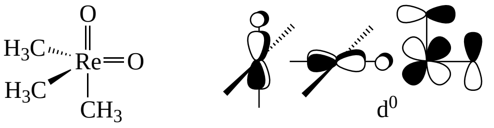
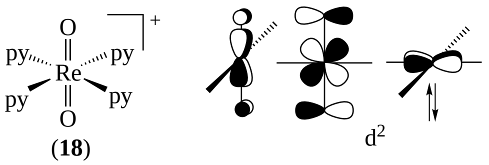


(**17**)



(**18**)

diagram for a transition metal ion (left) and an actinide ion (right) binding to six monodentate ligands in an octahedral geometry.

The transition metal diagram shows the valence shell 5d, 6s, and 6p orbitals being raised in energy due to interactions with the ligand's p-based σ-orbitals. The typical splitting of the d orbitals occurs and the electrons fill these orbitals on the basis of the transition metal being investigated. For the actinide, there is a greater energy mismatch between the ligand's orbitals and the 7s, 7p, and 6d orbitals. This energy difference weakens the covalent bonding. The 5f orbitals are also at energy levels that are below the 6d orbitals and therefore act as a reservoir of the metal-based electrons. As can be seen, the f-electrons have orbitals of the correct symmetry to interact, t_{1u}; however, their spatial expansion is believed to be insufficient to overlap with the ligand's orbitals. This lack of overlap is the reasoning for essentially leaving the f orbitals unaffected.

In general, the FEUDAL model appears to answer many of the fundamental questions regarding the bonding within f-electron systems; however, certain discrepancies exist within the physical data of the actinide systems and the theoretical understanding of the radial distribution functions of the actinides. Evidence that the f orbitals are accessible for covalent bonding continues to be found.

A number of important observations can be made from the calculated radial distribution functions of the f elements, including: the 4f orbital are considerably buried within the core; the 5f orbitals have a great enough spatial extension such that ligands that approach close enough to the metal center (<2 Å) can engage these orbitals for bonding; and the 7s and 7p orbitals are really too diffuse to be useful for chemical bonding.

On the basis of these observations and new quantum calculations[3] using density functional theory, a more accurate molecular orbital diagram for the linear dioxo actinide system has emerged (Figure 4). In this diagram, mixing of the actinide $5fz^3$ orbital with the filled 6pz occurs, which allows for a more significant overlap with the oxygen 2p σ-orbitals. For oxo ligands, the f orbitals can also engage in π-bonding as evidenced by the raising of the π_u 5f orbitals.

5 ELECTROCHEMICAL PROPERTIES

The ability of the light actinides to access multiple oxidation states leads to rich, and, sometimes, complex electrochemistry. The standard reduction potentials at pH $= 0$ for each of the

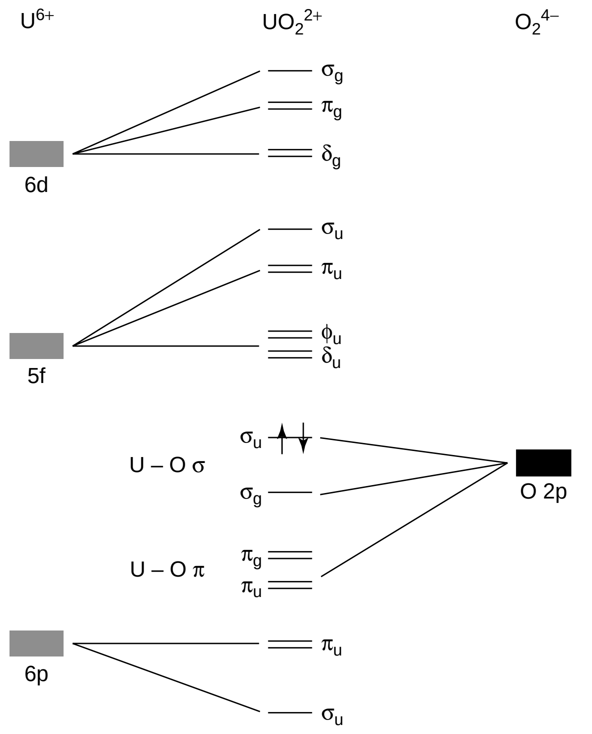


Figure 4 Bonding in uranyl complexes

actinides are given in Table 4. The stability of the oxidation states shown in Figure 1 are supported by these data and some interesting properties of the actinides can be derived. For example, U^{III} is able to reduce H_2O, while U^{IV} and Np^{IV} can be stabilized in anaerobic aqueous solutions. Another example is the unique electrochemical properties of plutonium. The reduction potentials for the four common oxidation states of plutonium under acidic conditions are all close to 1 V. The physical manifestation of having similar reduction potentials is an aqueous solution in which the plutonium can exist in four different oxidation states simultaneously (PuO_2^{2+}, PuO_2^{+}, Pu^{4+} and Pu^{3+}). Equations (1) and (2) dictate the equilibrium of these species. The equilibrium constants for these equations are dependent on the ionic strength and equation (2) has a fourth order dependence on the $[H^+]$, making the equilibria quite complicated. For a one molal solution ($HClO_4$), the equilibrium constants are 12.7 and 6.46×10^{-4}, respectively. With these constants, the speciation of an aqueous Pu solution at pH = 1 can be calculated at ~60% Pu^{III}, ~20% Pu^{VI}, and ~10% each of Pu^{IV} and Pu^{V}.

$$Pu^{4+} + PuO_2^{+} \rightleftharpoons Pu^{3+} + PuO_2^{2+} \qquad (1)$$

$$Pu^{4+} + 2H_2O \rightleftharpoons Pu^{3+} + PuO_2^{+} + 4H^{+} \qquad (2)$$

The reduction potentials are also dependent on the pH of the solution. Dramatic changes in the redox potentials of Np and Pu have been observed on progressing from acid (1 M) to base (1–10 M). For example, the reduction potential for Np^{VII}/NpO_2^{2+} is reduced by nearly 2 V! Scheme 3 shows the reduction potentials for Np and Pu at either 1 or 10 M NaOH solutions. As can be seen, the potentials are such that the

1 M NaOH

$$Np^{VII} \xrightarrow{+0.59\ V} NpO_2^{2+} \xrightarrow{+0.14\ V} NpO_2^{+} \xrightarrow{-0.95\ V} Np^{4+}$$

higher oxidation states can be stabilized in aqueous solutions, including the heptavalent ions of Np, Pu, and possibly Am. It should be noted that this phenomenon follows the expected trend based on an increase in the electron density on the metal center with changing the speciation from $AnO_2(H_2O)_x{}^{2+}$ in acidic conditions to $AnO_2(OH)_{4/5}{}^{2-/3-}$ in highly alkaline solutions.

The equilibria and variety of species discussed above would seem to make studying the specific oxidation states of actinides difficult. However, through careful control of the conditions, oxidation state pure solutions for all of the actinides can be obtained for synthetic, quantitative and/or qualitative studies.

6 CHARACTERIZATION OF ACTINIDE COMPLEXES

The radioactive nature of the actinides, especially the transuranics, can introduce significant challenges in the characterization of their complexes. In order to prevent contamination, multiple layers of containment are often required, which can limit the types of studies that can be undertaken. However, a suite of spectroscopic tools has been used to study the chemistry and speciation of the actinides. A partial list of these techniques includes absorption, emission and vibrational spectroscopies, X-ray absorption and diffraction, and multinuclear magnetic resonance.

The absorption spectroscopy in the UV-Vis-NIR is especially rich for the actinides, allowing for fairly simple determinations of the metal oxidation state. The primary absorption bands result from $f \rightarrow f$ transitions, $f \rightarrow d$ and ligand-to-metal charge transfers. The $f \rightarrow f$ transitions are typically weak since they are forbidden under the LaPorte selection rules. Distortions in symmetry allow for relaxation in these rules and bands in the visible to near-infrared range result. Complexes that contain an inversion symmetry, for example $PuO_2Cl_4{}^{2-}$, have weaker $f \rightarrow f$ transitions ($\varepsilon < 20\,M^{-1}\,cm^{-1}$). The direct interactions of the 5f orbitals with the ligand set generally make the absorption bands broader than the absorption spectra of comparable lanthanide species. The charge transfer bands in actinide complexes can be intense and lead to the variety of colors observed for the actinides with varying oxidation states or ligands. Vibronic coupling also plays a significant role in the absorption spectra of actinide complexes. The prime example of this vibronic coupling is observed in the visible spectra of $UO_2{}^{2+}$ species. In these complexes, the ν_1 stretching mode ($\sim$800–900 cm^{-1}) resulting from an excited state of the linear dioxo unit couples with the absorption manifold to give the appearance of multiple peaks with approximately the same energetic separation. Absorption techniques have been used extensively in studying the aqueous chemistry of the actinides, especially when linked with potentiometric titrations.

The emission spectroscopy is also used to study the speciation of the actinides. Compounds with isotopes of uranium, americium, and curium fluoresce in the visible range, making detection relatively easy. Neptunium and plutonium fluoresce in the near-infrared region, and recent developments in detectors may allow for more facile measurements. The power of emission spectroscopy is the ability to run at variable temperatures and low concentrations in both solution and solid phases. The luminescence from the actinide complexes is strongly dependent on both energy and lifetime of the speciation products. In a similar fashion as the absorption spectra of $UO_2{}^{2+}$, vibronic coupling occurs. The primary difference between the two is that in the emission spectra the ground-state vibrations of the $AnO_2{}^{2+}$ are probed.

The ubiquitous linear dioxo unit gives an excellent handle to use vibrational spectroscopy in studying the speciation of high-valent aqueous complexes of the actinides. Both IR and Raman spectroscopy have been utilized. For IR, the observation of the stretching frequencies of the dioxo unit are complicated by the relatively small window available for water. Attenuated total reflectance cells have significantly aided the examination of aqueous actinyl complexes by providing the requisite background subtraction. Raman spectroscopy does not have the same issues when measuring actinide complexes in water. For actinyl complexes, the ν_1 stretch is dependent on ligands in the equatorial plane. In general, the ν_1 stretch of the O=An=O weakens with the addition of better σ- or π-donor ligands.

Nuclear magnetic resonance (NMR) techniques have been increasingly used for studying the actinides. Th(IV), U(VI), and Np(VII) complexes are diamagnetic, and a range of multinuclear methods can be used, including ^{13}C, ^{1}H, ^{19}F, and so on. Most complexes with the other actinides and other oxidation states of uranium and neptunium are paramagnetic. The paramagnetism causes a shift and broadening of the NMR signals similar to transition metal species. One of the nuclei that has relatively narrow lines for paramagnetic complexes is the quadropolar ^{17}O. The oxo groups of the actinyl ions can be labeled with ^{17}O by reducing the metals to the tetravalent state and reoxidizing to the penta- or hexavalent state in an ^{17}O-enriched aqueous solution. Unlike the transition metals, the actinide complexes that have the narrowest line-widths are those with either an f^0 or odd f-electron configuration. For example, Np^{VII} (f^0) and $NpO_2{}^{2+}$ (f^1) have visible ^{17}O-NMR peaks, whereas the peaks for $NpO_2{}^{+}$ (f^2) are so broad that they cannot be observed.

Another technique that has been increasingly used for determining actinide speciation is X-ray absorption. These measurements are typically made at synchrotron radiation laboratories where extremely high energy X-rays (15–25 keV) with high fluxes can be generated and used to interrogate a sample. The techniques are element specific, which allows for the ability to probe heterogeneous samples, for example environmental substances. The X-ray absorption near edge spectrum (XANES) is able to give information on the oxidation state of the actinide. For example, a linear relationship between

the edge energy and oxidation state of plutonium has been reported. The structure near the absorption edge can also shed light on the structure of the actinide, for example, presence of an actinyl unit. The variability in the ligands can also cause a shift in the edge position; however, this is typically a much smaller effect than the oxidation state. The X-ray absorption fine structure (XAFS) that results after the primary absorption can be used to give structural information. This technique essentially gives the ability to obtain data from any solid or solution similar to that gained from a single-crystal X-ray diffraction study. The primary difference is that no angular information can be determined from XAFS, but the type, number, and bond distances of atoms bound to a metal can be.

7 AQUEOUS COORDINATION COMPLEXES

The most basic coordination complex in aqueous solutions is the aquo ion. For most metals in the periodic table that form ions in aqueous solutions, the coordination number and geometry of the aquo ion is well known. For a majority of the actinides, controversies still exist as to the exact number of H_2O molecules that are bound to the metal centers. The uncertainty in the structures is linked to the limited number of crystal structures that exist for actinide aquo complexes. This lack of data is related to the difficulty in crystallizing materials from aqueous solutions. The most well studied aquo ion of the actinides is $UO_2(H_2O)_5{}^{2+}$. This ion has been crystallized from noncoordinating perchloric acid solutions through either concentration or addition of 18-crown-6. For the latter case, the crown ether interacts with the H_2O molecules bound to the uranium through hydrogen bonds. These same crystallization techniques have been attempted to obtain crystal structures of the hexavalent Np, Pu, and Am ions; however, X-ray quality single crystals of the aquo ions have not been obtained, sometimes due to oxidation state changes or inner-sphere complexation by the crown ether. From EXAFS, structural data on the aquo ions have been obtained for the hexavalent ions, $AnO_2(H_2O)_5{}^{2+}$ (An = U–Am). For calibration purposes, the bond distance for the oxo ligands of the $UO_2{}^{2+}$ species obtained from XAFS and single-crystal analyses show a nearly identical length. The bond An = O distance was found to be 1.76, 1.75, 1.74, and 1.80 Å for An = U, Np, Pu, and Am, respectively. The An–OH_2 distance for the same complexes was found to be 2.42, 2.42, 2.41, and 2.40, respectively.

For those actinides stable in the pentavalent state, ions of the form $AnO_2(H_2O)_x{}^{+}$ (An = Np, Pu; x = 4, 5, 6) have been postulated. Pa^{V} is not included in this list since it readily hydrolyzes in aqueous solutions to form $Pa_2O_5 \cdot xH_2O$. All of the structural data for these complexes come from XAFS. The bond distances for both An=O (1.83 Å for both Np and Pu) and An–OH_2 (2.51 and 2.5 Å, respectively) expand in the pentavalent ions in line with an increase in the ionic radii with the change in oxidation state.

Tetravalent ions of the actinides can be stabilized in aqueous solutions for Th to Am. Owing to the more intense radiation fields generated by Am, maintaining oxidation state pure samples is difficult (α radiolysis spontaneously promotes the reduction of Am^{IV} to Am^{III}). For those ions that have been studied, complexes of the form $An(H_2O)_x{}^{4+}$ (An = Th, U, Np, Pu; x = 9–12) have been proposed. The most widely accepted values for the number of H_2O molecules bound to the metal center are 10 for Th and 9 for U to Pu. The An–OH_2 distances in these ions range from 2.50 to 2.46 Å.

The trivalent plutonium aquo ion, $[Pu(H_2O)_9]^{3+}$, has been crystallized with nine H_2O ligands in a tricapped trigonal prismatic geometry.[4]

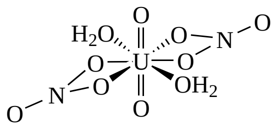
Salts of oxo anions, such as nitrate, sulfate, perchlorate, iodate, hydroxide, carbonate, phosphate, oxalate, and so on, are important for the separation and reprocessing of technologically important actinides, while hydroxide, carbonate, and phosphate ions are important for the chemical behavior of the actinides in the environment. The general trends of complexes formed in aqueous solutions are as follows:

- for $AnO_2{}^{n+}$ (n = 1, 2) complexes: as H_2O is replaced as a ligand by better σ-, π-, or ionic donors, for example, OH^-, F^-, Cl^-, $CO_3{}^{2-}$, the An=O distance increases and the ν_1 decreases;
- on transitioning between $AnO_2{}^{+}$ to An^{4+}: the lack of the linear dioxo unit in the lower valent complexes results in a slight decrease in the An–L bond distance;
- the determination of end members for a specific ligand in an aqueous-based actinide system will be the easiest to determine because of the ubiquitous presence of multiple equilibria, for example, $UO_2Cl_2(H_2O)_2$, $UO_2Cl_3(H_2O)^-$, and $UO_2Cl_4{}^{2-}$ for the uranyl chloride system.

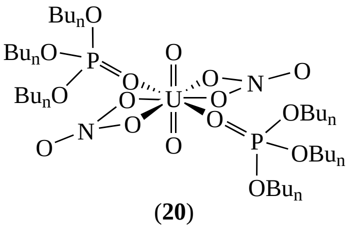
7.1 Nitrates

Hexavalent. Nitrate complexation with actinide ions is very weak, and the determination of the formation constants for aqueous nitrate solution species is extremely difficult. Under aqueous conditions with high nitric acid concentrations, complexes of the form $AnO_2(NO_3)(H_2O)_x{}^{+}$, $AnO_2(NO_3)_2(H_2O)_2$, and $AnO_2(NO_3)_3{}^{-}$ (An = U, Np, Pu) are likely to be present. Solids of the anionic trisnitrato complex have been isolated for U and Np[5,6] however, minimal structural data have been obtained. Solid uranyl nitrate, $UO_2(NO_3)_2 \cdot xH_2O$, is obtained as the orthorhombic hexahydrate from dilute nitric acid solutions and as the trihydrate from concentrated acid. The Np analog can be precipitated from a mixed aqueous HNO_3 and MeCN solution by the addition of 18-crown-6. Multiple structural determinations have been made for the hexavalent uranium nitrate complexes, and all show the common formula unit of

$UO_2(NO_3)_2(OH_2)_2$ (**19**) with a local hexagonal bipyramidal coordination about the central uranyl ion. The average An=O bond distances for the actinyl dinitrate complex were found to be 1.76 and 1.74 Å for U and Np, respectively, while the $An-OH_2$ distances (2.44 Å) and $An-O_{nitrate}$ (2.49 Å) distances were identical for the two actinides. The actinyl dinitrato complex is also known to bind other neutral donors to form compounds of the form $AnO_2(NO_3)_2L_2$ (L = TBP, MeCN, DMF, $MeCO_2Et$, etc.). As with all of the other neutral adducts, the technologically important $AnO_2(NO_3)_2(TBP)_2$ (An = U, Np, Pu) (**20**) complex displays trans nitrate ligands with the TBP ligands occupying the same coordination sides as H_2O in (**19**).



(**19**)



(**20**)

Pentavalent. The complexation of the Pa and Np pentavalent ions by nitrate is known; however, limited thermodynamic and structural data are known. For Pa, mixed hydroxo/nitrato or oxo/nitrato complexes have been proposed. The presumed structure for the Np^V species is $NpO_2(NO_3)(H_2O)_x$.

Tetravalent. Nitrate complexes for tetravalent actinides, for example, Th and Pu, are extremely important in actinide separation and purification processes. The limiting species in the nitrate series is the hexanitrato complex, $An(NO_3)_6{}^{2-}$.[7] There is reasonable evidence for the formation of aqueous U(IV) nitrate complexes of the general formula $U(NO_3)_n{}^{4-n}$, where $n = 1$ to 4. However, owing to the inherent weakness of the complexes, quantitative data on the formation constants is only available for $U(NO_3)^{3+}$ and $U(NO_3)_2{}^{2+}$. No neutral U(IV) nitrates have been obtained from aqueous solutions, but a number of anionic complexes of general formula $M_2[U(NO_3)_6]$, where M = NH_4, Rb, Cs, and $M[U(NO_3)_6]\cdot 8H_2O$, where M = Mg, Zn, have been isolated and characterized. These solids contain the 12-coordinate anionic U(IV) center. Neutral, U(IV) nitrate complexes of formula $U(NO_3)_4L_2$ (L = $OP(C_6H_5)_3$, $OP(NC_4H_8)_3$) have also been isolated from aqueous solutions and structurally characterized.

7.2 Sulfates

Hexavalent. The aqueous actinyl sulfate systems have been widely studied for uranium and complexes of formula $AnO_2(SO_4)_n{}^{2-2n}$, where $n = 0$, 1, and 2, are likely to be formed in solution. For the transuranics, the neutral compounds $AnO_2(SO_4)\cdot 2.5H_2O$ (An = Np, Pu) have been isolated and characterized by the X-ray analysis, which confirmed comparable structures with the U analog. A number of ternary An(VI) sulfates of the general formula $(M)_k(AnO_2)_m(SO_4)_n\cdot xH_2O$, where M = monovalent cation, that is, NH_4 or alkali metals, $M(AnO_2)_m(SO_4)_n\cdot xH_2O$, where M = bivalent cation, such as alkaline-earth or transition metals (Mn, Cd, Hg), have been reported. In one of the more simplistic systems, $K_4UO_2(SO_4)_3$, each uranium has a pentagonal bipyramidal geometry with five-coordinated oxygen atoms from four sulfate groups in the equatorial plane. The crystal structure for $Cs_2NpO_2(SO_4)_2$ is composed of anionic layers of $[NpO_2(SO_4)_2]_n{}^{2n-}$ with bridging sulfate groups.

In addition to traditional aqueous chemistry to produce actinide sulfate phases, hydrothermal synthetic methods have been utilized. The novel phases, $[N_2C_5H_{14}]_2[UO_2(SO_4)_3]$, $[N_2C_5H_{14}][UO_2(H_2O)(SO_4)_2]$, $[N_2C_4H_{14}][UO_2(SO_4)_2]$, and $[N_2C_4H_{14}][(UO_2)_2(H_2O)(SO_4)_3]\cdot H_2O$ have been synthesized by high-temperature organic-templated reactions.

Pentavalent. Protactinium is known to bind sulfate in solutions of H_2SO_4; however, very limited data are available on the molecular species. Sulfate complexes with the general formula of $NpO_2(SO_4)_n{}^{1-2n}$ ($n = 1-3$) have been reported. In most of these complexes, the Np is found in a seven-coordinate pentagonal bipyramid geometry.

Tetravalent. The An^{IV} (An = Th, U, Np and Pu) sulfate system has also been studied in strongly acidic solutions. $An(SO_4)_2\cdot xH_2O$ ($x = 4, 6, 8, 9$) can be precipitated from weak and concentrated sulfuric acid solutions. For $An(SO_4)_2\cdot 4H_2O$ (An = Th, U, Np, Pu), the actinide atoms are surrounded by a square antiprism of O atoms, with each An bonded to four molecules of water and linked by bidentate bridging sulfate groups to other metal atoms. In these compounds, the bond distances observed for the $An-O_{phosphate}$ are significantly shorter than the $An-OH_2$, for example, 2.308 Å and 2.361 Å, respectively for the Np compound. Ternary An(IV) sulfates have also been described in the literature. Many of the compounds have layered structures and/or unusual coordination environments. The trisulfate of Np(IV) has been isolated as a Cs salt, $Cs_2Np(SO_4)_3\cdot 2H_2O$. In this compound, the Np^{IV} cation is coordinated to nine oxygen atoms in an irregular geometry. The structure of $K_4Pu(SO_4)_4\cdot 2H_2O$ was determined from powder diffraction and consists of dimeric units of $[(\mu^2\text{-}SO_4)_3Pu(\eta^2\text{-}\mu^2\text{-}SO_4)_2Pu(\mu^2\text{-}SO_4)_3]^{8-}$.[8]

Trivalent. The trivalent ions of the actinides have been found to bind sulfate ions. The simple hydrated sulfate salt, $An_2(SO_4)_3\cdot xH_2O$ has been proposed for U, Np, Pu, Am, and Cm. A crystal structure of $Am_2(SO_4)_3\cdot 8H_2O$ showed significant cross-linking of the Am atoms through sulfate ligands and an extensive hydrogen bonding network. The

coordinate sphere of the Am atoms is composed of eight oxygen atoms, four from sulfate ions and four from H_2O molecules. The Am–$O_{sulfate}$ distances ranged from 2.38 to 2.95 Å while the Am–OH_2 distances varied from 2.41 to 2.55 Å. Ternary complexes of the trivalent actinides are also known. For example, $MPu(SO_4)_2{\cdot}xH_2O$ has been isolated with a number of alkali metals and ammonium. The Pu in these compounds is nine-coordinate and is analogous to the lanthanide compounds of the same formula. It is interesting to note that the U^{III} sulfates, $U_2(SO_4)_3{\cdot}xH_2O$ ($x = 2, 5, 8$) and $M_2U_2(SO_4)_4$ are essentially the only available salts of trivalent uranium.

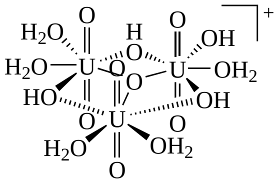
7.3 Hydroxides

Hydrolysis dominates the aqueous chemistry of actinide ions under conditions of high pH. The tendency for hydrolysis follows the acidity of the actinide cations, that is $An^{4+} > AnO_2^{2+} > An^{3+} > AnO_2^{+}$. The AnO_2^{2+} would appear to be an anomaly, since a 3+ cation would normally be predicted to be more acidic than a 2+ cation. However, the effective charge on the metal center is the key factor. The oxo groups of the AnO_2^{2+} ion do not completely 'quench' the hexavalent charge, and as a result, the residual effective charge on the metal center is approximately +3.3.

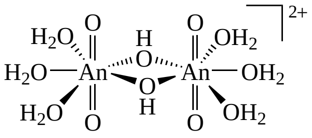
The hydrolysis products of the actinides have a tendency to undergo polymerization reactions, which can hamper the structural investigations of the speciation. One of the most observed plutonium species is the highly insoluble green colloidal Pu^{IV} hydroxide. In general, high concentrations of an actinide ion in near-neutral solution conditions (pH = 2–13) will lead to polymeric materials, while solutions with low actinide concentrations (10^{-5}–10^{-6} M, depending on the actual ion) favor monomeric complexes. Under highly alkaline conditions, some of the hydroxides of the actinides become amphoteric in nature, producing soluble monomeric and polymeric anions.

Tetravalent. The hydrolysis of tetravalent actinide ions can begin to occur in solutions with pH levels < 2. Under dilute conditions, species of the form $An(OH)_n^{4-n}$ ($n = 1$–4) are predicted; however, most hydrolysis studies have only been able to identify the first hydrolysis product, $An(OH)^{3+}$. It should be noted that in all of these compounds the remainder of the coordination sphere is made up of bound H_2O molecules. The end member of the speciation is the neutral $An(OH)_4$ or $AnO_2{\cdot}2H_2O$. This complex has low solubility but has been postulated to exist in solutions from solubility experiments when using the isolated solid as the starting material. Under more concentrated conditions, polymeric materials have been postulated. In modeling the hydrolysis of thorium at concentrations greater than mM, polynuclear species of the form $Th_2(OH)_2^{6+}$, $Th_2(OH)_4^{4+}$, $Th_4(OH)_8^{8+}$, $Th_6(OH)_{14}^{10+}$, and so on, have been included.

Hexavalent. As with most reactions, the hydrolysis of UO_2^{2+} is the best studied of the hexavalent actinides. The hydrolysis of UO_2^{2+} begins at pH ~ 3, while the onset for the hydrolysis of NpO_2^{2+} and PuO_2^{2+} each occur at a higher pH. The monomeric hydrolysis products of the uranyl ion, $UO_2(OH)_n^{2-n}$ ($n = 1, 2$) can be studied in solutions with uranium concentrations less than 10^{-4} M. For solutions with higher uranium concentrations, multinuclear cationic species dominate the speciation, for example, $(UO_2)_2(OH)_2^{2+}$, $(UO_2)_3(OH)_4^{2+}$, and $(UO_2)_3(OH)_5^{+}$. These cations have been crystallized from solutions with the formulas $(UO_2)_2(\mu_2\text{-}OH)_2(OH_2)_6^{2+}$ and $(UO_2)_3(\mu_3\text{-}O)(\mu_2\text{-}OH)_3(OH_2)_6^{+}$ (**21**). For Np and Pu, the dimer of the first hydrolysis product, $(AnO_2)_2(OH)_2^{2+}$ (**22**), has also been identified but not fully structurally characterized.



(**21**)



(**22**)

When alkali metal bases are used to raise the solution pH to moderate levels, the uranium will precipitate from the solution in the form of hydrous uranyl hydroxides or uranates, for example, $Na_2U_2O_7$. However, through judicious choice of a base, for example, tetramethylammonium hydroxide, (TMA)OH, or tetramethylammonium trifluoromethansulfonate, the study of the amphoteric behavior of uranyl hydroxides can be undertaken. Polynuclear anions of the form $(UO_2)_3(OH)_7^{-}$, $(UO_2)_3(OH)_8^{2-}$, and $(UO_2)_3(OH)_{10}^{4-}$ are examples of soluble species in solutions where the pH < 14. When the concentration of the (TMA)OH is increased (>0.6 M OH^-), highly soluble (~0.1 M) monomers of the form $UO_2(OH)_n^{2-n}$ ($n = 3, 4, 5$) have been reported. These three species are in equilibrium with each other; however, in solutions where the [OH^-] is greater that 1 M, the pentahydroxo complex predominates the speciation.

One of the common theories in actinide chemistry is the analog theory, which implies that the chemistry of the transuranics will mirror that of uranium. The behavior of Np and Pu in highly alkaline solutions offers an excellent example of the limitations of this theory. Unlike U, both Np and Pu are highly soluble (~0.1 M) in a variety of bases, for example MOH (M = Li, Na, K; [OH^-] > 1 M). Monomeric anions of the form, $AnO_2(OH)_x^{2-}$ ($x = 4, 5$) have been identified to be in equilibrium with each other, and, as for the uranium analog, the neptunyl tetrahydroxide has been crystallographically characterized by addition of $[Co(NH_3)_6]^{3+}$ to alkaline solutions. The bond lengths for the $AnO_2(OH)_4^{2-}$ have been established by both single-crystal X-ray diffraction studies and XAFS. The average An=O

distances for U, Np, and Pu are 1.82, 1.80, 1.77 Å, respectively, while the average An–OH distances are 2.26, 2.24, and 2.29 Å respectively.

Heptavalent. In highly alkaline solutions ($[OH^-] = 0.5–18$ M), the redox potentials for Np and Pu have shifted to the point that the heptavalent state can be stabilized for a limited time in aqueous solutions. The lifetime of the An^{VII} species is dependent on the base concentration; however, in general, Np^{VII} is significantly more stable than Pu^{VII}, for example, weeks versus days, respectively. Over the past few years, a significant interest has evolved in studying the structure of the heptavalent actinide ions. Two forms of Np^{VII} have been crystallographically characterized, $NpO_4(OH)_2^{3-}$ and NpO_4^-. The latter anion was isolated as a salt with Na^+ and K^+ cations. The structure of $KNpO_4$ is layered with the Np atoms bound to two oxo-type ligands (Np=O 1.?? Å) in axial positions and four bridging oxygen atoms (Np–O 2.?? Å) that make up the plane of the layer. The former complex has four shorter bonds (1.88 Å) corresponding to the four Np=O and two longer bonds Np–OH (2.33 Å) (**14**). This planar teraoxo arrangement is unique to heptavalent actinides having no transition metal or f element analogs.

7.4 Carbonates

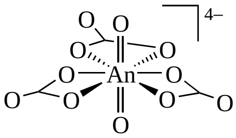
Actinide carbonate complexes are of interest not only because of their fundamental chemistry and environmental behavior but also because of extensive industrial applications, primarily in uranium recovery from ores and nuclear fuel reprocessing.

Trivalent. The trivalent actinides form simple carbonates of the formula $An_2(CO_3)_3$. When these solids are dissolved in aqueous solutions of alkali metal carbonates, anionic complexes are formed, for example $An(CO_3)_n^{3-2n}$ ($n = 2–4$).

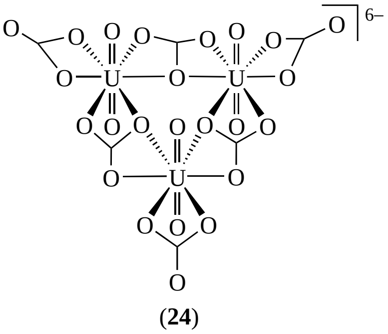
Tetravalent. The best-studied tetravalent actinide carbonato complex is $An(CO_3)_5^{6-}$ (An = Th, U, Pu). This anion has been isolated using a variety of cations, including Na^+, K^+, Tl^+, $[Co(NH_3)_6]^{3+}$ and $C(NH_2)_3^+/NH_4^+$. In solution, the pentacarbonato complex is the end member of the series $An(CO_3)_n^{4-2n}$ ($n = 1–5$); however, in the mineral tuliokite, $Na_6BaTh(CO_3)_6{\cdot}6H_2O$, thorium exists as a hexacarbonato complex. The analysis of the thermodynamic data for these actinide carbonate systems has led to differences of opinion on the actual speciation. The data appear to support both the stepwise addition of CO_3^{2-} and subsequent loss of H_2O molecules within the An^{4+} cation coordination sphere as well as the formation of mixed hydroxo carbonato complexes, for example $Pu(CO_3)_3(OH)^{3-}$.

Pentavalent. The binding of carbonate to pentavalent actinide ions has been studied for most of the light actinides (An = U, Np, Pu, Am). The primary species that have been reported are $AnO_2(CO_3)^-$, $AnO_2(CO_3)_2^{3-}$, and $AnO_2(CO_3)_3^{5-}$. As with all of the actinyl complexes, the carbonate ligands bind in the equatorial plane and in a bidentate fashion. As a result, the likely coordination geometry for the mono- and biscarbonato complexes in solution is a pentagonal bipyramid, while the triscarbonato complex has a hexagonal bipyramidal geometry. When crystallized, the mono- and biscarbonato complexes condense, allowing the carbonate ligands to bridge multiple actinide centers and typically resulting in a hexagonal bipyramidal geometry.

Hexavalent. The aqueous An(VI) carbonate system has been well studied. A multitude of An(VI) carbonate complexes have been identified, including monomeric, multinuclear, and mixed hydroxo carbonato complexes. The monomeric materials generally have the form $AnO_2(CO_3)_n^{2-2n}$ ($n = 1–3$). The end member of the carbonate series, $AnO_2(CO_3)_3^{4-}$ (**23**), has a hexagonal bipyramid geometry with the three bidentate carbonates occupying the equatorial plane. The mono- and biscarbonato complexes are typically five coordinate, with bidentate carbonate ligands and either three or one H_2O molecule. Under conditions with high actinide metal concentrations, multinuclear species can predominate, for example $(AnO_2)_3(CO_3)_6^{6-}$ (**24**). The U(VI) is the best studied of the hexavalent actinide carbonate complexes. The known uranium(VI) carbonate solids have empirical formulas $UO_2(CO_3)$, $M_2UO_2(CO_3)_2$, and $M_4UO_2(CO_3)_3$ (M = Na^+, K^+, Rb^+, Cs^+, NH_4^+, etc.). The monocarbonato compound, $UO_2(CO_3)$, is a mineral known as rutherfordine, and its structure has been determined from crystals of both the natural mineral and synthetic samples. Rutherfordine is a layered solid in which the local coordination environment of the uranyl ion consists of a hexagonal bipyramidal arrangement of oxygen atoms. Each uranium atom forms six equatorial bonds with the oxygen atoms of four carbonate ligands, two in a bidentate manner and two in a monodentate manner. The biscarbonato complex has been shown to form a trimeric anion of the form $(UO_2)_3(CO_3)_6^{6-}$ (**7**). This molecule possesses a D_{3h} planar structure in which all six carbonate ligands and the three uranium atoms lie within the molecular plane. The six uranyl oxygen atoms are perpendicular to the plane, with three above, and three below the plane. The local coordination geometry about each uranium is hexagonal bipyramidal.



(**23**)



(**24**)

7.5 Phosphates

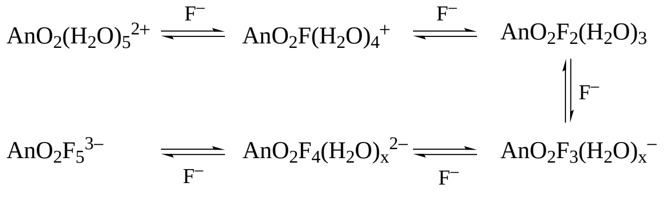
Inorganic phosphate ligands are important with respect to the behavior of actinides in the environment and as potential waste forms. There have been a number of experimental studies to determine the equilibrium constants in the actinide–phosphoric acid system, but they have been complicated by the formation of relatively insoluble solid phases and the formation of ternary actinide complexes in solution.

The chemistry of the phosphate system is complicated by the number of different ligands that are possible. In acidic solution (hydrogen-ion concentration range 0.25–2.00 M), H_3PO_4 and $H_2PO_4^-$ are potential ligands, whereas in neutral to basic solution, HPO_4^{2-} and PO_4^{3-} ligands are predominant. The phosphate salts are slightly soluble in water and dilute mineral acids. The synthetic methods to obtain solid phases of actinide phosphates include precipitation and high-temperature methods.

The trivalent actinides form simple insoluble phosphate salts of the form, $AnPO_4{\cdot}xH_2O$. Tetravalent actinides form a number of different phases including metaphosphates $An(PO_3)_4$, the pyrophosphate $An(P_2O_7)$, double phosphates $MAn_2(PO_4)_3$ and $M_2An(PO_4)_2$, and orthophosphates, $An(HPO_4)_2{\cdot}xH_2O$. Phosphates of the hexavalent actinyl ions also form complex complexes and solid phases. The predominate compounds include $AnO_2(HPO_4){\cdot}xH_2O$, orthophosphates $M(AnO_2)_n(PO_4)_m{\cdot}xH_2O$, hydrogenphosphates $M(AnO_2)_n(H_kPO_4)_m{\cdot}xH_2O$, pyrophosphates An_mO_n-P_2O_7, metaphosphates $(AnO_2)_n(PO_3)_m{\cdot}xH_2O$, and polyphosphates $(AnO_2)_n(P_aO_b)_m{\cdot}xH_2O$.

7.6 Halides

The best-studied aqueous actinide halide systems are the fluorides and the chlorides. Fluoride and chloride ions are added to the actinyl centers in a stepwise fashion (Scheme 4). The end member in the actinyl fluoride system is the pentafluoride, $AnO_2F_5^{3-}$. For the uranyl analog, the U = O and U–F bond distances were found to be 1.79 and 2.18 Å respectively. The uranium tetrafluoride ion, $UO_2F_4^{2-}$, has been isolated as a dimer with two bridging fluoride ligands. The U = O, U–$F_{terminal}$, and U–$F_{bridging}$ distances for this complex were found to be 1.79, 2.15 to 2.20 Å, and 2.30 Å, respectively.



Scheme 4

For the larger chloride ion, the final member in the series is the tetrachloride, $AnO_2Cl_4^{2-}$. The uranium, neptunium, and plutonium tetrachloride dianions have been isolated with a number of different cations, for example, Na^+, NH_4^+, K^+, Cs^+, $K^+{\cdot}$18-crown-6, and so on. The An=O distances were found to be 1.768, 1.751, and 1.737 Å for An = U, Np, and Pu, respectively. The An–Cl distances in these complexes is virtually unchanged: 2.675 Å (U), 2.659 Å (Np), and 2.656 Å (Pu). These structural data suggest that the chloride ligands are bound in essentially a purely ionic manner while the covalent nature of the An=O bond is preserved.

The lower valent actinide ions also bind the halides to form cationic complexes, for example, $AnX_n(H_2O)_m^{z-n}$ ($z = 3$, $n = 1$–6; $z = 4$, $n = 1$–7)[9] and $AnO_2X_n(H_2O)_m^{1-n}$ ($n = 1$–4).

7.7 Multidentate Ligands

Polycarboxylic Acids. Carboxylic acids have been found to bind strongly to actinide ions. The primary binding mode for the carboxylic acids is bidentate. The affinity of the low-valent actinides with these ligands increases with the density of the ligand, for example, ethylenediaminetetraacetate (EDTA) > acetate. For An^{4+}, the EDTA ligand is hexadentate with a twist conformation. Diethylenetriaminepentaacetate (DTPA) has an even higher affinity for both An^{3+} and An^{4+} ions.

Crown Ethers. The crown ether macrocycle, for example, 18-crown-6, has been found to coordinate An^{3+} and An^{4+} in both aqueous and nonaqueous conditions via an inner-sphere mechanism. For UO_2^{2+}, multiple compounds that contain crown ether ligands have been isolated. In most of these compounds, the crown ether interacts in an outer-sphere manner, engaging in hydrogen bonding with the ligands on the metal center. Inner-sphere coordination of UO_2^{2+} occurs only under strictly anhydrous conditions. For the Np system, the presence of a crown ether in aqueous solutions causes a reduction of the metal center from Np^{VI} and Np^{V} and a spontaneous inner-sphere coordination of the crown ether to form NpO_2(18-crown-6)$^+$. The linear dioxo unit in this complex sits perpendicular to the plane created by the six oxygen atoms of the crown ether molecule. The average Np=O distance for this complex is 1.85 Å and the average Np–O_{crown} distance is 2.?? Å.

8 NONAQUEOUS COORDINATION COMPLEXES

The coordination chemistry of the actinides, especially thorium and uranium, continues to be of great interest. Considered 'hard' metal ions, An(III to VI) have the

greatest affinity for hard donor atoms such as N, O, and the light halides. Tetravalent thorium and tetra- and hexavalent uranium, neptunium, and plutonium coordination complexes are the most common; however, trivalent and pentavalent complexes are being identified with increasing frequency. As with all of the actinides, the ionic radii of the ions are significantly larger compared to a transition metal ion in an identical oxidation state. The result of this increased ionic radius is an expansion of the possible coordination environments (3- to 14-coordinate) and electron counts (up to 24 electrons). The structure and bonding in the nonaqueous complexes of the actinides like that of the aqueous complexes involves a mixture of ionic and covalent bonding. While it is impossible to positively correlate which orbitals are being utilized or if bonding is covalent or ionic, the fact that the 5f elements form complexes with ligands like N_2 and CO suggests that a significant covalent component is present in the complex formation.

8.1 Starting Materials

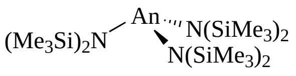
Choosing, obtaining, or synthesizing the appropriate starting material is critical in order to investigate the coordination chemistry of the actinides in nonaqueous environments. For thorium, the two most common starting materials are $ThCl_4$ and $ThBr_4(THF)_4$. In synthesizing $ThBr_4(THF)_4$, thorium metal is reacted with two equivalents of Br_2 in THF at 0 °C. This reaction can be run on very large scales, 100 to 200 g product. For uranium, neptunium, and plutonium, the three common starting materials for tri-, tetra- and hexavalent complexes are $AnI_3(THF)_4$, $AnCl_4$, and AnO_2Cl_2 (An = U, Np, Pu), respectively. The first material, $AnI_3(THF)_4$, is prepared in THF at 0 °C by adding I_2 to metal chips or turnings.[10] The uranium analog is deep purple, the neptunium is orange, and the plutonium analog is off-white. The synthetic routes to obtain $AnCl_4$ are provided in Section 9. For the green UCl_4, the preferred synthetic method involves the reaction of UO_3 with hexachloropropene. For the hexavalent starting material, AnO_2Cl_2, the most efficient synthetic route is the oxidation of $AnCl_4$ with O_2 at 350 °C.

8.2 Nitrogen Donors

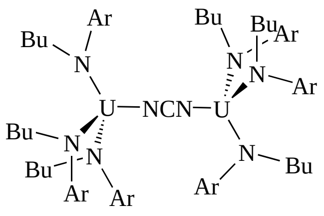
The coordination chemistry of the light actinides with N-donating ligands is one of the better-studied areas. Numerous N-donor ligands have been complexed with the actinides, including neutral mono-, bi-, and polydentate ligands, that is, ammonia, primary, secondary, and tertiary amines, alkyl–aryldiamines (en = ethylenediamine, 1,4-diaminobenzene), N-heterocycles (py = pyridine, bipy = bipyridine, terp = terpyridyl), nitriles (CH_3CN), anionic amides ($[N(C_2H_5)_2]^-$, $[N(Si(CH_3)_3)_2]^-$), thiocyanates, and polypyrazolylborates. A majority of the published work with these ligand sets has been with complexes of Th and U; however, some complexes of Np and Pu have also been reported.

Trivalent. The study of trivalent light actinide coordination complexes with N-donors is complicated by the relative ease of oxidation. Some examples of the isolated materials include $AnX_3(NH_3)_n$ (X = Cl, Br), AnI_3py_4, $AnI_3(tmed)_2$, and $AnCl_3(CH_3CN)$. The homoleptic complexes $[An(CH_3CN)_9]^{3+}$ (An = U, Pu)[11] have been synthesized by dissolution of $UI_3(THF)_4$ and oxidation of plutonium metal in CH_3CN. Both complexes have a nine-coordinate trigonal prismatic geometry. The pyramidal tris-silylamido complexes, $An[N(Si(CH_3)_3)_2]_3$ (An = U, Np, Pu)[10,12] (**25**) have been synthesized and have been shown to be useful starting materials for the synthesis of other trivalent or tetravalent compounds.

Other less bulky trisamido An^{III} complexes, for example, $U[N(R)Ar]_3$ (R = Bu and Ar = 3-5-$Me_2C_6H_3$), have been shown to elicit some interesting chemistry. When the $U(NRAr)_3$ complex is produced *in situ* by reduction of $UI(NRAr)_3$ in the presence of $Mo[NPh(t\text{-}Bu)]_3$ and N_2, an end-on N_2-bridged complex of the form $[(NRAr)_3U(\mu\text{-}N_2)Mo_3^{13}]$.[13] A similar reaction has also been found with cyanoimide where a dinuclear uranium complex was isolated, $(\mu^2;\eta^1,\eta^1\text{-NCN})\{U[N(R)Ar]_3\}_2$ (**26**).[14]



(**25**)



(**26**)

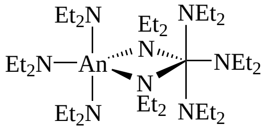
Another ligand that has received considerable attention in actinide chemistry over the past few years is tren- or trisamidoamine, $[N(CH_2CH_2N)SiMe_2Bu_t]^{3-}$ (NN_3').[15–20] This ligand forms more stable complexes than the trisamido complexes owing to the forced facial coordination and the chelate effect. The purple $U(NN_3')$ can be synthesized by reduction of the tetravalent $UI(NN_3')$ complex with K in pentane or by fractional sublimation of $[\{U(NN_3')\}_2(\mu\text{-Cl})]$. Lewis bases adducts, for example, pyridine, HMPA, of $U(NN_3')$ have been isolated. The oxidation of $U(NN_3')$ or its derivatives using trimethylamine N-oxide gives rise to U^{IV} and U^V complexes of the form, $[^{18}_{2}(\mu\text{-O})]$ and '$U(NN_3')O$', respectively. As with the other trisamido complexes, $U(NN_3')$ reacts reversibly with N_2 to give a side-on bound product, $[^{16}_{2}(\mu^2\text{-}\eta^2{:}\eta^2\text{-}N_2)]$. While the N–N bond distance in this complex is essentially the same as in free dinitrogen, the preference for the side-on over end-on bonding is explained on the basis of covalent interactions where the dinitrogen πp

orbital is a better σ-donor than the σp orbital to trivalent uranium.[21]

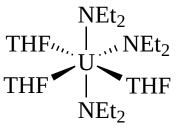
Polypyrazol-1-yl borates of the form $U(HBpz_3)_mI_{3-m}(THF)_n$ ($m = 1$, $n = 2$; $m = 2$, $n = 0$) and $[PuCl(\mu\text{-}Cl)^{22}\text{-}(Me_2pzH)]_2$[22] have been reported. For the $(UI[HB(Me_2pz)_3])_2$ complex, the pyrazolyl borate ligand binds in an unusual side-on fashion.

Tetravalent. A number of coordination complexes of An^{IV} with N-donor ligands have been characterized. Traditional adducts of AnX_4 (An = Th, U, X = halogen, alkoxide) have been isolated with a variety of neutral N-donor ligands, for example, monodentate (ammonia, primary to tertiary amines, nitriles, isocyanides, N-heterocyclics) and bidentate (diaminoalkanes, diaminoarenes, N-heterocyclics). The coordination numbers for these complexes generally range from 8 to 12. As with transition metals, increasing the steric bulk of the ligands can lead to lower coordination numbers, for example, $An(OR)_4(NH_3)_n$ (R = alkyl, aryl; $n = 1, 2$).

Amido complexes of An^{IV} are highly reactive to insertion reactions and protonation. For example, $[An(NR_2)_4]_n$ (R = alkyl, aryl)[23] undergo insertion reactions with CO_2, COS, CS_2, and CSe_2 to form carbamate complexes and react with alcohols to form alkoxide complexes. The structure of the amido complexes varies with the steric bulk of the ligand. With larger groups, for example, phenyl and pseudo-tetrahedral, monomeric complexes result, while with smaller alkyl groups, dimeric complexes with a trigonal bipyramidal geometry predominate (**27**). Cationic complexes have also been stabilized with amido ligands, for example, the pseudo-octahedral $[U(N(C_2H_5)_2)_3(THF)_3]B(C_6H_5)_4$ (**28**).[24–26]



(**27**)



(**28**)

As with the case of the trivalent actinides, the tren, trisamidoamine (NN'_3), ligand has been used to stabilize An^{IV} complexes. The preparation of $[An(NN'_3)Cl]_2$ is accomplished by the reaction of the trilithium salt of NN'_3 with $AnCl_4$ (An = Th, U).[27] The chloride ligand can be exchanged using metathetical reactions to form $An(NN'_3)X$ (X = Br, I, NR_2, OR). Anionic complexes, $An(NN'_3)XX'$ (X = OR, X′ = OR′) can also be formed by addition of alkoxide salts to the neutral species.[28] Complexes of An^{IV} with diamidoamine ligands have also been studied.[29]

Polypyrazol-1-yl borate coordination with An^{IV} also results in stable complexes. The fully characterized complexes are typically of the form, $AnCl_2L_2$ (L = $HBpz_3$, Ph_2Bpz_2, Bpz_4)[30,31] and AnL_4 (L = H_2Bpz_2, $HBpz_3$).

Another unique N-donor ligand is $Fe(CN)_6^{3-/2-}$. The ferrocyanide ion has been found to complex with An^{IV} (An = Th, U, Np)[32] to form molecular compounds. In these complexes, the $Fe(CN)_6$ octahedra are maintained with the An ion binding the N atoms of the ferrocyano ligands.

Pentavalent. A limited number of pentavalent actinide complexes have been isolated with N-donor ligands. The primary reason for this is the inability of Th to attain the pentavalent state and the propensity of U^V complexes to disproportionate into U^{IV} and U^{VI} complexes. Some of the typical complexes that have been reported are adducts of $U(OR)_5$ and UX_5 with the ligands described for the tri- and tetravalent actinide complexes.

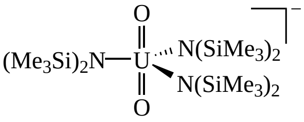
Homoleptic amido compounds of U^V, $U(NR_2)_5$, have been synthesized by oxidation of anionic tetravalent complexes, $[U(NR_2)_5]^-$. A unique hexakisamido U^V complex has been isolated using 2,3:5,6-dibenzo-7-azabicyclo[2.2.1]hepta-2,5-diene. The $[U(dbabh)]^-$ anion can be oxidized to form a U^{VI} species both of which have a near-perfect octahedral geometry with the six amido ligands.[33]

The oxidation of tetravalent or reduction of hexavalent uranium compounds with the tren ligand present can produce stable U^V complexes. The one-electron oxidation of $[U(NN'_3)(OBu_t)(OPh)Li\text{-}(THF)]$ by either electrolysis or chemical means yields the neutral $[U(NN'_3)(OBu_t)(OPh)]$. The reaction of $UO_2Cl_4^{2-}$ with the lithium salt of tren leads to the formation of a U^V/U^{VI} dinuclear trianion, $[UO(\mu^2\text{-}NCH_2CH_2N(CH_2CH_2NSiBu_tMe_2)_2)]_2^-$.[34] The formation of this anion is complex due to the activation of both the uranyl unit and the tren ligand. The structure for this complex consists of capped trigonal bipyramid uranium atoms. The tren ligand binds through the amine and two of the amido linkages with the third becoming an imido ligand. The remaining oxygen atoms complete the coordination sphere as a terminal ligand.

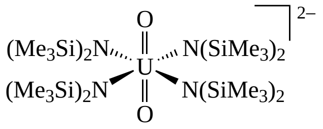
Hexavalent. The majority of An(VI) coordination chemistry with N-donors has been explored with the uranyl cation, UO_2^{2+}. Stable adducts with the ligands discussed in the tri- and tetravalent complexes have been described, for example, $UO_2X_2L_n$ (X = halide, OR, NO_3, RCO_2). The coordination numbers observed for these complexes are typically 6, 7, or 8 with octahedral, pentagonal bipyramidal, or hexagonal bipyramidal geometries, respectively. Neutral and anionic thiocyanates have also been isolated, for example $[UO_2(NCS)_x]^{2-x}\cdot yH_2O$ ($x = 2-5$).

A unique amido complex of UO_2^{2+} has recently been reported, $[UO_2(N(SiMe_3)_2)_3]^-$ (**29**).[35] This anion has a uranium center with a rarely observed coordination number of 5 in a trigonal bipyramidal geometry. This complex was synthesized by protonolysis of the dianion, $[UO_2(N(SiMe_3)_2)_4]^{2-}$ (**30**) or through a reaction of $UO_2Cl_2(THF)_2$ with three equivalents of $K[N(SiMe_3)_2]$. The crystal structure of this anion revealed long U=O bonds (1.80 Å) and relatively short U–N bonds (2.31 Å).

Homoleptic U^{VI} amido complexes are also known. $U(NMe_2)_6$ is synthesized by a two-electron oxidation of



(**29**)



(**30**)

the tetravalent anion $[U(NMe_2)_6]^{2-}$. The complex has an octahedral geometry and slowly decomposes over several hours.

8.3 Phosphorus Donors

The actinides are hard acids and therefore phosphine coordination complexes are rare. Most of the isolated actinide–phosphine complexes contain the chelating ligand 1,2-(bisdimethylphosphine)ethane, (DMPE), for example, $An(BH_4)_3$(dmpe) and $AnX_4(dmpe)_2$ (X = Cl, Br, I, CH_3). For thorium, dmpe complexes are the only ones that have been stabilized; however, uranium complexes with monodentate phosphines, that is, $P(CH_3)_3$, have been reported. Uranium(V) phosphine complexes have also been synthesized using amido ligands with phosphine linkages, for example, $UCl_2[N(CH_2CH_2PPr\textit{i}_2)_2]_3$.

The tetrakis(dialkylphosphido) complexes, $An(PPP)_4$ (An = Th, U); PPP = $P(CH_2CH_2P(CH_3)_2)_2$,[36] were prepared by reacting $AnCl_4$ with four equivalents of the lithium or potassium salt of the PPP tetra-anion. The structure of these compounds shows triangulated dodecahedra distorted toward bicapped trigonal prisms. These complexes represent one of the first actinide systems containing exclusively metal–phosphorus bonds. These complexes are known to undergo insertion reactions as seen in actinide amido compounds.[37]

A unique complex has been recently reported with uranium bound to elemental phosphorus, $(\mu\text{-}\eta^4,\eta^4\text{-}P_4)[U(NRAr)_3]_2$ (R = *t*-Bu, Ar = 3,5-dimethylphenyl).[38] The compound was prepared by reaction of the trivalent $U(NRAr)_3$ with white phosphorus.

8.4 Oxygen Donors

A wide variety of *O*-donors have been used to complex uranium. The predominate oxidation states are IV and VI; however, complexes with An(III) and An(V) are also known. The majority of the complexes have coordination numbers of 6 to 12, depending mostly on the steric bulk of the ancillary ligands. Owing to the prevalence of *O*-donating ligands in natural systems, that is, aquo, hydroxide, carbonate, phosphate, carboxylate, and catecholate, understanding the complexation of the actinides is important to environmental, waste processing and storage, and bioinorganic chemistry. Some of the other *O*-donating ligands that have been studied are crown ethers, Schiff bases, polyglycols, and cryptands. These ligands have been proposed as actinide sequestering agents.

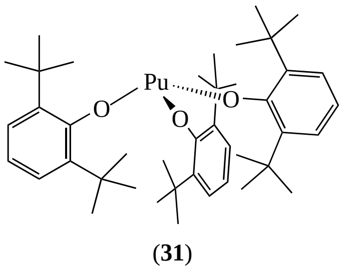
8.5 Oxygen-containing Organics

The actinides have a high degree of specificity for neutral and anionic oxygen-containing organic molecules. The actinide complexes with *O*-donor ligands that are most widely studied include alkoxides, aryloxides amide, carboxylates, and oxalates. Complexes with alcohols, ethers, esters, ketones, aldehydes, ketoenolates, and carbamates have also been reported.

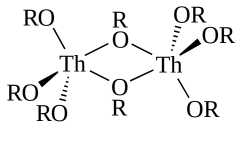
8.5.1 Alkoxides and Aryloxides

Alkoxide and aryloxide ligands are excellent ligands for the actinides. As a result, these ligands have been studied extensively in the coordination chemistry and reactivity[39] of tri-, tetra-, penta-, and hexavalent actinides. The alkoxides and aryloxides can be synthesized by a variety of routes; the two most popular routes include: direct reaction of actinide halides with alkali metal salts of the alkoxide or aryloxide of interest and protonolysis of actinide amides by alcohols.

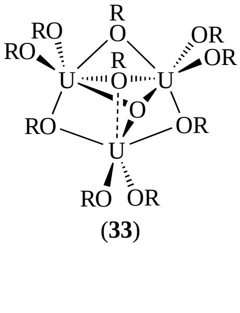
For the tri-, tetra-, and pentavalent light actinides, the structure of the alkoxide and aryloxides are strongly dependent on the steric bulk of the ligand. In order to stabilize monomeric complexes, for example, $An(OR)_n$ or $An(OAr)_n$ ($n = 3, 4, 5$), sterically demanding ligands must be utilized, for example $[O\text{-}2,6\text{-}t\text{-}(C_4H_9)_2C_6H_3]^-$. This ligand has been used to prepare monomers of Np^{III}/Pu^{III} $(An(O\text{-}2,6\text{-}t\text{-}(C_4H_9)_2C_6H_3)_3)$ (**31**), Th^{IV}/U^{IV} $(An(O\text{-}2,6\text{-}t\text{-}(C_4H_9)_2C_6H_3)_4$ (An = Th, U)), and so on. As the steric bulk is decreased, dimers $(Th_2(OCH(i\text{-}C_3H_7)_2)_8)$ (**32**), trimers $(U_3O(O\text{-}t\text{-}C_4H_9)_{10})$ (**33**), tetramers $(Th_4(O\text{-}i\text{-}C_3H_7)_{16}(py)_2$, and other oligomers can be formed. In the case of the pentavalent actinide alkoxide complexes, the actinide metal can significantly influence the degree of



(**31**)



(**32**)



(**33**)

oligomerization. For example, the reaction of $PaCl_5$ with five equivalents of NaOEt results in the formation of $Pa(OEt)_5$, which has been estimated to have a degree of oligomerization of 5.7. However, for U^V, a trimer is observed with the less bulky methoxide ligand, $U(OMe)_5$.

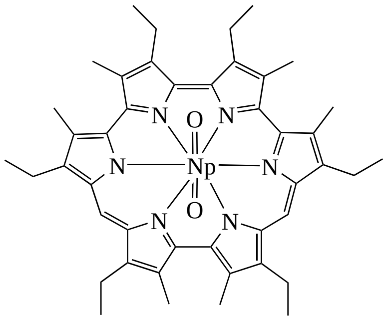
A mononuclear trivalent uranium complex has been synthesized with the six-coordinate trisalkoxide ligand, 1,4,7-tris(3,5-di-*tert*-butyl-2-hydroxybenzyl)-1,4,7-triazacyclononane), $((ArO)_3tacn)$.[40] The neutral complex $U((ArO)_3tacn)(CH_3CN)$ was found to react with organic azides to form U^{IV} azido or U^V imido compounds of the form $[((ArO)_3tacn)U(N_3)]$ and $[((ArO)_3tacn)U(NSiMe_3)]$, respectively.

Homoleptic An^{VI} alkoxides and aryloxides tend to form monomers of the formula $An(OMe)_6$. The octahedral $U(OMe)_6$ is synthesized by oxidation of the tetravalent $[U(OMe)_6]^{2-}$ by Pb^{IV} and sublimes at 87 °C. Other stable An^{VI} alkoxides and aryloxides include the actinyl unit. Using simple metathetical reactions, for example, $AnO_2Cl_2(THF)_2$ (An = U, Np, Pu) reacted with potassium salts of alkoxides and aryloxides, complexes of the form $AnO_2(OR)_n{}^{2-n}$ (R = alkyl, $CHPh_2$, CH(*t*-Bu)Ph, 2,6-($t$$Bu_2$)$C_6H_3$, 2,6-$Ph_2C_6H_3$, 2,6-$Cl_2C_6H_3$, 2,6-$Me_2C_6H_3$, other aryl) can be isolated.[41,42] As with the lower valent compounds, the steric bulk of the ligand dictates the nuclearity of the complex. For diphenylmethoxide, a monomer $UO_2(OCHPh_2)_2(THF)_2$ results, while the diisopropylmethoxide analog results in the formation of a tetramer, $[UO_2(OCH(i\text{-}Pr)_2)_2]_4$. Both of these compounds have pseudo-octahedral geometries. The coordination sphere of the latter complex has the following ligands: one terminal alkoxo, two bridging alkoxo, and one bridging oxo.

8.6 Macrocyclic Ligands

Porphyrins have been found to bind the tetravalent ions of Th and U in the form of the bisporphyrin complexes, $An(P)_2$ (An = Th, U; P = octaethylporphyrin, tetra-*p*-tolylporphyrin).[43] These sandwich-type complexes are useful for studying the electronic structure of porphyrins. For example, Th is electrochemically inactive, which allows the porphyrin-based electrochemistry to be studied exclusively for its role in photosynthesis.

Expanded porphyrins have recently been used to coordinate actinyl ions in an inner-sphere fashion.[44] The expanded porphyrins have 4–6 nitrogen-containing rings making very large cavities that can accommodate the actinide ions. The actinyl ions bind to the expanded porphyrins in an inner-sphere manner such that the ring of N atoms takes up the equatorial plane, leaving the oxo ligands above and below the porphyrin ring. The isolated and fully characterized neptunium-expanded porphyrin complex, $[NpO_2(Hexaphyrin(1.0.1.0.0.0))]^-$ (**34**), represented the first all-aza donor ligand to be bound to the neptunyl ion.[45]



(**34**)

9 SOLID-STATE MATERIALS

9.1 Metals

Actinides display a variety of metallic structures along the series, and many allotropic modifications are seen for Pa, U, Np, and Pu. In Table 5, the physical properties and metallic structures for the various allotropes are provided. Plutonium is probably one of the most interesting metals from a metallurgical standpoint. It has seven different allotropes existing between room temperature and the relatively low melting point of 641 °C. In addition to these phases, some high-pressure phases can also be stabilized. The α-phase of Pu is extremely brittle, with mechanical properties similar to cast iron. The δ-phase is quite ductile, having mechanical properties resembling aluminum, which makes it better suited for machining. The δ-phase can be stabilized at room temperature by alloying with small quantities of other elements, for example, Al, Ce, Ga, Si, and so on. In addition to the different phases of plutonium that can be stabilized by alloying, superconductivity has been discovered in a plutonium intermetallic compound, $PuCoGaa_5$. The T_c for this compound is unusually high at 18.5 K.[46]

The variety in metallic structure can be explained by the role of the 5f-electrons with their greater radial distribution. In the beginning of the actinide series, f-electrons interact with each other and with d- and s-electrons to give broad energy bands as in the transition metals. This delocalized character of the 5f-electrons differs greatly from the highly localized 4f-electrons found in the lanthanides beyond Ce. As the 5f level is filled moving across the actinide series, the extent of 5f-electron localization increases and the electron energy decreases below the Fermi band level. In the crossover region (U through Am), there is only a small energy difference between the localized and the delocalized 5f-electrons.

For elements with localized 5f-electrons (Am to Cf), the symmetric dhcp metal structure resembles that of the light lanthanides. However, high pressure relieves the f–f overlap and the americium structure becomes the same as uranium.

Table 5 Physical properties for selected actinide metals

		Thorium	Protactinium	Uranium	Neptunium	Plutonium	Americium	Curium	Californium

The consequent increase in the nuclear charge and reduction of the shielding of the 6d- and 7s-electrons lead to a contraction of the atomic radius, similar to that previously discussed for the ionic radius. In Am and Cm, the 5f-electrons are localized in the core, which causes an expansion of the atomic radius. The differences in localization of f-electrons between light and heavy actinides are also illustrated by their different superconductive and magnetic behavior. The Th, Pa, and Am metals are superconductors (T_c of 1.37, 0.42, and 0.79 K, respectively), whereas the heavier actinide metals are not superconductors but have larger magnetic moments at low temperatures.

The production of the light actinide metals is usually accomplished through the reduction of tri- or tetrafluorides with an electropositive metal, for example, Ca, Zn, or Mg. The heavy actinides are typically made through the direct reduction of oxide phases. An alternative method to access the actinide metals is through pyrochemical methods. In this technique, actinides in high-temperature molten salts, for example, NaCl-KCl or LiCl-KCl eutectics, are electrolyzed to give pure metals at the cathode. Pyrochemistry is currently being investigated as an alternative to the aqueous-based separation methods for nuclear fuel reprocessing since pure streams of Pu can be avoided, thereby reducing proliferation risks. All actinides in elemental form are lustrous silvery dense metals. Only Th has a rather high melting point, and both Th and Np have high boiling points. The other actinides can be purified by volatilization.

The reactivity of the actinide metals is in line with other electropositive highly reactive metals. In air, the actinides are rapidly covered with an oxide film. For Pu, the film has two distinct layers, PuO_2 on the surface and Pu_2O_3 on the subsurface. The relative quantity of each of these layers is dependent on the quantity of oxygen in the atmosphere. The metals also react with metalloids and nonmetals to form a number of solid-state stoichiometric and nonstoichiometric compounds. The following sections detail many of the products from direct interaction of the actinide metals with other elements.

9.2 Oxides

The oxides of the actinides are some of the most prevalent and technologically important binary actinide compounds known. The oxides of thorium, uranium, and plutonium are used throughout the nuclear fuel cycle and, for many of the actinides, are the stable phase in the environment. The oxides can be quite complex, forming nonstoichiometric and polymorphic materials. Anionic oxides of the actinides can also be formed, for example, $AnO_4{}^{2-}$, $An_2O_7{}^{2-}$, $AnO_4{}^{-}$, and so on. The focus of this section will be on the predominant or technologically relevant binary oxide phases. A complete summary of the properties and crystal structure data for actinide oxides can be obtained from *Kirk Othmer Encyclopedia of Chemical Technology*, 4th Edition: Actinides and Transactinides, Wiley-Interscience, NY, 1999.

The thorium oxide system is dominated by ThO_2. The dioxide can be synthesized by burning a number of thorium compounds, including hydroxides, oxalates, carbonates, and so on. The ThO_2 crystallizes in the cubic fluorite structure. ThO_2 is very heat resistant as are all of the actinide oxides and melts at 3390 °C, which is the highest for any known metal oxide.

Protactinium oxides can be stabilized in the tetravalent and pentavalent state. The most stable oxide phase obtained by the burning of metal or protactinium compounds is the white pentoxide, Pa_2O_5. The structure of the pentoxide is related to fluorite and has cubic symmetry. PaO_2 is a black solid that crystallizes in the cubic fluorite structure.

Numerous oxide phases of uranium have been characterized, including uranium oxide, UO, UO_2, U_4O_9, U_3O_7, U_3O_8, UO_3; hydrated species such as $UO_3{\cdot}xH_2O$ and the peroxo complex, $UO_4{\cdot}xH_2O$; and anionic uranates including $[U_2O_7]^{2-}$ and $[U_4O_{13}]^{2-}$. The most important phases for the nuclear fuel cycle are UO_2, U_3O_8, and UO_3. UO_2 is a brown to black solid that has a melting point of 2875 °C. UO_2 may be synthesized through a variety of mechanisms, including (i) oxidation of uranium metal, (ii) reduction of higher valent oxides, (iii) thermal decomposition of uranyl uranates, (iv) oxidation or reduction of uranium halides, (v) decarboxylation of uranium compounds of carbonic acids, (vi) hydrometallurgical preparation, and (vii) electrolysis of uranium halides. As with all of the actinide dioxides, it has a cubic fluorite structure and significantly high density at 10.95 g cm^{-3}. U_3O_8 is a mixed valent oxide, containing U^{IV} and U^{VI}. Two modifications of U_3O_8 are known both having a black-green color and crystallizing in an orthorhombic structure. The density of U_3O_8 at 8.16 to 8.41 g cm^{-3} is significantly less than the dioxide. This property is problematic in nuclear fuels. During the 'burning' of UO_2 nuclear fuel, the presence of O_2 within the fuel pins causes the formation of U_3O_8. Owing to the nearly 20% change in the density, any significant buildup of U_3O_8 will cause swelling and eventual cracking of the fuel pellet. UO_3 is the only well-characterized hexavalent actinide oxide. Six different modifications are known for the trioxide with the orange γ-UO_3 being the most important and having a density of 7.80 g cm^{-3}. The predominant method for synthesizing UO_3 is by thermal decomposition of U^{VI} compounds in the presence of O_2. While most actinide oxides are thermally stable with high melting points, γ-UO_3 decomposes at 650 °C.

Hyper- and hypostoichiometric, UO_{2+x} and UO_{2-x}, respectively, are also known and have been analyzed by X-ray crystallography. In the case of the UO_{2+x}, extra oxygen atoms occupy central lattice holes in the normal UO_2 structure.

The anhydrous oxide phases for Np consist of the tetravalent NpO_2 and pentavalent Np_2O_5. A hydrated form of a hexavalent neptunium oxide has also been characterized. The neptunium dioxide has an apple green color and can be synthesized by burning the metal in an atmosphere of O_2. The density of NpO_2 is 11.14 g cm^{-3}. Np_2O_5 is a dark brown solid that crystallizes in a monoclinic space group. The primary synthetic routes to obtain dineptunium pentaoxide include thermal decomposition of Np^V compounds or high-temperature ignition of the metal. The synthesis of the hexavalent neptunium oxide, $NpO_3{\cdot}xH_2O$, requires strongly oxidizing conditions. The most efficient synthetic route consists of reacting NpO_2 with O_3 in a high-temperature molten salt.

The plutonium oxygen phase diagram is complex. The two most important oxides of plutonium are the dioxide, PuO_2, and the sesquioxide, Pu_2O_3. PuO_2 is used in the nuclear fuel cycle with the fabrication of MOX in either the recycle of spent nuclear fuel or the destruction of plutonium from nuclear weapons. Having a fluorite structure, the yellow–brown to green PuO_2 has a density of 11.46 g cm^{-3} and a melting point of 2400 °C. Pu_2O_3 is a black solid with a hexagonal structure similar to the La_2O_3.

Both of these oxides are present on nearly any piece of plutonium metal that has undergone some corrosion. Under normal conditions, the outside surface of Pu contains PuO_2, while the sesquioxide forms between the PuO_2 layer and the metal. The relative amount of these phases is dictated by the partial pressure of oxygen in the atmosphere.

Obtaining pure and well-ordered PuO_2 is difficult. The presence of hypo- and hyperstoichiometric compounds, PuO_{2-x} and PuO_{2+x}, respectively, pervades nearly any synthetic technique. In recent years, interest in the study of the hyperstoichiometric, PuO_{2+x}, ($x < 0.27$) oxide phases has increased.[47–50] Through the use of a variety of techniques, it has been determined that Pu^V is present in the crystal lattice as the oxygen content increases. This finding was originally thought to have a significant impact on the modeling of nuclear waste repositories due to the increase in solubility of Pu^V species in the environment. However, all of the models were based on solubility studies with PuO_2 that inevitably had hyperstoichiometric oxide phases present. As a result, the published solubility data already represent the bulk solubility of plutonium oxides, including the Pu^V species in PuO_{2+x}.

For the actinide elements heavier than Pu, the predominant phases that have been isolated are An_2O_3 and AnO_2.

9.3 Nitrides

Actinide nitrides are known for Th through Cm. All of the nitrides are high melting compounds with melting points of 2630 °C, 2560 °C, and 2580 °C for Th, Np, and Pu, respectively. The actinide nitrides can decompose to give N_2. Thorium, uranium, and plutonium nitrides are well known and can be used as nuclear fuels. Fuels of this type, especially uranium and mixed uranium–plutonium nitrides, can be used in lead-cooled fast reactors, which have been proposed as a possible next-generation nuclear reactor and for use in deep-sea research vehicles.

Two stoichiometric phases of thorium nitrides have been investigated: ThN and Th_3N_4. ThN is a superconductor with a relatively low T_c. Both of these phases can be made by high-temperature reactions of thorium metal with N_2. An alternative synthetic route to Th_3N_4 involves the reaction of thorium metal with NH_3 to form $Th(NH)_2$, which upon further heating degrades to $Th_2N_2(NH)$ and finally to Th_3N_4.

For uranium, three nitrides of exact stoichiometry are known: UN, U_2N_3, and U_4N_7. As was the case with the oxides, nonstoichiometric complexes can also be synthesized to be of the form, U_2N_{3+x}, where the N/U ratio ranges from 1.64 to 1.84. The brown mononitride, which is the only nitride complex stable above 1300 °C, melts at 2600 °C, and has a density of 14.31 g cm^{-3}. The uranium nitrides can be made by direct interaction of the elements. Some of the other routes to access the nitrides include: uranium metal under static NH_3 at 300 to 350 °C to yield U_2N_3, uranium metal or uranium carbides with NH_3 or N_2 at 600 to 900 °C to produce U_2N_{3+x}, uranium carbide fuels reacted with N_2/H_2 to form UN, and a self-propagating metathetical reaction. The structures of some of the nitrides have been determined with the mononitride having a face-centered cubic NaCl-type structure. The sesquinitride complex has two modifications: the α-phase is found with a body-centered cubic Mn_2O_3-type structure, while the high-temperature β-phase crystallizes in a hexagonal Mn_2O_3-type structure.

The studies on the neptunium nitride system are somewhat limited with the mononitride, NpN, being the predominant phase. PuN is also the only known compound in the plutonium series. The AnN (An = Np, Pu) has been synthesized by reaction of an actinide hydride with NH_3 at high temperatures.

9.4 Carbides

Actinide carbides are also a potential nuclear fuel. The typical reactors that can be fueled by carbides are thermionic, used for space power and propulsion systems, and high-temperature gas-cooled reactors. Three basic carbides have been isolated for the light actinides, AnC, An_2C_3, and AnC_2. Ternary carbides formed from transition metals and the light actinides have also been studied. Uranium carbides are all dark gray solids with a metallic luster. The melting points of UC and U_2C_3 are 2400 and 2417 °C, respectively, and the dicarbide melts at 2475 °C and boils at 4370 °C (760 mm Hg). The densities of the uranium carbide series are 13.60 g cm^{-3} for UC, 12.85 g cm^{-3} for U_2C_3, and 11.69 g cm^{-3} for UC_2. Techniques for the synthesis include the reduction of AnO_2 with CO_2 and the direct interaction of uranium and carbon under highly exothermic conditions. The crystal structure of AnC is a face-centered cubic NaCl-type lattice, identical to that of UN. The sesquicarbides crystallize with a body-centered cubic Pu_2C_3-type structure. Multiple modifications of the AnC_2 are known, for example, α-phase UC_2 has a body-centered tetragonal CaC_2-type structure and the β-phase crystallizes in a face-centered cubic KCN-type lattice. Most of the carbides are sensitive to oxidation by air.

In order to be used as nuclear fuel, carbide microspheres are required. These microspheres have been fabricated by a carbothermic reduction of UO_3 and elemental carbon to form UC. In addition to these uses, the carbides are also precursors for uranium nitride–based fuels.

9.5 Hydrides

Actinide metals react with hydrogen at elevated temperatures to yield a number of hydride phases with compositions resembling AnH_2 and AnH_3. The dihydrides are known for Ac, Th, and Np–Bk and the trihydrides have been isolated for Pa–Bk. Thorium forms a unique hydride phase with the formula Th_4H_{15}. This compound is a superconductor with a T_c between 7.5 and 8 K. It is interesting to note that the superconductivity of thorium metal is destroyed by the primary hydrogenation, for example, formation of ThH_2. This behavior of alternating superconductivity could be attributed to the presence of two types of hydrogen atoms in the Th_4H_{15} structure.

The AnH_2 (An = Ac, Np–Bk) have the fluorite structure. ThH_2 is unique in that it has tetragonal symmetry. In β-UH_3, the metal atoms have a coordination number of 12 and the H atoms occupy tetrahedral intersites. For the other AnH_3 (An = Np–Bk), the crystals have a trigonal structure.

The hydrogenation reaction of the actinides is a reversible process. By heating the hydrides to high temperatures, H_2 gas is driven off, leaving the pure metal. This process has been adopted in the dismantling of plutonium pits from excess nuclear weapons.[51] In this process, the plutonium part is reacted with H_2 gas, which forms a powdered plutonium hydride. The powder is collected and heated past the melting point of plutonium to drive off the dihydrogen gas and leave a Pu ingot.

9.6 Borohydrides

The borohydrides of the tetravalent actinides can be prepared through the reaction of the tetrafluoride with $Al(BH_4)_3$. The products of this reaction are $An(BH_4)_4$ and $AlF_2(BH_4)$.[52] The uranium complex is polymeric in the solid state and is similar to the Zr and Hf analogs. The metal center is

bound to 14 hydrogen atoms from two tridentate BH_4^- ligands and four bridging bidentate BH_4^- ligands. These complexes represent the highest coordination number observed for an actinide species.

9.7 Borides

A number of borides of composition AnB_2, AnB_4, AnB_6, and AnB_{12} are known. The AnB_6 and AnB_{12} phases have cubic structures like CsCl and NaCl, respectively. All of the borides are resistant to the action of H_2SO_4, HCl, and HF, but readily dissolve in $HNO_3-H_2O_2$.

Recently, a novel synthesis of UB_4 has been accomplished through a solid-state metathesis reaction.[53] The reaction is performed at $\leq 850\,°C$ by mixing UCl_4 with 2 equivalents of MgB. The resulting UB_4 product can be purified by washing with H_2O.

9.8 Silicides

The silicides of the actinides have not been widely characterized. A uranium silicide of the form U_3Si_2 has received the maximum amount of study owing to its use as a dispersion fuel in research reactors. Another common phase observed for actinide silicides is $AnSi_2$. One of the common synthetic routes to the silicides is the reaction of actinide fluorides, for example, AnF_4, with elemental Si at high temperatures. One of the thermodynamic driving forces for this reaction is the release of SiF_4.

9.9 Pnictides

Five pnictide phases have been identified: An_4X_3, AnX, An_3X_4, An_2X_3, and An_4X_3. The best studied of the pnictides outside of the nitrides are the phosphides. Some interesting properties are observed for the phosphides; for example, Th_3P_4 is a semiconductor. Most of the actinide pnictides are prepared by direct interaction of the elements at high temperatures. Monopnictides have been obtained from U through Cf for Sb. They are produced by the direct interaction of the elements at elevated temperatures.

9.10 Chalcogenides

The interaction of the actinides or of their hydrides with chalcogens or H_2X, respectively, give a number of nonstoichiometric phases with a composition close to AnX, An_2X_3, AnX_2, An_2X_5, or AnX_3. Their thermal stability decreases in the order S > Se > Te. The magnetic susceptibility and Mössbauer spectroscopy show that the latter compounds may be formulated as $[An^{3+}]_2(S^{2-})_2(S\text{-}S)^{2-}$, $[An^{4+}]_2(S^{2-})_3(S\text{-}S)^{2-}$, and $[An^{4+}](S^{2-})(S\text{-}S)^{2-}$. These compounds have coordination numbers of 8, 10, and 6, respectively. The oxidation state of the actinides in monochalcogenides has metallic conductivity but U_2S_3 is a semimetal, while the Np and Pu analogs are ionic compounds.

Recently, the first quaternary plutonium metal thiophosphates of the form $KPu(PS_4)_2$ and $MPuP_2S_7$ ($M = K^+$, Rb^+, Cs^+) were prepared using reactive flux methods.[54,55] The structure of $KPu(PS_4)_2$ shows an eight-coordinate bicapped trional prism geometry about the Pu center. The polyhedra are linked through edge-sharing and thiophosphate tetrahedral. The $MPuP_2S_7$ contains $P_2S_7^{4-}$ corner-shared bitetrahedral ligands.

The first polychalcogenide complex, K_4USe_8, was obtained by a solid-state reaction.[56] It has a molecular structure with a distorted dodecahedral anion, $[U(Se_2)_4]^{4-}$, which is isostructural with the known peroxoanions $[M(O_2)_4]^{n-}$, where M = V, Nb, Ta, Cr ($n = 3$) or Mo, W ($n = 2$). Recently, two additional uranium selenides have been synthesized, MU_2Se_6 ($M = K^+$, Cs^+), using a reactive flux method. The oxidation state of the uranium in these compounds was found to be tetravalent. The selenium has two distinct oxidation states, Se^{2-} and one similar to a polyselenide network.

New solid-state compounds of phosphoselenates also have been synthesized by reaction of Th and P in a reactive flux of K_2Se_4/Se or Cs_2Se_3/Se at high temperatures.[57,58] For the potassium system, the β-$K_2ThP_3Se_9$ was crystallographically characterized and showed the Th atoms being coordinated to nine Se atoms from phosphoselenate ligands. The coordination geometry is best described as a distorted tricapped trigonal prism. In the Cs system, the compound $Cs_4Th_4P_4Se_{26}$ was isolated.[59,60] The molecule is best described as $[Cs_2Th_2(P_2Se_9)(Se_2)_2]_2$ with the $P_2Se_9^{6-}$ anion having a linear Se–Se–Se backbone.

9.11 Halides

Actinide halide compounds have found extensive utility in the processing of actinide materials as well as for starting materials for synthetic inorganic and coordination chemistry, for example, $AnX_m(THF)_n$ ($m = 3, 4, 5$). The actinide halides can be made in a variety of oxidation states (III–VI) through room-temperature and high-temperature techniques. The trihalides, AnX_3, are stable for all of the actinides except Th and Pa. As a result of the important industrial applications of binary fluorides and chlorides, the majority of the halide discussion focuses on the binary systems. A selected listing of physical constants for the binary uranium halides is provided in Table 6. The bond distances for ThX_4 and UX_4 compounds are given in Table 7.

Some of the general trends among the actinide halides are as follows:

- Stability of the halide is dependent on the redox chemistry of actinides (Pu^{IV} is reduced by Cl^-, Br^-, and I^-).
- Fluoride stabilizes the higher oxidation states of the actinides.

Table 6 Physical constants for selected uranium halides

Compound	Density, g mL^{-1}	Melting point, °C	Boiling point, °C
UF_6	4.68	64.5–64.8	56.2^{765}
UF_4	6.70	960	
UF_3		>1000	
Ucl_5	3.81	>300	
Ucl_4	4.87	590	792^{760}
Ucl_3	5.44	842	
Ubr_4	5.35	516	792^{760}
Ubr_3	6.53	730	Volatile
UI_4	5.6	506	759^{760}

Table 7 Bond distances for thorium and uranium halides, ThX_4 and UX_4

	F	Cl	Br	I
Th-X_{gas} (Å)	2.14	2.58	2.72	
Th-X_{solid} (Å)	2.34	2.88	3.00	3.21
U-$X_{terminal}$ (Å)	2.28	2.71	2.61	2.92
U-$X_{bridging}$ (Å)			2.88	3.10

Table 8 Coordination numbers and geometries for UX_4 and U^n bromides

UX_4	F	Cl	Br	I
CN	8	8	7	6
Geometry	Square anti-prism	Dodeca-hedron	Pentagonal bipyramid	Octa-hedral
U^n-bromides	V	IV	III	
CN	6	7	9	
Geometry	Octa-hedral	Pentagaonal bipyramid	Tricapped trigonal prism	

- Coordination numbers decrease with increasing size of the halogen (Table 8).
- Coordination numbers decrease with higher oxidation state (Table 8).
- Reactions with X_2 generally lead to high oxidation state materials (reaction of U with F_2 produces UF_6).
- Reactions with HX lead to stabilization of the lower oxidation states (reaction of PaO_2 with HF/H_2 produces PaF_4).

9.11.1 *Fluorides*

The fluorides of the actinides, especially uranium, play an important role in the nuclear fuel cycle as well as in the production of actinide metals.

Trivalent. The actinide trifluorides have a structure that is isomorphous with LaF_3, in which each metal has a basic tricapped triganol prismatic geometry with an additional two fluoride ions at a significantly longer distance. The trifluorides tend to be insoluble in H_2O but quite soluble in strong acids, that is, nitric, hot sulfuric, and perchloric. For the actinides with very stable trivalent oxidation states, for example heavy actinides, the synthetic routes to form the AnF_3 are straightforward (equations 3–5). For the light actinides, the isolation of the trifluorides requires the addition of a reducing agent, for example H_2 (equations 6–7).

$$Ac(OH)_3 \xrightarrow[700\,°C]{HF} AcF_3 \tag{3}$$

$$AmO_2 \xrightarrow[\Delta]{HF} AmF_3 \tag{4}$$

$$Cm^{3+}_{(aq)} \xrightarrow{F^-} CmF_3{\cdot}xH_2O \xrightarrow[P_2O_5]{dry} AmF_3 \tag{5}$$

$$MO_2 \xrightarrow[500\,°C]{HF/H_2} MF_3 \quad (M = Np, Pu) \tag{6}$$

$$UF_4 \xrightarrow[900\,°C]{Al \text{ or } UH_3 \text{ or } H_2} UF_3 \tag{7}$$

Tetravalent. The tetrafluorides of the actinides are typically synthesized through the reaction of HF or Freon with the actinide metals, oxides, or hydrides. Since the highest possible oxidation state for Th is the tetravalent state, F_2 can be used to synthesize ThF_4. The solid-state structure of the light actinide tetrafluorides consists of polymers that are created through bridging fluoride ions. The geometry around the metal center is a distorted square antiprism. In general, the tetrafluorides are soluble in strong acids and bases, insoluble in dilute acids and bases, and slightly soluble in cold water. Equations (8–10) provide some examples of potential synthetic routes.

$$U_{metal} \xrightarrow[\Delta]{HF} UF_4 \tag{8}$$

$$NpO_2 \xrightarrow[500\,°C]{HF} NpF_4 \tag{9}$$

$$Pu^{4+}_{(aq)} \xrightarrow{F^-} PuF_4{\cdot}xH_2O \xrightarrow[\Delta]{HF} PuF_4 \tag{10}$$

Pentavalent. The pentafluorides of Pa, U, and Np have been reported. The synthetic routes to obtain the pentafluorides are given in equations (11) and (12). Uranium pentafluoride, UF_5, gives two different modifications that have been structurally characterized, α (grayish white solid) and β (yellowish white). The α-phase, which is produced from the reaction of UF_6 with HBr or mildly heating a mixture of UF_6 and UF_4, has infinite chains of UF_6 units. The β-phase produced by heating a mixture of UF_6 and UF_4 to

higher temperatures has eight-coordinate uranium atoms in an irregular geometry.

$$Pa_2O_5 \xrightarrow{HF/H_2} PaF_4 \xrightarrow[700\,°C]{F_2} PaF_5 \quad (11)$$

$$NpF_4 \xrightarrow[500\,°C]{KrF_2/HF} NpF_5 \quad (12)$$

Hexavalent. Uranium hexafluoride, UF_6, is one of the best-studied uranium compounds in existence due to its importance for uranium isotope separation and large-scale production (~70 000 tons per year). All of the actinide hexafluorides are extremely corrosive white (U), orange (Np), or dark brown (Pu) crystalline solids, which sublime with ease at room temperature and atmospheric pressure. The synthetic routes into the hexafluorides are given in equation (13). The volatility of the hexafluorides increases in the order Pu < Np < U in the liquid state and Pu < U < Np in the solid state. UF_6 is soluble in H_2O, CCl_4, and other chlorinated hydrocarbons, is insoluble in CS_2, and decomposes in alcohols and ethers. The oxidative power of the actinide hexafluorides are in line with the transition metal hexafluorides and the order of reactivity is as follows: $PuF_6 > NpF_6 > UF_6 > MoF_6 > WF_6$. The UF_6 molecule can also react with metal fluorides to form UF_7^- and UF_8^{2-}. The same reactivity is not observed for the Np and Pu analogs.

$$An_{metal} \text{ or } AnO_2 \xrightarrow[500\,°C]{F_2} AnF_6 \quad (13)$$

9.11.2 Chlorides

Trivalent. The trichlorides, $AnCl_3$, are stable across the series, and two structure types have been observed: nine-coordinate UCl_3 (tricapped trigonal prism) and eight-coordinate $PuBr_3$ (bicapped trigonal prism). The early actinides favor the former structure type, while Bk and Cr are found in the latter. A variety of synthetic routes can be used to access the trihalides, including metathesis, reduction, oxidation, and so on (equations 14–19).

$$Ac(OH)_3 \xrightarrow[250\,°C \text{ or } 500\,°C]{NH_4Cl \text{ or } CCl_4} AcCl_3 \quad (14)$$

$$AmCl_3 \cdot xH_2O \xrightarrow[250\,°C]{NH_4Cl} AmCl_3 \quad (15)$$

$$M_2O_3 \xrightarrow[400-600\,°C]{HCl} MCl_3 \quad (M = Cm, Es) \quad (16)$$

$$Pu_{metal} \xrightarrow[450\,°C]{Cl_2} PuCl_3 \quad (17)$$

$$UH_3 \xrightarrow[350\,°C]{HCl/H_2} UCl_3 \quad (18)$$

$$NpCl_4 \xrightarrow[600\,°C]{H_2} NpCl_3 \quad (19)$$

Tetravalent. The tetrachlorides $AnCl_4$ are stable for all of the light actinides, Th–Pu. The structure for $AnCl_4$ (An = Th–Np) have a dodecahedral geometry of the chlorine atoms about a central actinide metal center. The methods used to synthesize the tetrachlorides are dependent on the actinide of interest. For Th, the direct interaction of the metal with Cl_2 is the most direct method. $PaCl_4$ can be made by reduction of $PaCl_5$ with hydrogen or aluminum at high temperatures. Uranium tetrachloride is a dark green solid that can be prepared in multiple ways. The most efficient synthesis involves the reaction of UO_3 with boiling hexachloropropene. UH_3 can also be treated with Cl_2 to give UCl_4. The red $NpCl_4$ is predominantly made by reacting CCl_4 at high temperatures. The reaction of $PuCl_3$ with Cl_2 results in an equilibrium between the tri- and tetrachloride.

Pentavalent. Actinide pentachlorides are limited to $PaCl_5$ and UCl_5. $PaCl_5$ has a chain-type structure with seven-chloride ions bound to each metal center. UCl_5 consists of an edge-sharing bioctahedral dimer, U_2Cl_{10}. The protactinium pentachloride is most easily accessed through a high-temperature reaction of Pa_2O_5 with a mixture of C, Cl_2, and CCl_4. UCl_5 is a reddish brown solid that can be prepared by reaction of UO_3 under flowing CCl_4. While this procedure can be used to make UCl_4, the reaction can be controlled to stop at U^V by lowering the temperature. The direct oxidation of UCl_4 by Cl_2 can also be used to synthesize the pentachloride. The pentachloride decomposes in H_2O and acid, is soluble in anhydrous alcohols, and insoluble in benzene and ethers.

Hexavalent. The best-studied actinide hexachloride is uranium hexachloride, UCl_6. This compound is prepared by chlorination of UCl_4 with $SbCl_5$. The disproportionation of UCl_5 to form UCl_4 and UCl_6 provides a second route to access the hexachloride. An alternative preparative approach is the disproportionation of UCl_5 to UCl_4 and UCl_6. The hexachloride is isostructural with the hexafluoride, being monomeric with an octahedral arrangement of the chlorine atoms around the uranium center.

9.11.3 Bromides and Iodides

Trivalent. Owing to the weakly oxidizing power of bromine and iodine, the majority of the isolated compounds consist of trivalent actinides, for example, AnX_3 (X = Br, I). The tribromides $AnBr_3$ have been isolated for An = Ac–Bk. The light actinides Ac–Np have the nine-coordinate UCl_3 structure, while Pu, Am, and Cm are found with an eight-coordinate bicapped trigonal prismatic geometry. With the decreasing ionic radius due to the actinide contraction, the Bk analog crystallizes with a six-coordinate structure. The general synthetic methods to synthesize the actinide tribromides are

given in equations (20–24).

$$M_2O_3 \xrightarrow[600-800\,^{\circ}C]{HBr} MBr_3 \quad (M = Cm, Cf) \tag{20}$$

$$U_{metal} \xrightarrow[500\,^{\circ}C]{Br_2} UBr_3 \tag{21}$$

$$UH_3 \xrightarrow[\Delta]{HBr} UBr_3 \tag{22}$$

$$NpO_2 \xrightarrow[\Delta]{Al/AlBr_3} NpBr_3 \tag{23}$$

$$PuBr_3{\cdot}xH_2O \xrightarrow[70-120\,^{\circ}C]{vac} PuBr_3 \tag{24}$$

As with the other trihalides, the structures of the triiodides vary across the actinide series. AcI_3 is nine-coordinate and AnI_3 (An = Pa–Am) are eight-coordinate. A six-coordinate isomer of AmI_3 with the $FeCl_3$ structure is also accessible at high temperatures. Equations (25–30) detail the synthetic methods used to obtain the actinide triiodides.

$$Ac_2O_3 \xrightarrow[\Delta]{AlI_3} AcI_3 \tag{25}$$

$$MO_2 \xrightarrow[350\,^{\circ}C]{AlI_3} MI_3 \quad (M = Np, Am) \tag{26}$$

$$PaI_5 \xrightarrow[360\,^{\circ}C]{vac} MI_3 \tag{27}$$

$$UH_3 \xrightarrow[300\,^{\circ}C]{HI} UI_3 \tag{28}$$

$$Pu_{metal} \xrightarrow[500\,^{\circ}C]{HgI_2} PuI_3 \tag{29}$$

$$CfCl_3 \xrightarrow[\Delta]{HI} CfI_3 \tag{30}$$

Tetravalent. Actinide tetrabromides, $AnBr_4$, are stable for An = Th, Pa, U, and Np. The tetraiodides, AnI_4, are known for An = Th, Pa, and U. The UI_4 is actually unstable over time, producing UI_3 and I_2. The best synthetic approach to AnX_4 (X = Br, I) is by direct interaction of the elements or AnX_3 with X_2 at elevated temperatures. The tetrabromide is soluble in H_2O and liquid NH_3 but decomposes in alcohols, whereas the tetraiodide is soluble in cold H_2O and acetonitrile and decomposes in hot H_2O.

Pentavalent. The only stable pentabromides and pentaiodides are found for the Pa system, $PaBr_5$ and PaI_5. The primary synthetic method to access $PaBr_5$ and PaI_5 is through the pentavalent oxide Pa_2O_5. The uranium pentabromide, UBr_5, is unstable toward reduction but can be made by reaction of UBr_4 with Br_2 or by bromination of uranium turnings with Br_2 in acetonitrile. The metastable pentabromide is isostructural with the pentachloride, having edge-sharing octahedra U_2Br_{10}.

9.11.4 *Oxyhalides*

Nearly all of the halides of the actinides can undergo partial oxidation or hydrolysis to form actinide oxyhalide compounds and complexes. Actinide tetrahalides react with dioxygen or other oxygen donors to give $AnOX_2$. Protactinium halides undergo a number of oxidation reactions to form compounds of the form PaO_2F, $PaOBr_3$, PaOI, and PaO_2I. The predominant uranium oxyhalides are of the form UOX_n ($n = 2, 3$) and $[UO_2X_n]^{2-n}$ ($n = 1$–4). Multiple oxidation states of neptunium(III–VI) have been found to form oxyhalides. Compounds of the form $NpOF_3$, NpO_2F_2, $NpOF_4$, NpOCl, and NpOI are examples of the breadth of neptunium oxyhalides. For plutonium, oxyhalides of the form PuOX (X = F, Cl, Br, I), $PuOF_4$, and PuO_2F_2 have all been reported.

9.11.5 *Anionic Complexes*

A wide variety of anionic actinide halide complexes are well known and typically are isolated with alkali or alkaline-earth metal ions. The tendency and stability of the anionic complexes follow the trend F $\gg$ Cl $>$ Br $\gg$ I. The trivalent fluorides and chlorides typically form complexes of the form AnX_4^- and AnX_6^{2-}. Plutonium has also been shown to give the following complexes: $PuCl_5^{2-}$, $Pu_2Cl_7^-$, and $PuCl_9^{6-}$. The anionic tetravalent actinide fluorides represent a broad class of complexes, for example, M_xAnF_y ($x = 1$, $y = 5$; $x = 2$, $y = 6$; $x = 3$, $y = 7$; $x = 4$, $y = 8$). Tetravalent actinide chloro, bromo and iodo complexes can be isolated from aqueous solutions in the form of octahedral $AnCl_6^{2-}$ ions.

The pentahalides of Pa and U generally add another ligand to form octahedral complexes of the form AnX_6^-. The fluorides of Np^V and Pu^V have been isolated as AnF_6^-, AnF_7^{2-} and AnF_8^{3-}. The predominate anionic complexes for the hexavalent actinides are based on UF_6. Uranium hexafluoride will add up to two additional fluoride ions to form UF_7^- and UF_8^{2-} using standard techniques. The unique UF_9^{3-} ion is formed from the thermal decomposition of Na_2UF_8.

9.12 Special Topics

Ionic Liquids. Room-temperature ionic liquids are molten salts that are liquid over a broad temperature range.[61] These liquids can be prepared with a variety of cations, for example, *N*-alkyl-pyradinium, asymmetric dialkyl-imidazolium, and so on, and anions, for example, PF_6^-, BF_4^-, $(CF_3SO_2)_2N^-$, and so on. Through judicious choice of the cation/anion pair, ionic liquids can be synthesized that are miscible and immiscible with H_2O. As a solvent, ionic liquids typically are highly solvating and noncoordinating. Being molten salts, the RTILs have high electrical conductivity, and based on the cation/anion combination can have very large electrochemical windows. As a result of these properties, significant research is being performed to study the behavior of the actinides in these novel solvents.[62–67] In addition to being potential 'green'

solvents for actinide separations, the large electrochemical windows allow for the use of pyrochemical methods to electroplate actinide metals at room temperature. The current pyroprocessing technologies for reprocessing spent nuclear fuel require the use of high-temperature molten NaCl/KCl eutectics.

Hydrothermal Synthesis. Hydrothermal synthesis[68,69] and reactive fluxes have been increasingly used as a method for synthetic actinide chemistry. Unique phases of actinide selenites, tellurites, iodates[70] and periodates[71] have all been synthesized under hydrothermal reaction conditions. New compounds and phases of oxyfluorides, phosphates, and sulfates using organic templates also have been synthesized with hydrothermal methods.[72–74]

10 HEALTH AND SAFETY FACTORS

10.1 Exposure and Health Effects

Actinides are heavy metals that can act as general cellular poisons, which can potentially affect any organ or tissue. The actinides and their compounds can be damaging due to chemical toxicity and by the injury caused by ionizing radiation. The chemical toxicities of actinide compounds depend on their solubility in biological media. Highly soluble, and therefore highly transportable, and toxic compounds include fluorides, chlorides, nitrates, and carbonates; slightly transportable compounds include oxides, hydrides, and carbides.

Most actinides can enter the human body orally, by inhalation, and through the skin and mucous membranes. Actinide compounds, both soluble and insoluble, are absorbed most readily from the lungs. Both uranium and plutonium have been found to be stored in bones, while deposition in soft tissues is almost negligible. Occupational exposure to actinides usually involves inhalation of aerosols carrying particles varying in size and density and containing a mixture of uranium compounds with different solubilities. Insoluble particles are deposited in the lungs, retained there for a long time, and can cause radiation damage of varying degree or silicosis.

Results of extensive studies have demonstrated that the consumption of drinking water containing uranium at elevated levels of 0.04 to 0.05 mg L^{-} is not detrimental to human health.

10.2 Personnel Protection and Radiation Considerations

The main adverse factor working with actinide materials is airborne dust. Personal protection should include respirators, protective clothing, surgical gloves, suitable footwear, use of wet processes wherever possible, and in operations involving dust formation, face masks, constant ventilation, and glove boxes. Finely divided actinide metals, some alloys, and the hydrides are pyrophoric; therefore, such materials should be handled in an inert atmosphere glove box.

Isotopes that emit fairly strong γ-radiation, should be handled in a hot cell; ^{238}Pu, ^{241}Am, ^{243}Am and similar isotopes should be handled in glove boxes; ^{237}Np, ^{239}Pu, ^{242}Pu, ^{244}Pu, and ^{248}Cm can be handled in a fume hood or glove box; ^{235}U and ^{238}U can be handled on the bench top or in a fume hood because of their lower radiation fields. The laboratory should be equipped as an α-laboratory. In the handling of the actinides, as in the case of all radionuclides, radioactivity due to the progeny, such as Th, Ra, Rn, and so on, should be considered, as should alternative radiation-generating decay paths, for example, α-n reaction from uranium fluorides.

Large quantities of fissile isotopes, ^{233}U and ^{235}U, ^{237}Np, ^{239}Pu, and so on, should be handled and stored appropriately to avoid a critical hazard. Clear and relatively simple precautions, such as dividing quantities so that the minimum critical mass is avoided, following administrative controls, using neutron poisons, and avoiding critical configurations (or shapes), must be followed to prevent an extremely treacherous explosion.

1 INTRODUCTION

The past 50 years have witnessed many important and exciting developments in the chemistry of transition metal complexes containing hydrocarbon-based ligands (often referred to as hydrocarbyl ligands, *see Hydrocarbyl*). Transition metal organometallic chemistry is a vibrant and evolving field, one stimulated by many factors including inorganic and organic chemists' interests in new synthetic, mechanistic, and structural chemistry, materials chemistry, nanoscience and nanotechnology, and homogeneous and heterogeneous catalysis. Despite a few early reports on the synthesis of uranium and thorium cyclopentadienyl complexes (see below), actinide or 5f-element organometallic chemistry is a field of more recent vintage. All known isotopes of these elements are radioactive, with half-lives varying from seconds to billions of years. Radioactive decay, and the attendant high costs of equipping laboratories for working with, monitoring, and disposing of radionuclides, represents an activation barrier (for the transuranic elements, a very significant one) for organoactinide research and there are relatively few academic and national laboratories equipped to explore this area of chemistry. It is the authors' belief that there is much more to be learned about the organometallic chemistry of the early actinides, that is, thorium through plutonium, particularly through systematic studies of related complexes.

The large size of actinide ions permits coordination numbers and attendant polyhedra that are uncommon among the transition elements. For the same set of ligands, a 5f-element ion will be more coordinatively unsaturated than a d-element ion. The availability of 5f valence orbitals also suggests a greater variety of metal–ligand binding possibilities, smaller ligand field stabilization energies, smaller energy barriers to intra- and intermolecular ligand exchange, and a greater degree of ionic character in metal–ligand bonding that leads to more electrophilic metal centers and correspondingly more nucleophilic ligand centers. Modern organoactinide chemistry is now characterized by the existence not only of actinide analogs to many classes of d-transition metal complexes, but increasingly common reports of compounds and types of reactions unique to the actinide series. We will touch on these points throughout this chapter.

The first actinide organometallic complex, red-brown $(C_5H_5)_3UCl$, was prepared and characterized by Reynolds and Wilkinson in 1956[1] or shortly after the discovery of ferrocene (*see Ferrocene*), $(C_5H_5)_2Fe$. However, it was not until the preparation and structural characterization of bis(cyclooctatetraenyl)uranium, $(C_8H_8)_2U$ ('uranocene', *see Uranocene*) in 1968[2] and the isolation and characterization of uranium alkyls (*see Alkyl Complexes*) in 1973[3] that the field developed momentum. The purpose of this chapter is to provide an overview of organoactinide chemistry that reflects historical as well as recent developments and achievements in the field; it is not meant to be an exhaustive review of the primary literature. More detailed discussion, background material, and extensive references to the literature can be found in several excellent reviews.[4–10]

Not every actinide element has known or well-developed organometallic chemistry. By far the most research has been done on thorium and uranium compounds, a consequence of favorable isotope-specific nuclear properties and, at least until recently, the commercial availability of key starting materials such as ^{232}Th metal, anhydrous $^{232}ThCl_4$, U metal, and anhydrous $^{238}UCl_4$.[11] Thorium chemistry is dominated by the +4 oxidation state and has some similarities to the chemistry of the heavier group 4 metals. For uranium, one can access oxidation states from +3 to +6 in organic media. Although there are some similarities to the chemistry of the heavier group 6 elements, for example, tungsten, there are also some remarkable differences made possible by the availability of the 5f valence orbitals.

2 CYCLOPENTADIENYL AND SUBSTITUTED CYCLOPENTADIENYL COMPLEXES

Organoactinide chemistry initially developed around the use of the ubiquitous cyclopentadienyl ligand (*see Cyclopentadienyl*), Cp = $C_5H_5^-$, and subsequently its alkyl- and silyl-substituted derivatives. The tetravalent oxidation state

dominates the cyclopentadienyl chemistry of the early actinides, but the number of reports on trivalent actinide cyclopentadienyl systems has grown steadily over the past decade. The literature on protactinium(IV) and tetravalent and trivalent *transuranic* cyclopentadienyl compounds is sparse, and the reaction chemistry of these compounds is not particularly well developed. A remarkable series of uranium(V) and uranium(VI) cyclopentadienyl compounds that have no transition metal analogs are of more recent vintage and will be described in due course.

2.1 Cp_4An Compounds

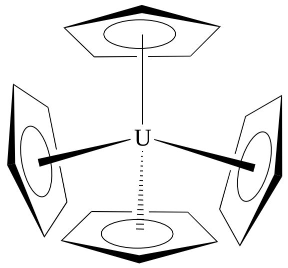
Tetrakis(cyclopentadienyl) actinide complexes, $(C_5H_5)_4An$, were among the earliest organoactinide complexes synthesized and can be prepared by metathesis (*see Metathesis*) of the anhydrous tetrachlorides ($AnCl_4$) with potassium cyclopentadienide (KCp) in refluxing benzene (equation 1, for An = Th, U, and Np).[12] Another member of this series, Cp_4Pa,

$$AnCl_4 + 4KCp \xrightarrow[\Delta]{C_6H_6} AnCp_4 + 4KCl \quad (1)$$

has been synthesized in a solvent-free reaction between protactinium tetrachloride, $PaCl_4$, and Cp_2Be (equation 2).[12] All of the Cp_4An compounds are sparingly soluble in organic

$$PaCl_4 + 2Cp_2Be \xrightarrow{\Delta} Cp_4Pa + 2BeCl_2 \quad (2)$$

solvents. The thorium and uranium compounds have been structurally characterized.[13] IR spectra and X-ray powder diffraction data indicate that the other two members of the series are isostructural. The molecular structure of Cp_4U features a nearly tetrahedral coordination geometry as shown in (**1**), with four η^5-cyclopentadienyl ligands whose average U–C_{ring} distance is 2.81(2) Å.



(**1**)

These U–C distances are roughly 0.1 Å longer than typically observed in other U(IV) cyclopentadienyl complexes and likely reflect the pronounced crowding associated with four η^5-C_5H_5 ligands about the metal center. The mean bond dissociation energy in Cp_4U has been estimated from thermochemical combustion data to be 247 kJ mol^{-1}.[14] The latter may be compared to the value of 297 kJ mol^{-1} found for Cp_2Fe (ferrocene, *Ferrocene*). Compilations of thorium and uranium metal–ligand bond disruption enthalpies (*see* ***Bonding Energetics of Organometallic Compounds***) are available and are quite useful for interpreting and even predicting the course of organoactinide reactions.[15]

Concomitant with the development of synthetic, mechanistic, and structural organoactinide chemistry, there has been an ongoing debate regarding the extent of covalency in actinide–ligand bonds.[8,10] It is important to emphasize that the debate is usually about the *degree* of covalency in a particular actinide–ligand bond, rather than whether or not it exists. Most workers in the field agree that covalency contributes to *early* actinide-ligand bonding in compounds where the formal oxidation state of the metal is +3 or greater. There is also general agreement that actinide-ligand interactions are predominantly ionic for late actinide organometallic compounds in which the formal oxidation state of the metal is +3. A discussion of current theoretical views on this topic will be delayed until later, but along the way we will cite experimental data that suggests that actinide–ligand bonds have appreciable covalent character. A comparison of the ^{237}Np Mössbauer spectra of Cp_4Np and $NpCl_4$ is one such example.[16] The organometallic compound exhibits an isomer shift that is 1.06 cm s^{-1} higher than that observed for the chloride. This difference has been taken as an indication of substantially greater shielding of the 6s shell in Cp_4Np and enhanced metal–ligand bond covalency.

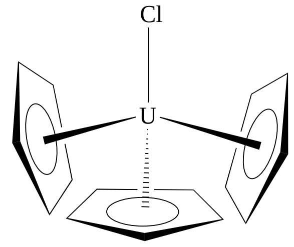
2.2 Cp_3AnX Compounds

As mentioned in the Introduction, $(C_5H_5)_3UCl$ was the first organoactinide compound reported in the literature. Its preparation from UCl_4 and sodium cyclopentadienide in tetrahydrofuran has been generalized, and most of the early actinide tris(cyclopentadienyl) halides can be prepared by the synthetic methodology outlined in equation (3).[1,6] Solvents for this reaction are generally polar organics such as THF or DME.

$$AnX_4 + 3M'Cp \xrightarrow{DME} AnCp_3X + 3M'Cl \quad (3)$$

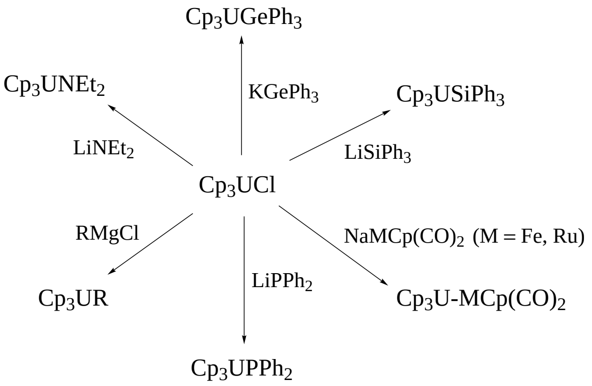
The X-ray structure of Cp_3UCl reveals a distorted tetrahedral uranium coordination geometry as shown in (**2**) with three η^5-Cp ligands at 2.74(1) Å from the metal center and the U–Cl bond (2.559(16) Å) coincident with the molecular threefold axis.[17] This type of structure is essentially identical for all Cp_3UX derivatives. A more accurate X-ray diffraction study of tris(benzylcyclopentadienyl)uranium(IV) chloride gave an average U–C_{ring} distance of 2.733(1) Å and a U–Cl distance of 2.627(2) Å.[18]

In contrast to the reactions of trivalent lanthanide Cp compounds (Cp_3Ln) with iron(II) chloride, Cp_3UCl does



(**2**)

not react with $FeCl_2$ to give ferrocene and it decomposes rather slowly in water. Although the latter results may be taken as an indication of a greater degree of covalency in the uranium(IV)–Cp bond, theoretical considerations suggest that the bonding is more ionic than found in the vast majority of d-block cyclopentadienyl compounds.[8,10] The chloride ligand of Cp_3UCl, on the other hand, is labile and this lability has facilitated the syntheses of a rather large number of other tris(cyclopentadienyl)-uranium(IV) compounds. Thus Cp_3UX compounds with U–P, U–N, U–Si, U–Ge, U–Fe, and U–Ru bonds have been synthesized by metathesis of the chloride ligands in Cp_3UCl.[9] The uranium(IV) diphenylphosphido compound, Cp_3UPPh_2, can also be isolated from the reaction of $Cp_2U(NEt_2)_2$ with $HPPh_2$, during which a redistribution of Cp ligands occurs, presumably after $Cp_2U(NEt_2)(PPh_2)$ is generated.[19] Redistribution reactions (*see Redistribution Reaction*), as we shall see below, are frequently encountered in the chemistry of Cp_2AnX_2 compounds. A reaction scheme illustrating the utility of Cp_3UCl as a synthon in Cp_3UX chemistry is delineated in Scheme 1. Noteworthy in Scheme 1 is the preparation of unbridged metal–metal bonds between uranium and iron or ruthenium.[20] The molecular structures of a number of Cp_3AnX complexes have been determined, as well as the structures of related tris(indenyl)actinide halide compounds (see below). All possess a pseudotetrahedral geometry with the X ligand on an approximate threefold axis of symmetry. The An–C_{ring} and An–X bond lengths are normal for most of the complexes, with Th–C_{ring} and Th–X distances being slightly longer than their counterparts in analogous uranium complexes, consistent with the slightly larger ionic radius of thorium. The average U–C_{ring} and U–X bond lengths are significantly longer in the tris(pentamethylcyclopentadienyl) complexes, $(C_5Me_5)_3UX$ or $Cp^*{}_3UX$ (X = F, Cl), reported by Evans and coworkers.[21] For example, the average U–C_{ring} distance (2.833(9) Å) in $Cp^*{}_3UCl$ is ~0.1 Å longer and U–Cl bond length (2.90(1) Å) is ~0.3 Å longer than that found in $(C_5H_5)_3UCl$. The origin of this difference is clearly the steric crowding engendered by the bulky pentamethylcyclopentadienyl ligands.



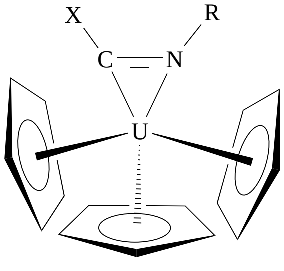
Scheme 1 Some reactions of tris(cyclopentadienyl)uranium(IV) chloride

In addition to metathesis reactions involving Cp_3UCl, it is possible to protonate one Cp ring off of Cp_4U to generate Cp_3UX complexes. A prototypical reaction is shown in equation (4).[22] In addition to neutral Cp_3UX complexes, it is possible, with the appropriate

$$UCp_4 + HCN \xrightarrow{C_6H_6} UCp_3CN + CpH \qquad (4)$$

choice of reaction conditions, to prepare anionic $[Cp_3UX_2]^-$ complexes,[23] and cationic species such as $[Cp_3U(THF)]^+$,[24] $[(t\text{-}BuC_5H_4)_3U]^+$,[25] and $[Cp_3U(CH_3CN)_2]^+$.[26]

Many complexes of general formula Cp_3UX (X = NEt_2, PPh_2, $SiPh_3$) are known to react with substituted isocyanides (*see Isocyanide Ligands*) to give insertion products of general formula $Cp_3U[C(X)=NR]$ in which the resulting carbamoyl ligand is coordinated in an η^2 fashion; the basic structural type is shown in (**3**).[27]



(**3**)

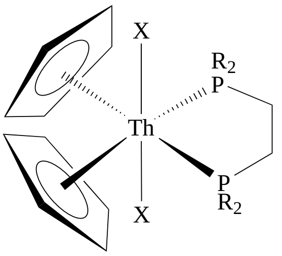
A remarkable, and at the time surprising, addition to the family of Cp_3UX complexes were the organouranium(V) imido complexes (*see Imide Complexes*) of formula $(MeC_5H_4)_3U{=}NR$.[28] These compounds were prepared via the 2-electron oxidation of trivalent $(MeC_5H_4)_3U(THF)$ with the organic azides Me_3SiN_3 and PhN_3 (equation 5). An X-ray structure of the phenylimido complex reveals a very short U–N bond distance of 2.019(6) Å and a nearly linear U–N–C angle of 167.4(6)°, indicative of substantial multiple bond character between uranium and nitrogen.

$$(MeC_5H_4)_3U(THF) + PhN_3 \xrightarrow{Et_2O} (MeC_5H_4)_3U(NPh) + N_2 \qquad (5)$$

2.3 Cp_2AnX_2 Compounds

Complexes of general formula $(C_5H_5)_2AnX_2$ have proven difficult to synthesize and are prone to redistribution reactions. Thus, 'Cp_2UCl_2' prepared in DME via the metathesis of UCl_4 with two equivalents of thallium(I) cyclopentadienide is actually a mixture of Cp_3UCl and $CpUCl_3$(DME).[29] Cp_2AnCl_2 compounds have, in some instances, been successfully stabilized against ligand redistribution by adding ancillary ligands. The Cp_2ThX_2 unit, for example, can be stabilized by adding the chelating alkyl phosphine $Me_2PCH_2CH_2PMe_2$ (dmpe) to form Cp_2ThX_2(dmpe) for X = Cl, Me (equation 6).[30] Analysis of X-ray diffraction data reveals a pseudo-octahedral coordination environment as shown in (**4**).

$$ThCl_4(dmpe) + 2NaCp \xrightarrow{THF} Cp_2ThCl_2(dmpe) + 2NaCl \quad (6)$$



(**4**)

Stabilization against redistribution has also been achieved through the use of sterically demanding X groups (e.g. η^3-BH_4^-), the use of ligands capable of both σ- and π-donation to the actinide metal center (e.g. NEt_2^-), or the use of ring-bridged Cp ligands $[Me_4C_5–X–C_5Me_4]^{2-}$ (X = CH_2, Me_2Si, $CH_2CH_2CH_2$).[31] For example, treatment of $Cp_2U(NEt_2)_2$ with bulky alcohols gives a variety of stable Cp_2UX_2 complexes (X = OC(t-Bu)$_3$, O-2,6-$Me_2C_6H_3$, etc.)[32] and reaction of thorium or uranium tetrachloride with two equivalents of (C_5Me_5)MgCl(THF) in toluene gives stable $(C_5Me_5)_2AnCl_2$ complexes (equation 7).[33]

$$AnCl_4 + 2(C_5Me_5)MgCl(THF) \xrightarrow[\Delta]{PhCH_3} (C_5Me_5)_2AnCl_2 + 2MgCl_2 \quad (7)$$

The C_5Me_5 or Cp* ligand has evolved as one of the most widely used ligands in organoactinide chemistry owing to the thermal stability, solubility, and crystallizability it imparts to compounds. The molecular structures of $Cp^*_2UCl_2$ and $Cp^*_2ThX_2$ (X = Cl, Br, I) have been determined.[34] All of the $Cp^*_2AnX_2$ complexes are mononuclear and members of the pseudotetrahedral, 'bent metallocene' (*see Bent Metallocenes*) family. The analogous neptunium complex has been reported from the reaction of $NpCl_4$ with Cp*MgCl·THF.[35]

Other substituted cyclopentadienyls, such as $[1,3\text{-}(Me_3Si)_2C_5H_3]^-$ and $[1,3\text{-}(Me_3C)_2C_5H_3]^-$ (Cp″ and Cp‡ for short), have been used to stabilize tetravalent thorium and uranium ions. The complexes can be synthesized by reaction of the metal tetrachlorides with either lithium or magnesium reagents.[36] Metathetical reactions of Cp''_2UCl_2 or $Cp^{‡}_2UCl_2$ with $XSiMe_3$ (X = Br, I) or $BF_3(Et_2O)$ provide a convenient route to the other halide analogs. The molecular structures of $(1,3\text{-}R_2C_5H_3)_2UX_2$ (R = $SiMe_3$, X = F, Cl, Br; R = CMe_3, X = F, Cl) have been reported, as well as the structure of $[1,3\text{-}(Me_3Si)_2C_5H_3]_2ThCl_2$. With the exception of $[Cp''_2UF(\mu\text{-}F)]_2$, all of the complexes are monomeric in the solid state. In solution, the fluoride dimer is apparently in equilibrium with its mononuclear counterpart. The ^1H NMR chemical shifts and magnetic susceptibility data for the two fluoride complexes indicate that the ligands produce significantly different electronic environments about the uranium(IV) center.[36]

In some cases where bulky cyclopentadienyl ligands are used, it is still possible to isolate Lewis base adducts. Two examples are $Cp^*_2UCl_2$(pz) (pz = pyrazole)[37] and $[1,3\text{-}(Me_3Si)_2C_5H_3]_2ThCl_2$(dmpe).[38] In compounds of the type $Cp^*_2UX_2$(L), the neutral ligand L occupies the central position in the equatorial wedge.

Metathesis routes have been used to prepare terminal amido, phosphido, and thiolato complexes (equations 8–10) from $Cp^*_2AnCl_2$ starting materials.[39] For the bulky bis(trimethylsilyl)phosphido ligand, only mono substitution occurs.

$$Cp^*_2AnCl_2 + 2LiNR_2 \xrightarrow{Et_2O} Cp^*_2An(NR_2)_2 + 2LiCl \quad (8)$$

$$Cp^*_2ThCl_2 + 2LiPPh_2 \xrightarrow{PhCH_3} Cp^*_2Th(PPh_2)_2 + 2LiCl \quad (9)$$

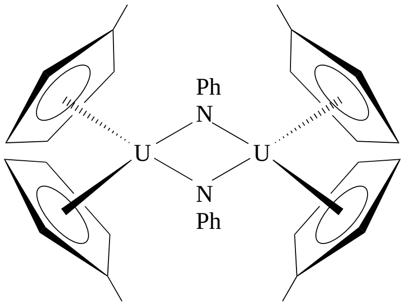
$$Cp^*_2UCl_2 + 2NaSR \xrightarrow{THF} Cp^*_2U(SR)_2 + 2NaCl \quad (10)$$

Toluene solutions of the thorium complex, $Cp^*_2Th(PPh_2)_2$ reacts smoothly with $Pt(COD)_2$ in the presence of trimethylphosphine to provide $Cp^*_2Th(\mu\text{-}PPh_2)_2Pt(PMe_3)$, a complex with a thorium–platinum bond. The latter can be regarded as a formal donor–acceptor or dative bond from the filled d^{10} shell of Pt into the empty d shell of Th.[40]

The bis-MeC_5H_4 or bis-Cp* framework is a useful template for organoimido and organophosphinidene complexes. Comproportionation of uranium(III) and uranium(V) metallocenes provides a route to dinuclear uranium(IV) imido complexes (equation 11).[41] The molecular structure of $[(MeC_5H_4)_2U(NPh)]_2$ is depicted in (**5**).

$$(C_5H_4Me)_3U(THF) + (C_5H_4Me)_3U(NPh) \xrightarrow{THF} [(C_5H_4Me)_2U]_2(\mu\text{-}NPh)_2 \quad (11)$$

Terminal organoimido complexes of uranium(IV) are a more recent discovery. An α-elimination reaction (*see α-Elimination*) was designed for the synthesis of $Cp^*_2U(=N\text{-}2,4,6\text{-}t\text{-}Bu_3C_6H_2)$ (equation 12). The structure of $Cp^*_2U(=N\text{-}2,4,6\text{-}t\text{-}Bu_3C_6H_2)$ reveals a very short U=N distance 1.95(1) Å



(**5**)

and a large U–N–C_{ipso} angle of 162.3(10)°.[42]

$$Cp^*_2UMe_2 + H_2N\text{-}t\text{-}Bu_3C_6H_2 \xrightarrow{\Delta} Cp^*_2U({=}N\text{-}t\text{-}Bu_3C_6H_2) + 2CH_4 \quad (12)$$

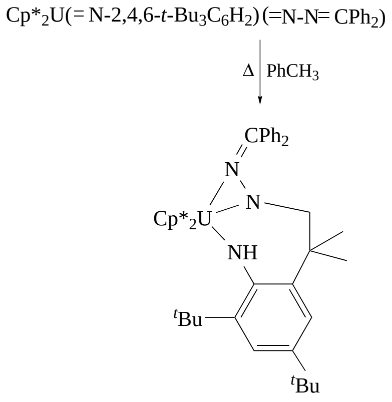
With less bulky aryl groups on nitrogen, it is possible to isolate Lewis base adducts (*see Lewis Acids & Bases*) of the type $Cp^*_2U^{IV}({=}NAr)L$ (Ar = C_6H_5, 2,4,6-$Me_3C_6H_2$, 2,6-*i*-$Pr_2C_6H_3$; L = py, THF, $Me_3P{=}O$). These complexes are precursors to a remarkable series of uranium(VI) bis-imido complexes, for example, $Cp^*_2U({=}NPh)_2$, and mixed imido-oxo compounds, for example, $Cp^*_2U({=}N$-2,4,6-*t*-$Bu_3C_6H_2)({=}O)$. Organic azides are used to oxidize the uranium(IV) mono-imido complexes to bis-imido uranium(VI) complexes (equation 13). Either N_2O or pyridine-N-oxide is effective in introducing the oxo functional group (equation 14). The uranium(VI) bis-imido and imido-oxo complexes have no counterparts in the chemistry of the group 6 elements, a reflection of the availability of additional valence orbitals on the 5f metal center that facilitate an unprecedented degree of actinide–ligand multiple bonding.[42] We should also point out that these complexes are isoelectronic with compounds containing the familiar uranyl ion, $[O{=}U{=}O]^{2+}$. The O=U=O angle is always 180° (trans) in such compounds, but the N=U=N angle in, for example, $Cp^*_2U(NPh)_2$ is 98.7(4)° and the U–N distance is 1.952(7) Å. The N=U=N unit may be viewed as the cis equivalent of the uranyl group.

$$Cp^*_2U({=}NPh)(py) + PhN_3 \xrightarrow{Et_2O} Cp^*_2U({=}NPh)_2 + N_2 + py \quad (13)$$

$$Cp^*_2U({=}N\text{-}t\text{-}Bu_3C_6H_2) + N_2O \xrightarrow{PhCH_3} Cp^*_2U({=}N\text{-}t\text{-}Bu_3C_6H_2)({=}O) + N_2 \quad (14)$$

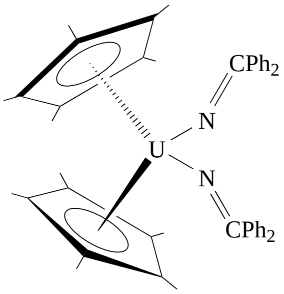
A terminal uranium(IV) phosphinidene complex has been prepared in fashion similar to that used to prepare $Cp^*_2U({=}N$-2,4,6-*t*-$Bu_3C_6H_2)$. Reaction of $Cp^*_2U(Me)Cl$ with K(HP-2,4,6-*t*-$Bu_3C_6H_2$) in the presence of trimethylphosphine oxide yields the adduct $Cp^*_2U({=}P$-2,4,6-*t*-$Bu_3C_6H_2)(O{=}PMe_3)$.[43]

The uranium(IV) imido complex $Cp^*_2U({=}N$-2,4,6-*t*-$Bu_3C_6H_2)$ also reacts with diphenyldiazomethane to give the uranium(VI) mixed bis-imido complex $Cp^*_2U({=}N$-2,4,6-*t*-$Bu_3C_6H_2)({=}N{-}N{=}CPh_2)$.[44] The latter compound does not lose dinitrogen to give a uranium(VI) alkylidene (*see Alkylidene*) complex. Instead, mild solution thermolysis (toluene, 100 °C, 20 min) provides a novel cyclometalated (*see Cyclometalation*) uranium(IV) bis(amide) complex, a consequence of the addition of a C–H bond from one of the ortho *t*-butyl groups across the N=U=N core (equation 15).[44]



(15)

Another interesting uranium(IV) system is the bis-ketimido complex, $Cp^*_2U(–N{=}CPh_2)_2$, formed via the reduction of $Cp^*_2UCl_2$ in ether with 2 mol of potassium graphite (KC_8) in the presence of benzophenone azine, $Ph_2C{=}N{-}N{=}CPh_2$. The molecular structure is depicted in (**6**).[45]



(**6**)

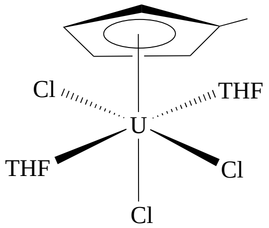
2.4 CpAnX$_3$ Compounds

Compounds of general formula $CpAnX_3L_2$ were first prepared by the metathesis of $AnCl_4$ with a cyclopentadienyl reagent in ethereal solvents (equation 16).[46] Since that time, other Lewis base adducts employing both monodentate and bidentate ligands have been synthesized.

$$AnCl_4 + TlCp \xrightarrow{DME} CpAnX_3(DME) + TlCl \quad (16)$$

The molecular structure of $(MeCp)UCl_3(THF)_2$ has been determined by single-crystal X-ray diffraction and reveals an approximately octahedral coordination environment about U as indicated in (**7**).[29] The average U–Cl distance is 2.620(9) Å, the average U–C_{ring} distance is 2.70(4) Å, and

the average U–O distance is 2.44(2) Å. The disposition of the Cl ligands cis and trans to the cyclopentadienyl ring apparently minimizes intramolecular nonbonded repulsions. Other routes to $CpUX_3L_2$ compounds begin with the corresponding UX_4L_2 complexes. Thorium and uranium pentamethylcyclopentadienyl complexes of the type $Cp^*AnCl_3(THF)_2$ can be prepared from $AnCl_4$ and one equivalent of Cp*MgCl·THF in THF.[47] Lithium reagents, for example, Li[1,2,4-$(Me_3Si)_3C_5H_2]^-$ (Cp‴) can lead to 'ate' complexes (equation 17).[48]



(**7**)

$$UCl_4 + Li[1,2,4\text{-}(Me_3Si)_3C_5H_2] \xrightarrow{THF} Cp'''Cl_2U(\mu\text{-}Cl)_2Li(THF)_2 + LiCl \quad (17)$$

One study has examined the metathesis reactions of $Cp^*ThBr_3(THF)_2$ where $Cp^*ThBr_2(OAr)(THF)$ and $Cp^*ThBr(OAr)_2$ (OAr = O-2,6-*t*-$Bu_2C_6H_3$) are produced via reaction with one or two equivalents of KOAr in THF, respectively.[49]

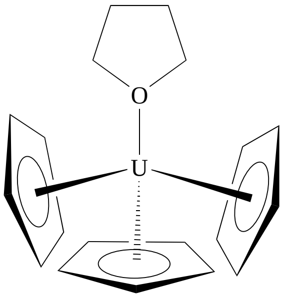
2.5 Cp_3An Complexes

Tris(cyclopentadienyl) actinide complexes are strong Lewis acids and form adducts with a wide variety of Lewis bases. Many routes exist for their preparation, but a fairly general route to the THF adducts is via reduction of Cp_3AnCl (An = Th, U, Np) in THF solution (equation 18). By introducing bulky substituents on the Cp ring, Andersen was able to synthesize monomeric, base-free $(C_5H_4R)_3U$ complexes for R = *t*-Bu and $SiMe_3$.[50] Methyl-substituted complexes $(MeC_5H_4)_3UL$ were employed for the study of equilibrium constants for the ligand displacement reaction shown in equation (19), and demonstrated that the order for ligand displacement is $PMe_3 > P(OMe)_3 >$ pyridine > THF > quinuclidine > CO.[51]

$$Cp_3AnCl + NaC_{10}H_8 \xrightarrow{THF} Cp_3An(THF) + NaCl + C_{10}H_8 \quad (18)$$

$$(MeCp)_3UL + L' \underset{}{\overset{PhCH_3}{\rightleftharpoons}} (MeCp)_3AnL' + L \quad (19)$$

The molecular structure of $Cp_3U(THF)$ features a distorted tetrahedral coordination geometry (**8**) with U–C = 2.76–2.82 Å and U–O = 2.55(1) Å,[52] while $(Me_3SiC_5H_4)_3U$ ($Cp^\dagger{}_3U$) is trigonal planar.[53] The trigonal geometry of $Cp^\dagger{}_3U$ is only moderately perturbed by interaction with ethyl isocyanide to form $Cp^\dagger{}_3U(CNEt)$.[54]



(**8**)

The trivalent thorium complex $(C_5H_5)_3Th$ has been reported from the sodium naphthalide reduction of Cp_3ThCl in THF solution. The violet product can be isolated as a THF adduct; the THF can be removed in vacuo.[55] Cp_3Th was characterized by elemental analysis, IR and UV–V is spectroscopies, and magnetic susceptibility ($\mu_{eff} = 0.403\mu_B$). Cp_3Th is isomorphous (*see Isomorphous*) with other tris(cyclopentadienyl) complexes of the 4f and heavier 5f elements. A dark-green $(C_5H_5)_3Th$ has been prepared from $Cp_3Th(i\text{-}Pr)$ or $Cp_3Th(n\text{-}Bu)$ via UV irradiation. At room temperature, $\mu_{eff} = 0.404\mu_B$. The mechanism of the photochemical process, β-hydride elimination (*see β-Hydride Elimination*), was supported by deuterium labeling studies and other experiments.[56] The relationship of the violet and green forms of Cp_3Th has not been established and neither complex has been crystallographically characterized.

The homoleptic (*see Homoleptic Compound*), dark-blue, paramagnetic organothorium(III) compounds [1,3-$(Me_2RSi)_2C_5H_3]_3Th$ (R = Me, *t*-Bu) were obtained in good yield from the appropriate precursors and Na/K in toluene at room temperature with sonication (equation 20). The coordination environment around thorium is trigonal planar in both complexes, with a Th–C_{ring} distance of ca. 2.80(2) Å. The EPR spectra are consistent with $6d^1$ ground states.[57]

$$[1,3\text{-}(Me_2RSi)_2C_5H_3]_3ThCl + Na/K \xrightarrow{PhCH_3} [1,3\text{-}(Me_2RSi)_2C_5H_3]_3Th + MCl \quad (20)$$

Transneptunium tris(cyclopentadienyl) complexes can be prepared on a microscale from the reaction of molten Cp_2Be with the anhydrous trichlorides (equation 21).[58] The products are isolated by fractional sublimation. X-ray powder diffraction indicates that these Cp_3An complexes are

isostructural with their early actinide analogs.[4]

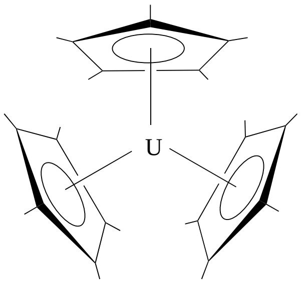
$$2AnCl_3 + 3BeCp_2 \xrightarrow{\Delta} 2AnCp_3 + 3BeCl_2 (An = Pu, Am, Cm, Bk, Cf) \quad (21)$$

A useful development in the synthetic chemistry of trivalent actinide complexes in recent years has been the development of the more soluble iodide starting materials, AnI_3L_4 (An = U, Np, Pu; L = THF, py, DMSO, etc.).[59] These species, generated from actinide metals and iodide sources (e.g. HgI_2, I_2, etc.) in coordinating solvents, are readily soluble in organic solvents, and serve as convenient precursors to a variety of trivalent actinide species. Potassium reagents are preferred for reactions in THF as the metathesis by-product KI is quite insoluble in this solvent. Interestingly, a tungsten(III) analog of $UI_3(THF)_4$, viz., octahedral, *mer*-$WCl_3(THF)_3$, has only recently been prepared.[60] It illustrates the fact that actinide centers typically accommodate a larger ligand set than their transition metal analogs.

Despite the common use of the pentamethylcyclopentadienyl ligand in actinide and lanthanide chemistry, it is only recently that a tris-complex, Cp^*_3An, has been prepared with this ligand. It was previously thought that the large steric bulk associated with this ligand might preclude incorporation of three Cp* groups in the coordination sphere of an actinide and, in fact, direct metathesis routes are not successful. The complex $(\eta^5\text{-}C_5Me_5)_3U$ was initially prepared by reaction of a trivalent hydride complex with tetramethylfulvene (equation 22).[61] Since its discovery, several other routes to Cp^*_3U

$Cp^*_2UH(dmpe)$ +  $\xrightarrow{PhCH_3}$ Cp^*_3U + dmpe (22)

have been developed.[61] The molecular structure is depicted in (**9**). The average U–C_{ring} bond distance in this compound (2.858(3) Å) is longer than in other crystallographically characterized U(III) pentamethylcyclopentadienyl complexes (~2.77 Å), suggesting a significant degree of steric crowding.



(**9**)

One of the most remarkable reactions of Cp^*_3U is that with dinitrogen at moderate pressure (80 psi) to yield the mononuclear, end-on bonded $Cp^*_3U(\eta^1\text{-}N_2)$. The latter is the first monometallic f-element dinitrogen complex.[62]

2.6 Cp_2AnX Complexes

While complexes of general formula Cp_2MX are very common in organolanthanide chemistry, they are relatively rare in organoactinide chemistry. Sodium amalgam or *tert*-butyl lithium reduction of Cp''_2UX_2 and $Cp^‡_2UX_2$ provides dimeric $[Cp''_2UX]_2$ or $[Cp^‡_2UX]_2$ (equation 23).[63] The dimers are readily cleaved in THF to give monomeric $Cp''_2UX(THF)$ or $Cp^‡_2UX(THF)$. The related compound $Cp^*_2UI(THF)$ is conveniently prepared by reaction of two equivalents of KCp* with $UI_3(THF)_4$ in THF solution (equation 24).[64]

$$Cp^‡_2UX_2 + t\text{-BuLi} \xrightarrow{C_6H_{14}} [Cp^‡_2UX]_2 + LiCl \xrightarrow{THF} 2Cp^‡_2UX(THF) \quad (23)$$

$$UI_3(THF)_4 + 2KCp^* \xrightarrow{THF} Cp^*_2UI(THF) + 2KI \quad (24)$$

The uranium(III) complexes $\{[1,3\text{-}R_2C_5H_3]_2U(\mu\text{-}OH)\}_2$ (R = Me_3Si or Me_3C) have been prepared by reaction of one equivalent of water with Cp''_3U and $Cp^‡_2UH$, respectively. Upon heating, these complexes undergo an unusual 'oxidative elimination' reaction to yield the corresponding μ-oxo uranium(IV) complexes (equation 25).[65] The kinetics of this process has been examined, and the reaction is found to be intramolecular, probably

$$Cp^‡_4U_2(\mu\text{-}OH)_2 \xrightarrow[\Delta]{PhCH_3} Cp^‡_4U_2(\mu\text{-}O)_2 + H_2 \quad (25)$$

involving a stepwise α-elimination process (*see* α-*Elimination*).

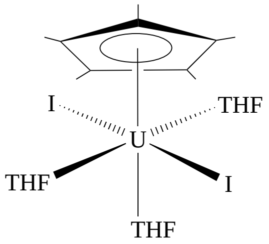
One of the most thoroughly investigated 'Cp_2AnX' systems is the chloride-bridged, trimeric complex $[Cp^*_2U(\mu\text{-}Cl)]_3$.[66] The complex can be prepared by a number of routes, one of which is shown in equation (26). $[Cp^*_2U(\mu\text{-}Cl)]_3$ reacts with a variety of Lewis bases to generate mononuclear adducts, and will undergo metathesis reactions.

$$Cp^*_2UH_2 + Cp^*_2UCl_2 \xrightarrow{PhCH_3} \frac{2}{3}[Cp^*_2U(\mu\text{-}Cl)]_3 + H_2 \quad (26)$$

A cationic bis(pentamethylcyclopentadienyl)uranium(III) complex has been reported. $[Cp^*_2U(THF)_2][BPh_4]$ is generated by protonation of the complex $Cp^*_2U[N(SiMe_3)_2]$ with $[NH_4][BPh_4]$.[67]

2.7 $CpAnX_2$ Complexes

Mono-ring cyclopentadienyl complexes of trivalent actinides are exceedingly rare. The borohydride ligated anions $CpU(BH_4)_3^-$ and $Cp^*U(BH_4)_3^-$ have been reported through sodium amalgam reduction of the corresponding uranium(IV) precursors.[68] Neutral $Cp^*UI_2(THF)_3$ is readily prepared by treatment of $UI_3(THF)_4$ with one equivalent of KCp* in THF solution. The solid-state structure reveals a pseudo-octahedral coordination geometry with a trans–mer arrangement of iodide and THF ligands, as indicated in (**10**).[59]

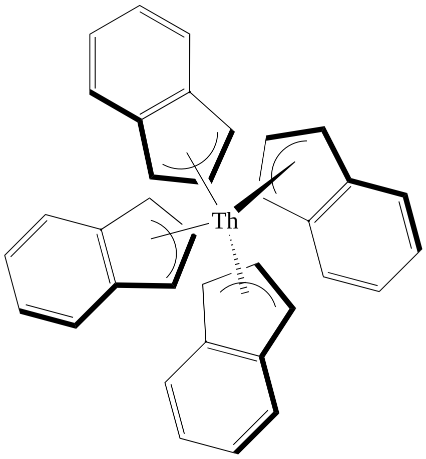


(**10**)

In the presence of excess pyridine, this complex can be converted to the analogous pyridine adduct $Cp^*UI_2(py)_3$. $Cp^*UI_2(THF)_3$ will react further with KCp* to generate the bis-ring product, $Cp^*{}_2UI(THF)$, or will react with two equivalents of $K[N(SiMe_3)_2]$ to produce $Cp^*U[N(SiMe_3)_2]_2$. The solid-state structure of the bis(trimethylsilyl)amide derivative reveals close contacts between the uranium center and two of the methyl carbons (2.80(2), 2.86(2) Å).[64]

2.8 Indenyl Compounds

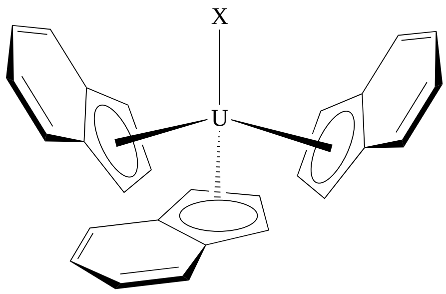
Tetrakis(indenyl)thorium(IV), $Th(C_9H_7)_4$, is known and well characterized.[69] As depicted in (**11**), the thorium is bonded to carbons of the five-membered ring of the indenyl ligand, albeit not in an η^5 fashion. The shortest thorium–carbon distances are to the three nonbridging carbons in a tri-hapto or η^3 fashion (Th–C_{ave} = 2.83 Å).[70]



(**11**)

The indenide anion is analogous to the cyclopentadienide anion, but differs significantly in electronic structure and steric requirements. Tris(indenyl)thorium(IV) and uranium(IV) halides, $(C_9H_7)_3AnX$, have been prepared by metathesis of the halide ligands of AnX_4 with 3 equivalents of indenyl potassium in THF solution.[71] Mono(indenyl)thorium, -uranium, and -neptunium compounds of the type $(C_9H_7)AnX_3L$, where L is a Lewis base, can be prepared by modifying the reaction stoichiometry.

The molecular structure of $(C_9H_7)_3UCl$ is indicated in (**12**) and reveals a distorted tetrahedral coordination geometry with η^5-indenyl ligation. The U–Cl distance is 2.593(3) Å, and the average U–C_{ring} distance is 2.78 Å, with a range of 2.67(1)–2.89(1) Å. The $(C_9H_7)_3ThX$ compounds can be converted to alkoxide and tetrahydroborate derivatives by straightforward metathesis.[72] In the case of $(C_9H_7)_3UCl$ plus $NaBH_4$, reduction to trivalent $(C_9H_7)_3U(THF)$ is reported to occur. Complexes similar to $(\eta^5\text{-}C_9H_7)_3MCl$ compounds have also been prepared and characterized with substituted indenyl ligands.



(**12**)

The bis(indenyl) complex $(\eta^5\text{-}C_9H_7)_2U(BH_4)_2$ can be prepared by the reaction of $Na(C_9H_7)$ with $U(BH_4)_4$ and its structure has been reported.[73] Peralkylated indenyl ligands have also been used to produce 'metallocene' (*see Metallocene Complexes*) derivatives. Thus, reaction of $ThCl_4$ with $Li(C_9Me_7)$ yields the dichloride complex $(\eta^5\text{-}C_9Me_7)_2ThCl_2$.[74] This species serves as a reagent for the synthesis of a number of derivatives, including $(C_9Me_7)_2Th(NMe_2)_2$ and $(C_9Me_7)_2Th(\eta^3\text{-}H_3BH)_2$. The permethylindenyl ligand binds with a nearly idealized η^5-coordination mode, with the Th–C bonds for the five-membered ring of the indenyl ligands varying by less than 0.05 Å. The indenyl rings are not entirely planar, indicating that there are steric repulsions between the proximal methyl groups of the two $(\eta^5\text{-}C_9Me_7)$ ligands.

Thorium(III) and uranium(III) indenyl compounds, $(C_9H_7)_3An$, are also known and the molecular structure of $U(C_9H_7)_3$ has been reported. The uranium coordination geometry is approximately trigonal, with U–C bond distances ranging from ca. 2.75(2) to 2.81(2) Å.[75]

3 CYCLOOCTATETRAENE COMPLEXES

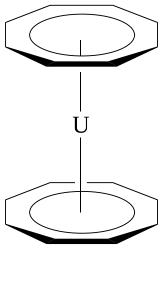
3.1 $(cot)_2An$ Complexes

Streitwieser's synthesis of the bright green uranium(IV) sandwich complex $(C_8H_8)_2U$ (*see Uranocene*) was an important and stimulating discovery in the history of organoactinide chemistry.[2] Bis(cyclooctatetraene)actinide(IV) complexes were subsequently prepared for thorium, protactinium, neptunium, and plutonium.[76] These complexes are generally synthesized by metathesis of the actinide tetrachloride $AnCl_4$ with $K_2(C_8H_8)$ in THF (equation 27). The exception is plutonium, which does not have a stable tetrachloride. Its preparation has, however, been achieved using the pyridinium salt of $PuCl_6{}^{2-}$ (equation 28).

$$AnCl_4 + 2K_2C_8H_8 \xrightarrow{THF} An(C_8H_8)_2 + 4KCl \quad (27)$$

$$(pyH)_2PuCl_6 + 2K_2C_8H_8 \xrightarrow{THF} Pu(C_8H_8)_2 + 4KCl + 2pyHCl \quad (28)$$

The molecular structure of uranocene has been determined by single-crystal X-ray diffraction, and is shown schematically in (**13**).[77] The molecule possesses rigorous D_{8h} symmetry with the eight-membered rings arranged in an eclipsed conformation. The mean U–C bond distance is 2.647(4) Å, and the mean C–C bond distance is 1.392(13) Å. The C_8 rings are planar to within experimental error. The structure of thoracene in the solid state is isomorphous with that of uranocene, with mean Th–C and C–C bond distances of 2.701(4) and 1.386(9) Å, respectively.[78] X-ray powder diffraction data on the Pa, Np, and Pu analogs indicate that these complexes are also isomorphous with uranocene. The neptunium(IV) complex $(C_8H_8)_2Np$ exhibits a ^{237}Np Mössbauer isomer shift (*see Isomer Shift*) of $+1.94\,cm\,s^{-1}$. This may be compared to the shifts of $-0.34\,cm\,s^{-1}$ found for $NpCl_4$ and $+0.72\,cm\,s^{-1}$ found for Cp_4Np and is taken as an indication of appreciable covalency in the Np^{IV}–ring bond.[76]



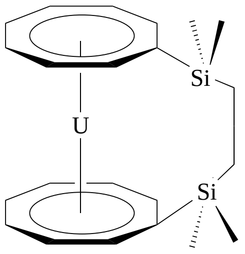
(**13**)

All of the $(C_8H_8)_2An$ complexes are exceedingly sensitive to oxygen. Metal–ring bonding appears to be more 'ionic' in thoracene than uranocene. $(C_8H_8)_2Th$ is rapidly destroyed by protic reagents, whereas uranocene is hydrolyzed only slowly. Mechanistic studies indicate that electron-withdrawing ring substituents accelerate $C_8H_8{}^{2-}$ cleavage, suggesting a rate-limiting ($k_{H_2O}/k_{D_2O} = 11.8$) proton transfer from a uranium-bound water molecule.[79]

A large number of substituted (cyclooctatetraenyl) complexes have also been reported. The addition of substituents has been employed to improve solubility, alter electronic properties, or investigate the dynamics of ring rotation. The largest class are the 1,1′-disubstituted derivatives (equation 29).[80]

$$UCl_4 + 2K_2C_8H_7R \xrightarrow{THF} U(C_8H_7R)_2 + 2KCl \quad (29)$$

A number of uranocene derivatives with higher degrees of substitution have been reported, including several with exocyclic ligands. The tri-silylated derivatives $[1,3,5\text{-}(SiMe_3)_3C_8H_5]_2An$ have been prepared for An = Th, U, and Np.[81] There is also one example of a ring-bridged uranocene, [1,2-bis(cyclooctatetraenyldimethylsilyl)-ethane]uranium (**14**).[82]

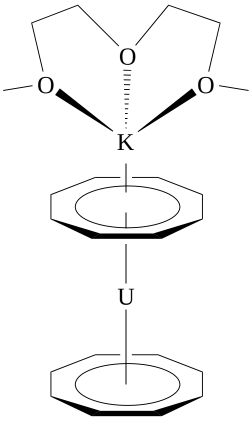


(**14**)

Ring dynamics (rotation and exchange) have been studied by means of variable-temperature NMR spectroscopy for substituted derivatives (*see* ***Stereochemical Nonrigidity of Organometallic Complexes***). Uranocenes undergo rapid ligand exchange with cyclooctatetraene dianions, and the barrier to ring rotation has been estimated at $8.3\,kcal\,mol^{-1}$ for $(1,4\text{-}t\text{-}Bu_2C_8H_6)_2U$.[83]

Actinide(III) complexes of the type $[K(solvent)][An(cot)_2]$ are known for U, Np, Pu, and Am.[84] They may be prepared by interaction of $K_2(cot)$ with a trivalent halide or reduction of $(RC_8H_7)_2U$ with KC_8H_{10} in diglyme. The structure of $[K(diglyme)][(MeC_8H_7)_2U]$ has been determined and is shown schematically in (**15**).[85] The U–C distances average 2.707(7) and 2.732(8) Å; the shorter average is associated with the ring remote from the potassium cation. These are both appreciably longer than the U–C distance of 2.647(4) Å found in uranocene, consistent with the larger size of U^{+3}.

The Mössbauer spectrum of the neptunium compound $[(C_8H_8)_2Np]^-$ confirms that the metal is in the trivalent oxidation state, and suggests a lower overall degree of covalency in metal–ligand bonding than in tetravalent derivatives.[84] Most recently, the reduction route has been extended



(**15**)

to generate the trivalent actinocenes, $[K(DME)_2]\{[1,4\text{-}(t\text{-}BuMe_2Si)_2C_8H_6]_2An\}$ (An = Th, U).[86] The complexes also display asymmetric An–C_{ring} distances, owing to the 'capping' of one ring by the potassium counterion. The Th(III) compound has a $6d^1$ ground state as shown by the room temperature EPR (*see Electron Paramagnetic Resonance*) spectrum ($g_{ave} = 1.918$).

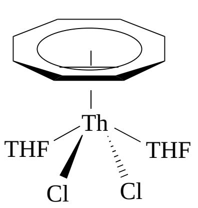
Intermolecular electron-transfer rates have been studied for uranocene and substituted derivatives of uranium, neptunium, and plutonium by examining the variable-temperature NMR spectra of mixtures of $(C_8H_8)_2An$ and $[(C_8H_8)_2An]^-$.[87] In all cases, electron-transfer rates are rapid. Specific rates could not be derived for uranium and plutonium derivatives owing to the small chemical shift differences between analogous An(IV) and An(III) compounds, but in the case of $(t\text{-}BuC_8H_7)_2Np$, the rate has been estimated to be of the same order of magnitude as comparable lanthanide cyclooctatetraene compounds ($\sim 10^7\ M^{-1}\ s^{-1}$).[87]

3.2 (cot)AnX_2 Complexes

The chemistry of actinide complexes containing a single cyclooctatetraenyl ring ('half-sandwich' complexes) began with a report of $(C_8H_8)NpI(THF)_x$, prepared by reaction of $NpI_3(THF)_4$ and one equivalent of $K_2(C_8H_8)$ in THF.[88] Mono-ring Th(IV) complexes, with cyclooctatetraene and substituted cyclooctatetraenes have been prepared by reaction of $ThCl_4$ with one equivalent of $K_2[C_8H_7R]$ (R = alkyl or H) or by redistribution between $(C_8H_7R)_2Th$ and $ThCl_4$ in THF solution (equation 30).[89,90]

$$ThCl_4 + Th(C_8H_7R)_2 \xrightarrow{THF} 2(C_8H_7R)ThCl_2(THF)_2 \quad (30)$$

The solid-state molecular structure of $(C_8H_8)ThCl_2(THF)_2$ reveals a half-sandwich (*see Half-sandwich Complexes*) structure that is similar to the four-legged piano stool in transition metal systems, and this structural unit is shown in (**16**). The average Th–Cl distance is 2.686(6) Å, the average



(**16**)

Th–O distance is 2.57(2) Å, and the average Th–C_{ring} distance is 2.72(2) Å.[91]

The aforementioned preparative routes are not applicable to mono-cot uranium(IV) complexes. The groups of Cloke,[92] Streitwieser,[93] and Ephritikhine[94,95] have developed several successful routes for the preparation of such complexes; some of these are indicated in equations (31–34). The displacement of a π-coordinated ligand under oxidizing conditions (equation 32) is quite remarkable and otherwise unprecedented in organoactinide chemistry.

$$U(C_8H_8)_2 + U(BH_4)_4 \xrightarrow{PhCH_3} 2U(C_8H_8)(BH_4)_2 \quad (31)$$

$$U(C_8H_8)_2 + I_2 \xrightarrow{THF} U(C_8H_8)I_2(THF)_2 + C_8H_8 \quad (32)$$

$$(Et_2N)_2UCl_2 + K_2C_8H_8 \xrightarrow{THF} (C_8H_8)U(NEt_2)_2(THF) + 2KCl \quad (33)$$

$$U(C_8H_8)_2 + 3LiNEt_2 \xrightarrow{OEt_2} Li[(C_8H_8)U(NEt_2)_3] + Li_2C_8H_8 \quad (34)$$

The mono-cot complexes are more reactive than their actinocene congeners, and all react with Lewis bases to form adducts, such as $(C_8H_8)UCl_2(PMe_3)$, $(C_8H_8)UCl_2(py)_2$, $(C_8H_8)UI_2(HMPA)_2$, and $(C_8H_8)U(BH_4)_2(THF)$. In addition, considerable effort has been expended on the metathesis of the halide ligands to produce mono(cyclooctatetraenyl) actinide amides and alkyls (equations 35 and 36).[90,95]

$$(C_8H_8)ThCl_2(THF)_2 + 2NaN(SiMe_3)_2 \xrightarrow{THF} (C_8H_8)Th[N(SiMe_3)_2]_2 + 2NaCl \quad (35)$$

$$(C_8H_8)UI_2(HMPA) + 2LiCH(SiMe_3)_2 \xrightarrow{PhCH_3} (C_8H_8)U[CH(SiMe_3)_2]_2(HMPA) + 2LiCl \quad (36)$$

Cationic derivatives, for example, $[(C_8H_8)U(BH_4)(THF)_2][BPh_4]$, may be produced by protonation of tetravalent $(C_8H_8)U(BH_4)_2(THF)$ with $[NEt_3H][BPh_4]$.[96] Reaction of $(C_8H_8)U(BH_4)_2(THF)$ with additional ammonium salt in the presence of hexamethylphosphoramide (HMPA) yields the unique dicationic species $[(C_8H_8)U(HMPA)_3][BPh_4]_2$.[96]

An interesting class of pentavalent complexes supported by the cyclooctatetraenyl ligand has been developed. Oxidation of anionic U(IV) mono-ring amide complexes with $TlBPh_4$ or $AgBPh_4$ generates the corresponding pentavalent amide

complexes as shown in equations (37) and (38).[97] The molecular structure of $[(C_8H_8)U(NEt_2)_2(THF)][BPh_4]$

$$\text{Li}[(C_8H_8)U(NEt_2)_3] + \text{TlBPh}_4 \xrightarrow{\text{THF}} (C_8H_8)U(NEt_2)_3 + \text{Tl}^0 + \text{LiBPh}_4 \quad (37)$$

$$(C_8H_8)U(NEt_2)_2(\text{THF}) + \text{AgBPh}_4 \xrightarrow{\text{THF}} [(C_8H_8)U(NEt_2)_2(\text{THF})][\text{BPh}_4] + \text{Ag}^0 \quad (38)$$

has been determined. The amide ligands are susceptible to protonation by alcohols to yield alkoxide complexes. Pentavalent cyclooctatetraenyluranium compounds have been studied by EPR and X-ray absorption spectroscopy. Analysis of EPR spectra suggest that chemical bonding with the cyclooctatetraenyl ligand occurs principally with the uranium 6d orbitals, except possibly in the case of the tris(isopropoxide) complex $(C_8H_8)U(O\text{-}i\text{-Pr})_3$.[98]

3.3 Mixed-ring (cot)AnCp Complexes

$(C_8H_8)ThCl_2(THF)_2$ has been employed as a precursor to mixed-ring cot-Cp* complexes via the metathesis reactions indicated in equations (39) and (40).[90] Brown (cot)UCp*(I)(THF) can be prepared from $(cot)UI_2(THF)_2$ and KCp*.[99]

$$(C_8H_8)\text{ThCl}_2(\text{THF})_2 + \text{Cp}^*\text{MgCl(THF)} \xrightarrow{\text{PhCH}_3} (C_8H_8)\text{ThCp}^*\text{Cl(THF)} + \text{MgCl}_2 \quad (39)$$

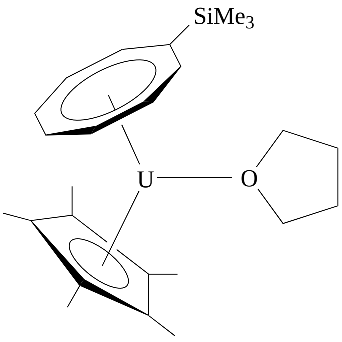
$$(C_8H_8)\text{ThCp}^*\text{Cl(THF)} + \text{LiCH(SiMe}_3)_2 \xrightarrow{\text{PhCH}_3} (C_8H_8)\text{ThCp}^*[\text{CH(SiMe}_3)_2] + \text{LiCl} \quad (40)$$

The only successful preparation of a mixed-ring uranium(III) complex was achieved by reacting $Cp^*UI_2(THF)_3$ with $K_2[C_8H_7R]$ (R = H, alkyl, silyl) to produce $(C_8H_7R)Cp^*U(THF)$ (equation 41).[100] Several Lewis base adducts have been prepared and the solid-state structures of $[(Me_3Si)C_8H_7]Cp^*U(THF)$ and $(C_8H_8)Cp^*U(4,4'\text{-}Me_2\text{-}2,2'\text{-bipy})$ have been determined. A schematic representation of $[(Me_3Si)C_8H_7]UCp^*(THF)$ is shown in (**17**).

$$\text{Cp}^*\text{UI}_2(\text{THF})_3 + K_2C_8H_8 \xrightarrow{\text{THF}} \text{Cp}^*\text{U}(C_8H_8)(\text{THF}) + 2\text{KI} \quad (41)$$

$(C_8H_8)Cp^*U(THF)$ reacts with cyclooctatetraene to form the cot-bridged uranium(IV) compound $[(C_8H_8)Cp^*U]_2(\mu\text{-}C_8H_8)$ in quantitative yield. The same compound can be prepared from the reaction of 2 mol of $Cp^*{}_3U$ and 3 mol of cyclooctatetraene (equation 42).[101]

$$2(C_8H_8)\text{UCp}^*(\text{THF}) + C_8H_8 \xrightarrow{\text{PhCH}_3} [(C_8H_8)\text{Cp}^*\text{U}]_2(\mu\text{-}C_8H_8) \quad (42)$$



(**17**)

4 ALLYL, PENTADIENYL, AND RELATED COMPLEXES

4.1 Allyl (*see Allyl Complexes*) Complexes

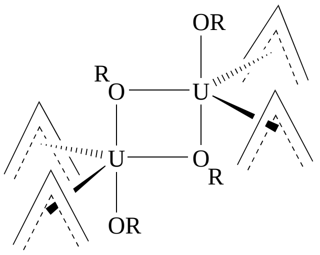
Tetrakis(allyl) complexes of thorium and uranium have been synthesized via the addition of allyl Grignard to the metal tetrachloride (equation 43).[102,103] Alkyl-substituted allyl

$$\text{AnX}_4 + 3C_3H_5\text{MgCl} \xrightarrow{\text{Et}_2\text{O}} \text{An}(C_3H_5)_4 + 4\text{MgCl}_2 \quad (43)$$

complexes can be prepared using a similar approach. The parent $An(\eta^3\text{-allyl})_4$ complexes are unstable above about 0 °C. Low-temperature proton NMR spectroscopy reveals the characteristic A_2B_2X patterns indicative of η^3-allyl ligation. $U(\eta^3\text{-}C_3H_5)_4$ is readily protonated by hydrogen halides or alcohols to remove successive allyl ligands (equations 44 and 45).[104] The molecular structure of the t-butoxyallyl dimer is shown schematically in (**18**), and consists of a centrosymmetric, alkoxy-bridged dimer with η^3-allyl ligands (U–C = 2.644(16)–2.736(18) Å).

$$U(C_3H_5)_4 + \text{HX} \xrightarrow{\text{Et}_2\text{O}} U(C_3H_5)_3X + C_3H_6 \quad (44)$$

$$2U(C_3H_5)_4 + 4\text{HOR} \xrightarrow{\text{Et}_2\text{O}} [U(C_3H_5)_2(\text{OR})_2]_2 + 4C_3H_6 \quad (45)$$



(**18**)

Quite recently, Hanusa and coworkers have isolated the bulky allyl complexes $[(Me_3Si)_nC_3H_{5-n}]_4Th$ (n = 1,2)

from the reaction of $ThBr_4(THF)_4$ and four equivalents of $K[(Me_3Si)_nC_3H_{5-n}]$ in THF at $-78\,°C$. The isolated complexes are stable up to $90\,°C$ ($n = 1$) or $124\,°C$ ($n = 2$) and are the first structurally authenticated homoleptic (*see Homoleptic Compound*) Th-allyl complexes. The Th–C distances in $[(Me_3Si)_2C_3H_3]_4Th$ range from 2.617(5) to 2.892(5) Å, a spread (0.275 Å) similar to that of the Th–C bond lengths in the slipped indenyl complex $(C_9H_7)_4Th$ (2.66(3)–2.97(4) Å).[105]

4.2 Pentadienyl (*see Pentadienyl Ligand*) and Related Complexes

A more stable 'open' π-system is provided by the pentadienyl ligand. The 2,4-dimethylpentadienyl ligand was first used in the generation of homoleptic (η^5-2,4-$Me_2C_5H_5)_3U$ (equation 46).[106] The mixed-ligand uranium(III) complex [K(18-crown-6)][(2,4-$Me_2C_5H_5)_2U(BH_4)_2$] has been prepared by reaction of (2,4-$Me_2C_5H_5)_3U$ with

$$UCl_3(THF)_x + 3K(2,4\text{-}Me_2C_5H_5) \xrightarrow{THF} (2,4\text{-}Me_2C_5H_5)_3U + 3KCl \quad (46)$$

potassium borohydride in the presence of the crown ether.[107] The reaction of (2,4-$Me_2C_5H_5)_3U$ with $[Et_3NH][BPh_4]$ generates the cationic U(III) complex [(2,4-$Me_2C_5H_5)_2U][BPh_4]$.[107] The tetravalent uranium derivatives (2,4-$Me_2C_5H_5)_2U(BH_4)_2$ and (2,4-$Me_2C_5H_5)U(BH_4)_3$ have been synthesized by the reactions of (2,4-$Me_2C_5H_5)_3U$ with $TlBH_4$, or $U(BH_4)_4$ with K(2,4-$Me_2C_5H_5$), respectively.[108]

Similar reactions have also been carried out with the related 6,6-dimethylcyclohexadienyl ligand. Reaction of $U(BH_4)_4$ with K(6,6-$Me_2C_6H_5$) provides the bis(ligand) compound, (η^5-6,6-$Me_2C_6H_5)_2U(BH_4)_2$ as shown in equation (47).[108]

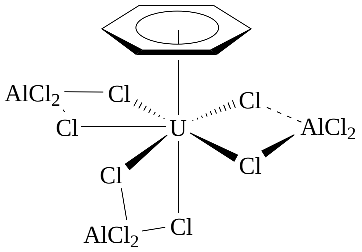
$$U(BH_4)_4 + 2K(6,6\text{-}Me_2C_6H_5) \xrightarrow{THF} (BH_4)_2U(\eta^5\text{-}6,6\text{-}Me_2C_6H_5)_2 \quad (47)$$

5 ARENE (*See Arene Complexes*) COMPLEXES

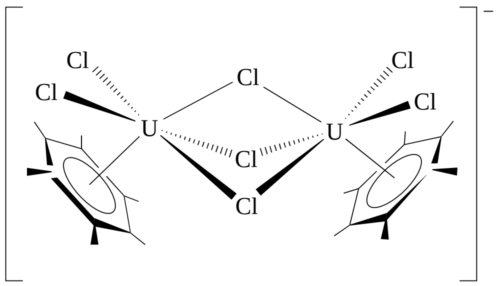
The first organoactinide arene complex (η^6-$C_6H_6)U(AlCl_4)_3$ was prepared in 1971 by Cesari and coworkers via the Friedel–Crafts reduction of UCl_4 in benzene (equation 48).[109] This reducing Friedel–Crafts methodology was developed further by Cotton *et al.*, who isolated a series of hexamethylbenzene complexes whose stoichiometry was dependent upon the reaction conditions and the quantities of $AlCl_3$ and reducing agent (Zn or Al) used in the synthesis. One of these reactions is shown in equation (49). The molecular structures of all of these complexes have been determined, and those of $(C_6H_6)U(AlCl_4)_3$ and $[(C_6Me_6)_2U_2Cl_7][AlCl_4]$ are shown schematically in (**19**) and (**20**). The arene ligands are all bonded in an η^6 fashion with relatively long average $U–C_{ring}$ distances in the range of 2.92–2.94 Å.[110]

$$UCl_4 + Al + AlCl_3 \xrightarrow{C_6H_6} (C_6H_6)U(AlCl_4)_3 \quad (48)$$

$$UCl_4 + Zn + xs\ AlCl_3 \xrightarrow{C_6Me_6} [(C_6Me_6)_2U_2Cl_7][AlCl_4] \quad (49)$$



(**19**)

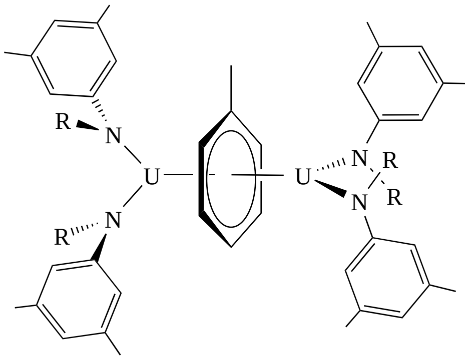


(**20**)

Ephritikhine showed that thermal reduction of $U(BH_4)_4$ in mesitylene produces $(C_6H_3Me_3)U(BH_4)_3$.[111] Unlike the tetrachloroaluminate complexes, this complex is soluble in toluene and NMR spectroscopy shows that the arene ligand undergoes reversible dissociation. X-ray diffraction reveals a pseudotetrahedral coordination geometry with an average U–C distance of 2.93 Å.

More recently, Cummins and coworkers have reported that reduction of tetravalent uranium amide complexes provides an interesting series of *bridging* (*see Bridging Ligand*) arene complexes. Reduction of $[N(t\text{-}Bu)Ar]_3UI$ (Ar = 3,5-$Me_2C_6H_3$) by KC_8 in toluene generates the complex $[N(t\text{-}Bu)Ar]_2U(\mu\text{-}\eta^6,\eta^6\text{-}C_7H_8)U[N(t\text{-}Bu)Ar]_2$. Structural characterization reveals that the complex contains a bridging toluene molecule bound symmetrically to the two metal centers (**21**).[112]

The $U–C_{ring}$ distances are short relative to other η^6-arene complexes, ranging from 2.503(9) to 2.660(8) Å. In addition, there is a slight distortion in the bound toluene ligand; the average C–C distance increases by approximately 0.04 Å compared to that found in free toluene. Density functional calculations carried out on the molecule suggest that four



(**21**)

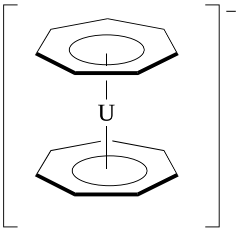
electrons are engaged in the formation of two δ-symmetry back-bonds (*see Back Bonding*) involving U 6d and 5f orbitals and the LUMO of the bridging arene molecule. [N(t-Bu)Ar]$_2$U(μ-η^6,η^6-C_7H_8)U[N(t-Bu)Ar]$_2$ presents something of a dilemma in terms of assigning formal oxidation states. In the limit of complete transfer of electrons from the metal to the arene, uranium would be in the +4 oxidation state and the bridging ligand would be [arene]$^{4-}$. At the other extreme of negligible electron transfer, uranium would be in the +2 oxidation state and the bridging ligand would be [arene]^0. In between, we obviously have U^{+3} and [arene]$^{2-}$. The authors prefer the latter interpretation based on the metrical data and the reduction potential of the free ligand. Further experimental studies, for example, using techniques such as X-ray adsoprtion near edge structure spectroscopy (XANES), will be required to sort out the actual degree of oxidation of the uranium centers. We note that a similar oxidation state ambiguity exists in the complex [Cp$^*_2$U]$_2$(μ-η^6,η^6-C_6H_6) recently reported by Evans *et al.*[113] On the basis of chemical, structural, and electronic structure analysis, these authors propose that [Cp$^*_2$U]$_2$(μ-η^6,η^6-C_6H_6) contains U(III) metal centers complexed to an arene dianion.

6 OTHER CARBOCYCLIC LIGANDS

Complexes of the early actinides with five-, six-, and eight-membered rings have already been described. The series was completed recently with the addition of complexes employing the cycloheptatrienyl ligand. The sandwich complex [K(18-crown-6)][(η^7-C_7H_7)$_2$U] was prepared according to equation (50) and the structure determined by X-ray crystallography.[114] The molecular structure of the anion [(C_7H_7)$_2$U]$^-$ is depicted in (**22**).

$$UCl_4 + 4KC_7H_7 \xrightarrow[\text{18-crown-6}]{\text{THF}} [K(18\text{-crown-6})][U(C_7H_7)_2] \qquad (50)$$

The complex has crystallographically imposed C_{2h} symmetry and the cycloheptatrienyl ligands are planar to

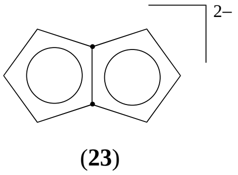


(**22**)

within 0.02 Å. The uranium–carbon bond distances average 2.53(2) Å, significantly shorter than those found for typical tetravalent uranium cyclopentadienyl and cyclooctatetraenyl complexes. Similar bond shortening has been observed in M–C bonds in early transition metal cycloheptatrienyl complexes and has been explained in terms of electron transfer from the metal to the ligand, with an increase in metal valency.

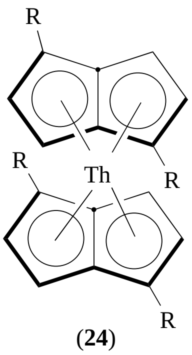
Treatment of UX_4 (X = NEt_2, BH_4) with K[C_7H_9] affords the inverse cycloheptatrienyl sandwich complexes K[X_3U(μ-η^7:η^7-C_7H_7)UX_3].[115]

Another C_8 system, the pentalene dianion ($C_8H_6^{2-}$), has been far less studied than the cyclooctatetraenyl ligand. This ligand may be considered to be derived from $C_8H_8^{2-}$ by removal of two hydrogen atoms with generation of a C–C bond to yield two fused five-membered rings (**23**)



(**23**)

A substituted derivative of the pentalene ligand, [1,5-(i-Pr_3Si)$_2C_8H_4$]$^{2-}$, has been employed to generate the neutral bis(ligand) uranium and thorium compounds [1,5-(i-Pr_3Si)$_2C_8H_4$]$_2$Th and [1,5-(i-Pr_3Si)$_2C_8H_4$]$_2$U, which are rare examples of η^8-coordinated pentalene ligands.[116] The molecular structure of the thorium compound revealed it to be a near-equal mixture of staggered and eclipsed sandwich isomers in a disordered structure (**24**). The two isomers are



(**24**)

generated by thorium binding to two different prochiral faces of the ligand. The isomers do not interconvert on the NMR timescale in solution.

The larger actinide ion accommodates a smaller bending, or 'folding' angle about the bridgehead C–C bond (24° compared to 33° in a related tantalum compound). The Th–C_{ring} bond lengths vary from 2.543(10) to 2.908(11) Å. Photoelectron spectroscopy (PES) studies and density functional calculations present a consistent picture of the bonding in these complexes. Metal–ligand bonding takes place chiefly through four molecular orbitals with both 6d and 5f orbital involvement; the uranium accommodates two unpaired electrons in 5f-based orbitals. Both the f-ionization and the highest-lying ligand orbitals have lower ionization energies than uranocene or $(C_5H_5)_4U$, suggesting that the pentalene dianion is a stronger π-donor than these other carbocyclic groups.[117]

Cloke and Hitchcock have also prepared an interesting uranium(III) complex containing the silyl-substituted pentalene ligand.[118] Reaction of anhydrous UI_3 with KCp* in ether, followed by addition of $K_2[1,5\text{-}(i\text{-}Pr_3Si)_2C_8H_4]$ to the isolated Cp^*UI_2 in toluene affords the deep purple complex, $Cp^*(1,5\text{-}(i\text{-}Pr_3Si)_2C_8H_4)U$. The latter complex has been structurally characterized; it is a slightly bent sandwich compound. The most interesting chemistry reported thus far for $Cp^*(1,5\text{-}(i\text{-}Pr_3Si)_2C_8H_4)U$ is the reversible reaction with dinitrogen to form binuclear $[Cp^*(1,5\text{-}(i\text{-}Pr_3Si)_2C_8H_4)U]_2(\mu\text{-}\eta^2{:}\eta^2\text{-}N_2)$ in which the two uranium units are bridged by a sideways-bound dinitrogen molecule. The key structural feature of the latter is the N–N bond length of 1.232(10) Å, consistent with an N–N double bond.[118] DFT calculations on the model compound $[(C_5H_5)(C_8H_6)U]_2(\mu\text{-}\eta^2{:}\eta^2\text{-}N_2)$ support the initial hypothesis that $[Cp^*(1,5\text{-}(i\text{-}Pr_3Si)_2C_8H_4)U]_2(\mu\text{-}\eta^2{:}\eta^2\text{-}N_2)$ consists of two U(IV) centers bridged by an N_2^{2-} ligand.[119]

Among the largest of discrete organometallic ligands are the class of molecules called fullerenes (*see* ***Carbon: Fullerenes***), and many metal-encapsulated derivatives, or endometallofullerene complexes, have been synthesized. The first reports of uranium encapsulation suggested that the principal products from laser vaporization experiments using graphite impregnated with UCl_3 in a supersonic cluster beam apparatus included $U@C_{60}$ and a product of the unusually small cage $U@C_{28}$.[120] X-ray photoelectron spectroscopic (XPS) studies of the bulk product suggested a uranium valence of +4. Most recently, metallofullerenes of uranium, neptunium, and americium have been produced via arc-discharge using a carbon rod containing lanthanum as a carrier with ^{237}U, ^{239}Np, and ^{240}Am as radiotracers.[121] The metallofullerenes were purified by CS_2 extraction and toluene HPLC elution. The dominant products identified for neptunium and americium were $An@C_{82}$. Two uranium-containing metallofullerenes were identified, $U@C_{82}$ and $U_2@C_{80}$. Based upon comparison with the optical spectra of lanthanide analogs, it was suggested that the oxidation state in these complexes might best be regarded as +3.

7 ALKYL COMPLEXES

7.1 Homoleptic Alkyls

The synthesis of stable, homoleptic (*see Homoleptic Compound*) actinide alkyl (*see Alkyl Complexes*) complexes has been a goal of inorganic and organometallic chemists since early days of the Manhattan Project. Standard alkylation techniques involving UCl_4 and alkyllithium reagents in diethyl ether or saturated hydrocarbons afford thermally sensitive mixtures. Marks and Seyam demonstrated that the unstable products, assumed to be uranium(IV) tetraalkyl complexes, readily undergo β-hydride elimination (*see β-Hydride Elimination*) for R = n-butyl.[122] Some aspects of this work were subsequently challenged by Evans and coworkers, who concluded that UCl_4 suspended in alkane solvent is reduced to UCl_3 by the first equivalent of added RLi.[123]

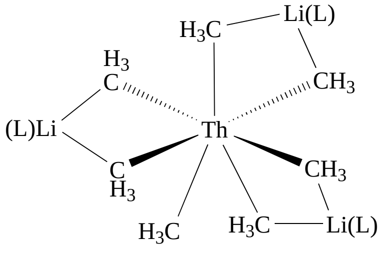
Sigurdson and Wilkinson found that the reaction of UCl_4 with a stoichiometric *excess* of alkyllithium reagents in ether gives isolable products of formula $[Li(L)_4]_2UR_6$ (L = Et_2O, THF) through saturation of the metal coordination sphere (equation 51). With TMEDA the $[Li(L)_4]_2UR_6$ complexes produce $Li_2UR_6{\cdot}7TMEDA$ derivatives.[124]

$$UCl_4 + \text{xs LiR} \xrightarrow{Et_2O} [Li(Et_2O)_4][UR_6] \qquad (51)$$

Marks and coworkers isolated a heptamethyl complex, stable at room temperature for many hours, from the reaction between $ThCl_4$ and excess methyllithium in the presence of TMEDA in ethereal solvents (equation 52).[125]

$$ThCl_4 + \text{xs LiMe} + \text{TMEDA} \xrightarrow{Et_2O} [Li(TMEDA)]_3ThMe_7{\cdot}TMEDA + 4LiCl \qquad (52)$$

The molecular structure has been determined by X-ray diffraction, and the result is illustrated schematically in (**25**). Seven methyl groups surround the thorium atom in a distorted monocapped trigonal prismatic arrangement. Six of the methyl groups [Th–C = 2.667(8)–2.765(9) Å] are coordinated in a pair-wise manner to $Li(TMEDA)^+$ cations, while the seventh [Th–C = 2.571(9) Å] is not.



(**25**)

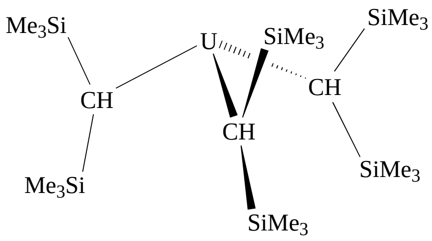
Homoleptic tetrabenzyl complexes are prepared by reaction between $ThCl_4$ and benzyllithium in THF solution at low temperature (equation 53).[126] It is unlikely that these complexes are η^1-alkyls, since the X-ray structure of $Cp^*Th(CH_2Ph)_3$ revealed multihapto coordination of the benzyl ligand.[127]

$$ThCl_4 + 4LiCH_2Ph \xrightarrow[-20\,°C]{THF} Th(CH_2Ph)_4 + 4LiCl \quad (53)$$

The first example of a neutral homoleptic uranium(III) alkyl complex was prepared by reaction of bis(trimethylsilyl)methyllithium with a monomeric uranium aryloxide, U(O-2,6-t-$Bu_2C_6H_3)_3$, in hydrocarbon solution (equation 54).[128] Attempts to prepare

$$U(O\text{-}2,6\text{-}t\text{-}Bu_2C_6H_3)_3 + 3LiCH(SiMe_3)_2 \xrightarrow{C_6H_{14}} U[CH(SiMe_3)_2]_3 + 3LiO\text{-}2,6\text{-}t\text{-}Bu_2C_6H_3 \quad (54)$$

$U[CH(SiMe_3)_2]_3$ by direct combination of $UCl_3(THF)_x$ and the alkyllithium reagent produced a salt of formula $[Li(THF)_3][UCl\{CH(SiMe_3)_2\}_3]$. The X-ray structure of $U[CH(SiMe_3)_2]_3$ revealed a monomeric trigonal pyramidal coordination geometry about the uranium metal center, as illustrated in (**26**). Agostic M–H–C interactions were suggested by the metrical parameters. The royal blue compound decomposes in solution over a period of several hours at room temperature.



(**26**)

7.2 Phosphine and Amido Stabilized Alkyls

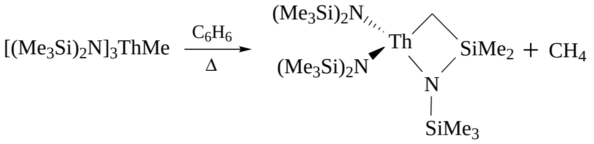
Andersen has found that chelating phosphine ligands greatly enhance the thermal stability of certain actinide alkyls. Methyl, benzyl, and mixed methyl/benzyl derivatives can be prepared according to equation (55) using dmpe.[129] Equation (55) does not provide stable compounds with alkyl groups containing β-hydrogen atoms.

$$AnCl_4(dmpe)_2 + 4LiR \xrightarrow{Et_2O} AnR_4(dmpe)_2 + 4LiCl \quad (55)$$

Thermally stable thorium(IV) and uranium(IV) methyl compounds of the type $MeAn[N(SiMe_3)_2]_3$ have been prepared from the corresponding chlorides via the routes shown in equations (56) and (57).[130] Thermolysis of the methyl compounds (equation 57) or treatment of $ClAn[N(SiMe_3)_2]_3$ with alkylating agents other than those shown in equations (56) and (57) leads to γ-hydrogen atom abstraction and formation of the corresponding metallacycles (*see Metallacycle*) (equation 58).[131] The metallacycles exhibit a rich chemistry themselves, some of which is outlined in Scheme 2.

$$[(Me_3Si)_2N]_3UCl + LiMe \xrightarrow{Et_2O} [(Me_3Si)_2N]_3UMe + LiCl \quad (56)$$

$$[(Me_3Si)_2N]_3ThCl + Me_2Mg \xrightarrow{Et_2O} [(Me_3Si)_2N]_3ThMe + MgCl_2 \quad (57)$$



(58)

7.3 Cyclopentadienyl Alkyls

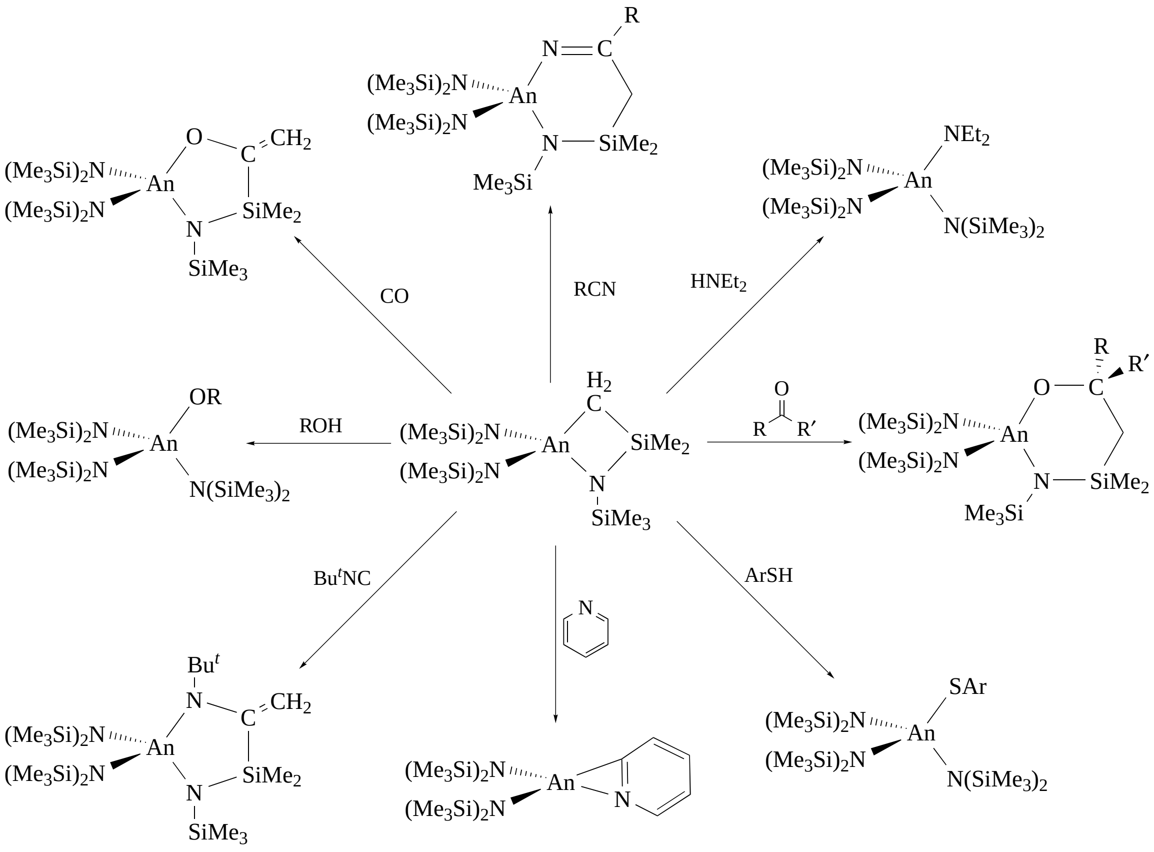
A review of the literature reveals that cyclopentadienyl or substituted cyclopentadienyl ligands play an important role in stabilizing alkyl complexes of the actinides, and there is a great deal of organometallic chemistry associated with these complexes.

7.3.1 *Tris(cyclopentadienyl) Alkyls*

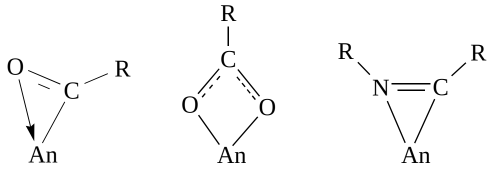
As noted earlier, the chloride ligand in Cp_3AnCl (An = Th, U, Np) is labile and this feature has facilitated the synthesis of a great many tris(cyclopentadienyl)actinide(IV) alkyl derivatives by metathesis with alkyllithium or Grignard reagents. The properties and reactivity of these complexes have been extensively studied and reviewed.[4] They exhibit remarkable thermal stability. As members of the general class of Cp_3AnX complexes, they adopt the ubiquitous pseudotetrahedral coordination geometry that was illustrated earlier in (**2**).

The Cp_3ThR complexes have been used to measure metal–alkyl bond disruption enthalpies for a series of thorium alkyl complexes for both solution and gas phases. The thorium–carbon bonds appear to be relatively strong when compared to other metal–carbon linkages, and solution bond disruption enthalpies range from ca. 75 to 90 kcal mol^{-1}.[15]

The reactivity of Cp_3AnR complexes has been studied in some detail and is dominated by insertion of CO, CO_2, and CNR ligands to give η^2-acyl, η^2-carboxylate, and η^2-iminoalkyl complexes. The resulting insertion products are illustrated schematically in (**27**), (**28**), and (**29**), respectively.



Scheme 2 Some reactions of the actinide (IV) metallacycles of the type 



(27) **(28)** **(29)**

7.3.2 *Bis(peralkylcyclopentadienyl) Actinide Alkyls*

Bis(pentamethylcyclopentadienyl)actinide(IV) mono- and dialkyl complexes are readily prepared from $Cp^*_2AnCl_2$.[132] A rather large number of alkyl groups have been employed, and compounds of this class are generally prepared by metathesis (equation 59). In the solid state, complexes of formula $Cp^*_2AnR_2$ adopt a pseudotetrahedral coordination geometry about the actinide metal. A neutron diffraction study of the thorium neopentyl complex $Cp^*_2Th(CH_2\text{-}t\text{-}Bu)_2$ also revealed agostic Th–H–C interactions with the α-CH bonds.[133]

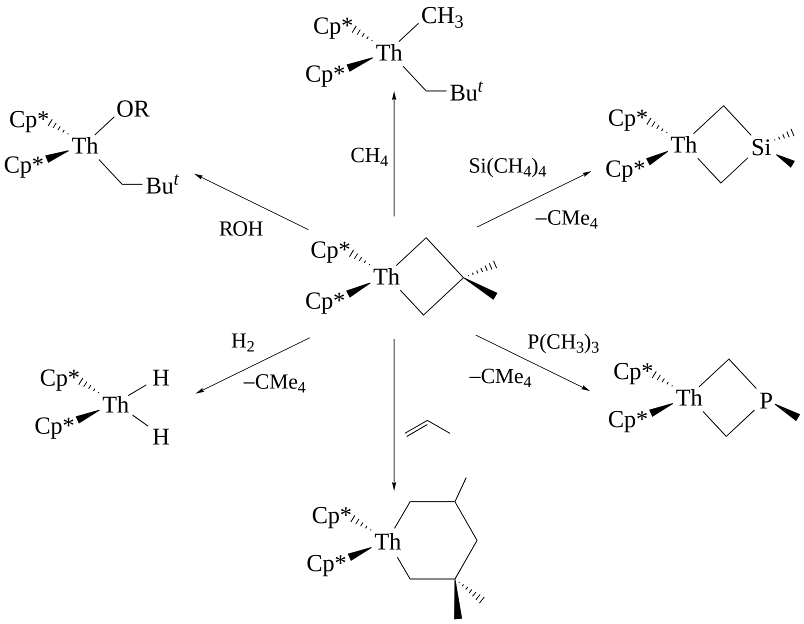
$$Cp^*_2AnCl_2 + LiR \xrightarrow{Et_2O} Cp^*_2AnClR + LiCl \quad \xrightarrow[+LiR]{-LiCl} \quad Cp^*_2AnMe_2 \qquad (59)$$

The $Cp^*_2ThR_2$ complexes exhibit a rich variety of thermally induced C–H activating cyclometalation processes. Kinetic and labeling studies indicate that the reactions involve rate-limiting intramolecular abstraction of a γ-hydrogen atom. The thermochemical data indicate that these reactions are largely endothermic and are entropically driven ($T\Delta S > \Delta H > 0$). Steric crowding is evident in the structural studies of $Cp^*_2Th(CH_2\text{-}t\text{-}Bu)_2$ and no doubt makes a significant enthalpic contribution to the driving force for cyclometalation.[133]

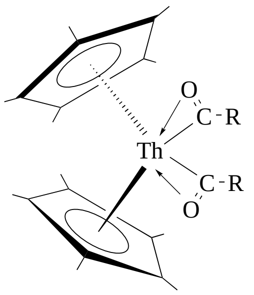
The reaction chemistry of thoracyclobutanes is rich and can be predicted largely on the basis of thermochemical data.[15] Scheme 3 illustrates some representative transformations.

The $Cp^*_2AnR_2$ compounds also display a rich CO migratory insertion (*see Migratory Insertion*) chemistry. The key products in this chemistry are carbene-like η^2-acyl complexes (**30**).

There is a class of cationic bis(pentamethylcyclopentadienyl)thorium alkyls that deserve special mention. Marks and coworkers have discovered that treatment of $Cp^*_2ThMe_2$ with protolytic reagents, in the form of sterically encumbered ammonium salts, provides an efficient route to $Cp^*_2ThMe^+X^-$ complexes (equation 60).[134] These complexes exhibit characteristic low-field thorium-methyl ^{13}C NMR signals that



Scheme 3 Some reactions of the thorium(IV) metallacycle, Cp^*_2Th 



(**30**)

are in good agreement with surface spectroscopic data (see Section 11 below). The catalytic activity of $[Cp^*_2ThMe]^+[B(C_6F_5)_4]^-$ for homogeneous 1-hexene hydrogenation (*see Hydrogenation*) approaches that of $Cp^*_2ThMe_2$ adsorbed on dehydroxylated alumina (DA).

$$Cp^*_2ThMe_2 + R_3NH^+X^- \xrightarrow{C_5H_{12}} [Cp^*_2ThMe]^+X^- + R_3N + CH_4 \quad (60)$$

Burns and coworkers have discovered a remarkable reaction involving $Cp^*_2U(Me)Cl$. Treatment of the latter with 1-lithio-1,2-diphenylhydrazine in ether solution generates lithium chloride and methane, and provides the uranium(VI) bis-imido compound $Cp^*_2U(NPh)_2$, conceivably via a uranium(IV) hydrazido species $Cp^*_2U(\eta^2\text{-PhNNPh})$.[42,135] A plausible reaction sequence is laid out in equations (61) and (62). $Cp^*_2U(NPh)_2$ was the first uranium(VI) organometallic complex. In the solid state, $Cp^*_2U(NPh)_2$ adopts the familiar pseudotetrahedral geometry common to all Cp_2MX_2 species; the U–N distance is 1.952(7) Å and the imido groups are essentially linear with U–N–C_{ipso} = 177.8(6)°. The electronic absorption spectrum in toluene, devoid of f–f transitions, is consistent with the U^{VI} assignment.

$$Cp^*_2U(Me)Cl + Li[PhNNPh(H)] \xrightarrow{Et_2O} Cp^*_2U(Me)[N(Ph)N(Ph)(H)] + LiCl \quad (61)$$

$$Cp^*_2U(Me)[N(Ph)N(Ph)(H)] \longrightarrow Cp^*_2U[\eta^2\text{-}N(Ph)N(Ph)] + CH_4 \longrightarrow Cp^*_2U({=}NPh)_2 \quad (62)$$

In the case of uranium, it is also possible to prepare a uranium(III) alkyl complex of the type Cp^*_2UR via metathesis of $[Cp^*_2U(\mu\text{-Cl})]_3$.[66] The only stable compound isolated from such reactions is the bis(trimethylsilyl)methyl compound $Cp^*_2U[CH(SiMe_3)_2]$.

7.3.3 *Mono(peralkylcyclopentadienyl) Actinide Alkyls*

Considerably less is known about single ring complexes of the type Cp^*AnR_3. According to Marks, thermal stability is a sensitive function of both the metal and the alkyl group. The synthetic approach of equation (63) has yielded only a few isolable compounds despite considerable effort. The X-ray structures of the tris-benzyl compounds $Cp^*Th(CH_2C_6H_5)_3$ and $Cp^*U(CH_2C_6H_5)_3$ revealed multihapto metal–benzyl interactions.[127,136] The latter may explain the stability of

these compounds relative to those compounds prepared with simple alkyls such as methyl and neopentyl. In contrast to the literature on $Cp^*{}_2AnR_2$ compounds, very little is known about the chemistry of Cp^*AnR_3 compounds.

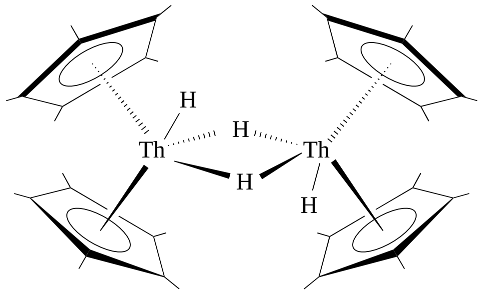
$$Cp^*AnCl_3(THF)_2 + 3LiR \xrightarrow{Et_2O} Cp^*AnR_3 + 3LiCl \qquad (63)$$

8 HYDRIDE COMPLEXES

8.1 Peralkylcyclopentadienyl Hydrides

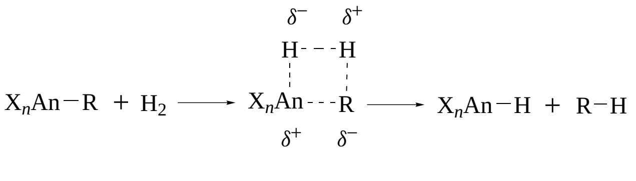
The first organoactinide hydrides (*see* ***Hydride Complexes of the Transition Metals***) were prepared by hydrogenolysis of the bis(pentamethylcyclopentadienyl)alkyls, $Cp^*{}_2AnR_2$ (equation 64).[33] These reactions are thought to take place via σ-bond metathesis, as depicted in Scheme 4. The neutron diffraction structure of $[Cp^*{}_2ThH_2]_2$ has been determined: it adopts the geometry indicated in (**31**).[137] The mean Th–H(terminal) and Th–H(bridge) distances are 2.03(1) and 2.29(3) Å, respectively. The H–Th–H angle is 58(1)° and the Th–H–Th angle is 122(4)°. These angles and the Th–Th separation of 4.007(8) Å indicate minimal direct metal–metal interaction.

$$Cp^*{}_2AnR_2 + H_2 \xrightarrow{C_5H_{12}} Cp^*{}_2AnH_2 + 2RH \qquad (64)$$



(**31**)

$[Cp^*{}_2UH_2]_2$ is unstable with respect to the uranium(III) hydride $[Cp^*{}_2UH]_x$, which can be trapped with dmpe (equation 65).[138] Earlier, Marks and coworkers had observed that the reaction of $Cp^*{}_2U(R)Cl$ with H_2 does not provide the anticipated $Cp^*{}_2U(H)Cl$ but rather a trinuclear uranium(III) chloride compound $[Cp^*{}_2U(\mu\text{-}Cl)]_3$ mentioned earlier.[66]



Scheme 4 Sigma bond metathesis of actinide-alkyl bonds

$$Cp^*{}_2UH_2 + dmpe \xrightarrow{C_5H_{12}} Cp^*{}_2U(dmpe)H + 0.5H_2 \qquad (65)$$

One $(C_5H_5)_3UX$ molecule that has proven elusive is Cp_3UH. As noted above, uranium(IV) hydrides can decompose via intermolecular reactions that produce hydrogen and generate uranium(III) products. Surprisingly then, the complexes $[\eta^5\text{-}RC_5H_4]_3UCl$ (R = $SiMe_3$, CMe_3) react with $KBEt_3H$ in THF to yield the thermally stable hydrides $[RC_5H_4]_3UH$.[139] Related thorium compounds, $[RC_5H_4]_3ThH$ and $Cp^*{}_3ThH$, can also be prepared.[140,141]

Actinide hydrides are rather 'hydridic' and undergo rapid reactions typical of such systems; for example, reactions with ketones and halocarbons provide actinide alkoxides and halides, respectively. Rapid quantitative addition of terminal alkenes (the reverse of β-hydride elimination) is consistent with the known bond disruption enthalpies (equation 66).[15]

(66)

9 CARBONYL COMPLEXES

Stable homoleptic (*see Homoleptic Compound*) mononuclear and polynuclear complexes (*see* ***Polynuclear Organometallic Cluster Complexes***) of carbon monoxide are known for most of the transition elements (*see* ***Carbonyl Complexes of the Transition Metals***). One might ask whether an actinide carbonyl compound, such as $U(CO)_6$, an analog of the well-known group 6 carbonyls $M(CO)_6$ (M = Cr, Mo, W), could also be prepared. Uranium carbonyls, $U(CO)_x$, have in fact been observed in cryogenic matrices. The cocondensation of uranium vapor with CO in an argon matrix at 4 K yields species clearly identifiable as uranium carbonyls $U(CO)_x$ by IR spectroscopy.[142] Derived force constants suggest bonding patterns similar to those observed for zerovalent early transition and lanthanide metal carbonyls. Complete decomposition of these uranium carbonyls occurs at temperatures above ca. 30 K. In dilute matrices, the chemistry of uranium atoms and CO is much more complex and initially leads to insertion of uranium into the C≡O bond to form CUO.[143]

The first 'stable' actinide complex of carbon monoxide was prepared by reaction of $(Me_3SiC_5H_4)_3U$ ($Cp^\dagger{}_3U$) with CO in solution or in the solid state to produce $Cp^\dagger{}_3U(CO)$, which reversibly dissociates CO.[144] $Cp^\dagger{}_3U(CO)$ exhibits a carbonyl stretch in the IR spectrum at 1976 cm^{-1}, or approximately 170 cm^{-1} lower than the υ_{CO} for free carbon monoxide. This is taken as an indication of uranium-to-carbonyl π-back bonding (*see Back Bonding*). Electronic structure calculations on the model complex Cp_3UCO indicated a significant U 5f–CO 2π

back bonding, which results in a stabilization of the uranium 5f atomic orbitals.[145] Other $(R_nC_5H_{5-n})_3U(CO)$ complexes have been prepared and characterized.[144] The molecular structure of $(C_5Me_4H)_3U(CO)$ ($\upsilon_{CO} = 1880\,cm^{-1}$) possesses a short U–$C_{CO}$ bond distance of 2.383(6) Å.[146] Comparison of the ν_{CO} stretching frequencies for a series of compounds with different ring substituents indicates that electron-donating substituents increase the electron density at the metal center and increase metal-to-ligand back donation.[146] $Cp^*_3U(CO)$ is a more recent addition to the family of tris-Cp uranium carbonyl complexes.[147] The U–C_{CO} distance in the latter complex is 2.485(9) Å and its C–O stretching mode is located at $1922\,cm^{-1}$.

10 PHOSPHOYLIDE COMPLEXES

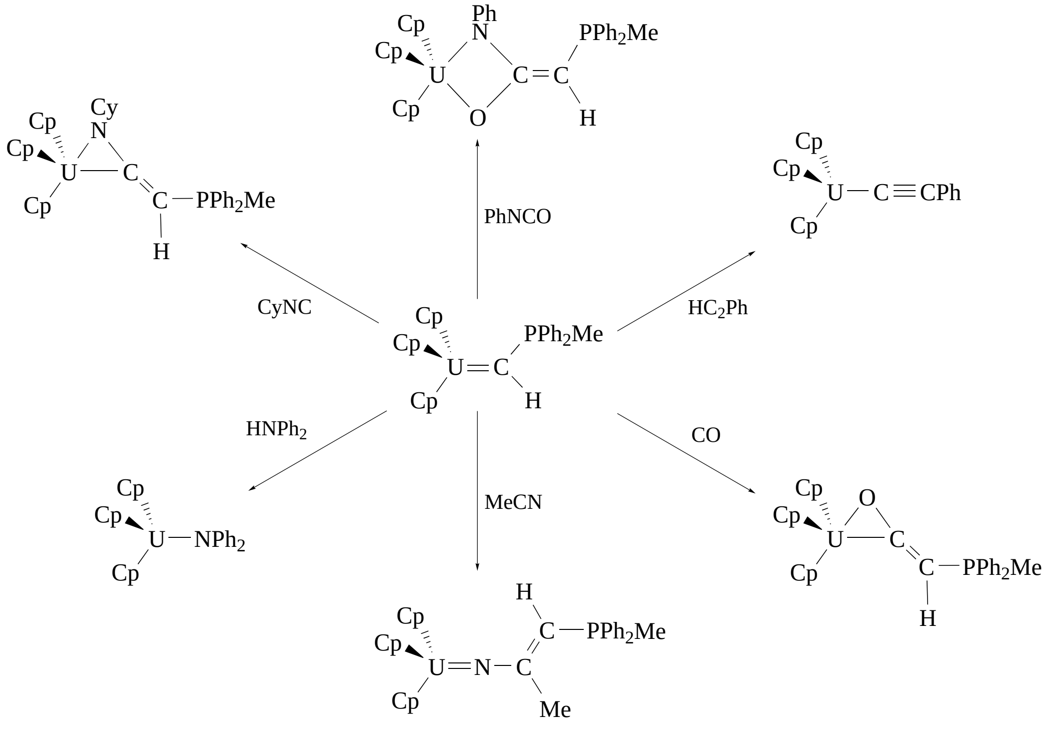
Gilje, Cramer, and their coworkers have studied the synthesis, structure, and reactivity of uranium(IV) phosphoylide complexes prepared according to equation (67).[148] The X-ray

$$Cp_3UCl + Li(CH_2)_2PRR' \xrightarrow{THF} Cp_3UCHPMeRR' + LiCl \quad (R, R' = Me, Ph) \tag{67}$$

structure of $Cp_3UCHPMe_2Ph$ and the neutron diffraction structure of $Cp_3UCHPMe_3$ revealed the shortest U–C distances yet measured (~2.29 Å) and large U–C–P angles (~143°), indicative of uranium–carbon multiple bond character.[149] The negative charge on the α-carbon in these systems is stabilized by the presence of an electron-withdrawing heteroatom substituent. Reactions of these compounds with weak acids and polar unsaturated molecules are summarized in Scheme 5. Despite repeated efforts, no one has yet developed the requisite synthetic methodology to prepare actinide alkylidenes (*see Alkylidene*), $L_nAn{=}CR_2$. The authors are, however, optimistic that the synthesis of such molecules will be achieved in the next few years.

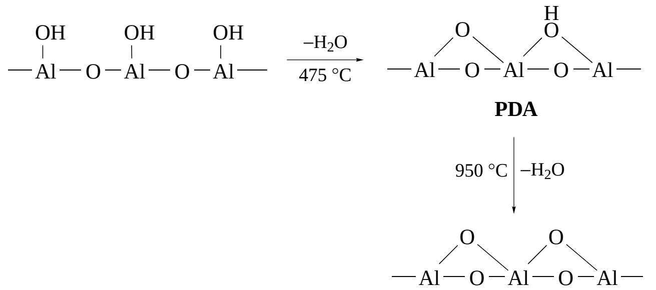
11 ORGANOACTINIDE SURFACE CHEMISTRY AND CATALYSIS

Studies of organoactinide surface chemistry and catalysis have been carried out by the Marks group under rigorously anhydrous/anaerobic conditions on either partially dehydroxylated alumina (PDA) or DA at surface coverages of $\approx$0.25–0.50 molecules nm^{-1}.[150] The PDA and DA surfaces are represented schematically in equation (68). Product yields, isotopic labeling, and surface reactivity indicate that the irreversible γ-alumina adsorption chemistry of $Cp^*_2AnMe_2$ can be described by three methane-evolving pathways (equations 69–71). Equation (69) dominates on PDA. On DA,



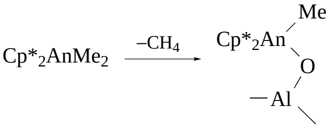
Scheme 5 Some reactions of the uranium(IV) phosphoylide complex, $Cp_3U{=}CHPPh_2Me$

equations (70) and (71) account for ≤16% of all available actinide methyl groups. The majority of methyl groups remain bound to the surface in some way not revealed in the experiments. Chemical probes, such as H_2, reveal that an additional 10–20% of the methyl groups can be liberated by hydrogenolysis. $Cp^*_2ThMe_2$ and $Cp^*_2UMe_2$ are virtually indistinguishable in these experiments, arguing that changes in metal oxidation state are not an important aspect of the surface adsorption chemistry. In addition, there is no evidence for significant Cp*H liberation.



DA

(68)

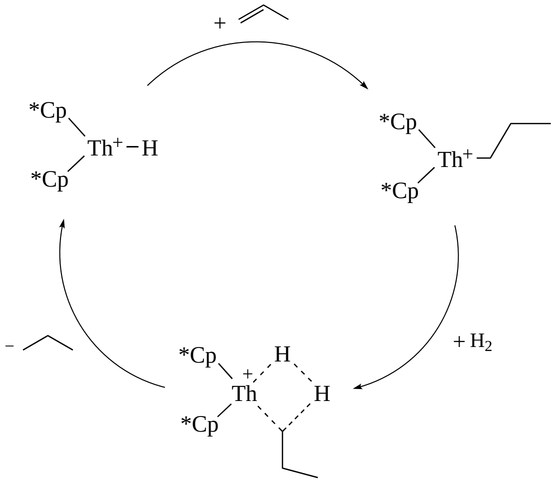


(69)

(70)

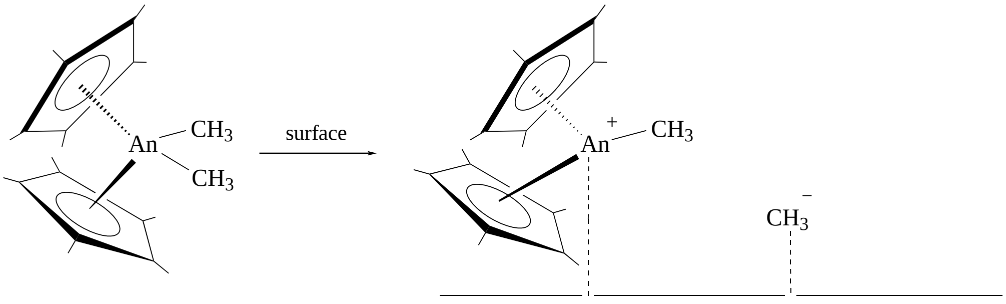
$$Cp^*_2AnMe_2 \xrightarrow{-CH_4} Cp^*(\eta^5, \eta^1\text{-}C_5Me_4CH_2)AnMe \quad (71)$$

Complexes such as $Cp^*_2ThMe_2$ are only marginally active for alkene hydrogenation or polymerization in homogeneous solution (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***). Adsorption on DA effects a dramatic enhancement in catalytic activity. Using propylene hydrogenation as a probe reaction, kinetic experiments revealed catalytic activities comparable to those of heterogeneous platinum metal catalysts. Separate 'poisoning' studies indicated that only ≈4% of the actinide sites sustain the bulk of hydrogenation activity. These sites have turnover frequencies for propylene hydrogenation greater than the active sites of Pt/SiO_2 under the same conditions ($N_t \sim 2\,s^{-1}$ vs. $0.05\,s^{-1}$ at −63 °C). Kinetic/mechanistic studies are in accord with the sequence outlined in Scheme 6 but leave unanswered atomic-level questions regarding the exact nature of the organoactinide–surface interaction. This question can, however, be addressed using ^{13}C cross polarization with magic angle spinning (CPMAS) NMR spectroscopy. The spectra of $Cp^*_2ThMe_2$/DA have been completely assigned and lead to the remarkable conclusion that a methide ion is transferred from the actinide center to a Lewis acid site on the surface. This is shown pictorially in (**32**). The CPMAS spectra of $Cp^*_2ThMe_2$ on PDA is quite different and indicates structure (**33**).[151]

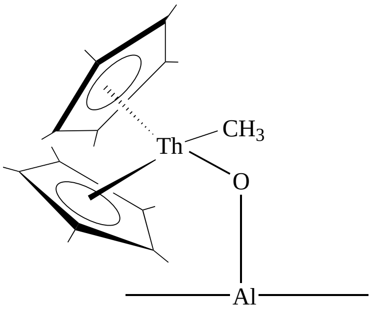


Scheme 6 Proposed catalytic cycle for alkene hydrogenation mediated by supported cationic complexes derived from $Cp^*_2ThMe_2$

The tetraallyl complex $Th(\eta^3\text{-}C_3H_5)_4$ supported on dehydroxylated γ-alumina is an outstanding heterogeneous catalyst for arene hydrogenation that rivals the most active platinum metal catalysts in activity. $Th(\eta^3\text{-}C_3H_5)_4$/DA also catalyzes the rapid and selective deuteration of linear and cyclic alkanes. C–H reactivities fall in the order primary > secondary > tertiary.[152]



(**32**)



(**33**)

12 ELECTRONIC STRUCTURE AND BONDING

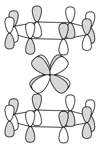
In contrast to the situation with main-group and d-block elements, a detailed understanding of the electronic structure and bonding of the 5f elements has posed a considerable theoretical challenge. There are no simple rules that help rationalize the stoichiometry of organoactinide complexes or that guide the synthesis of new organoactinide compounds (e.g. the effective atomic number or EAN rule in transition metal organometallic chemistry). One of the more passionate issues discussed in the literature concerns the level of involvement of 5f orbitals in the metal–ligand bonding of organoactinide complexes.

12.1 Molecular Orbital Calculations

Moffitt's seminal contribution in 1956,[1] that ligand-based orbitals could span a space of the proper symmetry to interact with either d or f orbitals, or both, preceded a number of detailed theoretical studies of organoactinide bonding. These symmetry considerations were an extension of the bonding theories that were widely accepted and had worked very well in describing 'sandwich' compounds (*see Sandwich Compound*) of the transition elements such as ferrocene (*see Ferrocene*). Since that time, descriptions of organoactinide electronic structure ranging in complexity from 'back-of-the envelope', to extended Hückel, to SCF-Xα, to DV-Xα, to DFT, to ab initio calculations (*see Ab Initio Calculations*) (including spin–orbit coupling, configuration interaction, and relativistic core potentials) have been reported.

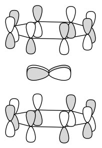
One of the most thoroughly investigated organoactinide compounds is the uranium sandwich complex uranocene.[8,10] Simple symmetry considerations predicted its existence, which in turn prompted its synthesis.[2] Early extended Hückel calculations on uranocene produced a bonding scheme that was very attractive. In this model, the $[C_8H_8]^{2-}$ ligand orbitals only interacted with uranium atomic 5f orbitals; the virtual atomic 6d orbitals were considered too high in energy for significant interaction. This overlap of orbitals of e_{2u} symmetry (metal 5f and ligand pπ) seemed a logical extension of the bonding descriptions of d-block sandwich compounds.

When more sophisticated computaional methods were applied to the uranocene system,[153] it became clear that the simple Hückel treatment was misleading. Incorportaion of relativistic effects (*see Relativistic Effects*) has provided a more complete and accurate description of the bonding. Although the various relativistic calculations differ in methodology (relativstically-parameterized extented Hückel. Xα-SW, DV-Xα, DFT, ab initio), they present a consistent picture wherein the primary metal-ligand bonding is derived through a combination of 6d(e_{2g}) and 5f(e_{2u}) atomic orbital interactions with the ligands. Both interactions are between metal-based δ-symmetry orbitals and pπ orbitals of the C_8H_8 rings. All of the calculations indicate that the ligand field generated by the cot ligands lifts the degeneracy of the atomic 5f orbitals, spreads them out in energy, and results in a ground state with two unparied electrons, consistent with the observed paramagnetism (*see Paramagnetism*) of the complex. This general model for the bonding in uranocene is supported by gas phase photoelectron spectroscopy (PES) experiments.[154] Comparison of PES spectra for thorocene and uranocene revealed that the lowest energy ionizaion of uranocene is from valence 5f electrons, and that the next two ionizations occur from the e_{2u}(5f) and e_{2g}(6d) metal-ligand bonding orbitals (see Figure 1). Variable photon energy PES studies reveal a substantial increase in relative intensity of the e_{2u} band demonstrating a significant 5f orbital covalent interaction. The relative stability of the e_{2g} orbital with respect to the e_{2u} orbtial was taken as evidence for strong 6d bonding.[155] These two metal-ligand bonding orbitals are shown qualitatively in (**34**) and (**35**). PES data on substituted uranocenes indicate that overlap with both 6d and 5f orbitals increases with alkylation on the cot ring.[156]



e_{2u}–f_δ

(**34**)



e_{2g}–d_δ

(**35**)

Cyclopentadienyl complexes (*see Cyclopentadienyl*) have also received a considerable amount of attention from theoretical chemists, primarily to gain a better understanding of metal–ligand bonding in organotransition metal versus organoactinide complexes. Here again, a range of computational techniques have been employed that, in general, predict that the uranium 5f manifold is only slightly perturbed by Cp ligand interactions. A comparison of the bonding of UCl_4, Cp_2UCl_2, and Cp_4U revealed a progressive destabilization and splitting of the 5f manifold, which was interpreted as indicating a stronger metal–ligand interaction in metal–Cp than metal–chloride bonds.[8] Concomitantly, a stabilization of the Cp ligand π_2 orbitals was interpreted as

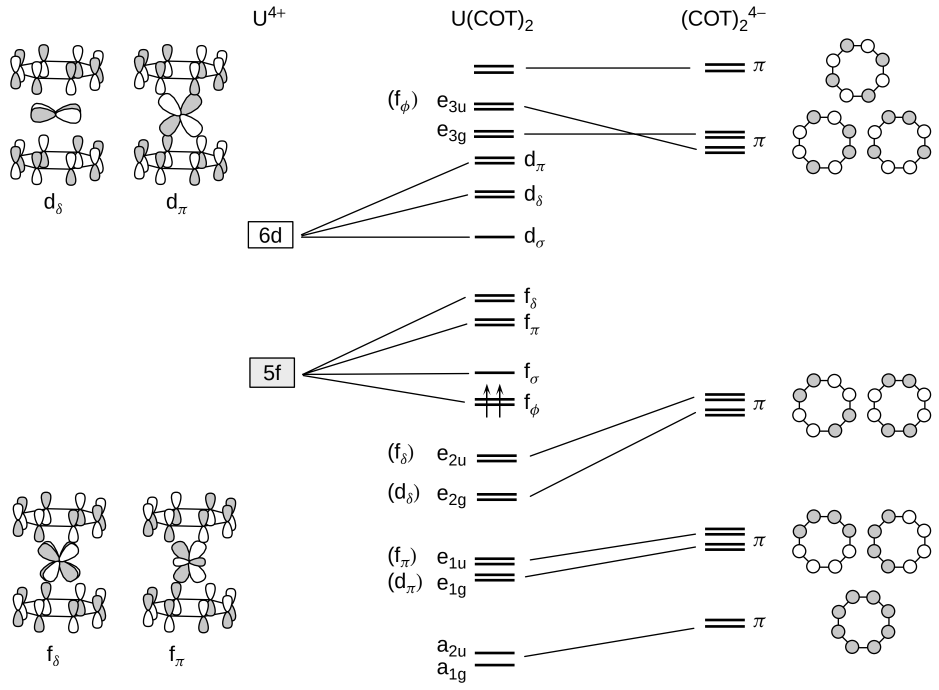


Figure 1 Molecular orbital diagram of uranocene[155]

a stronger metal–ligand d orbital interaction. Computational studies have been reported for a fair number of complexes containing cyclopentadienyl ligands. Collectively, all the calculations on complexes containing cot and Cp ligands indicate that the 6d atomic orbitals of the early actinides dominate the metal–ligand bonding and that the 5f orbitals are relatively unaffected, and serve as a reservoir for the valence electrons. Relativistic corrections tend to increase the contribution of the uranium 6d orbitals and decrease the contribution of the 5f orbitals. This view of bonding has been extended to heterobimetallic complexes (*see* ***Dinuclear Organometallic Cluster Complexes***), which contain a direct actinide–transition metal interaction such as $Cp^*{}_2Th(\mu\text{-}PPh_2)_2Pt(PMe_3)$ and $(I)Cp^*{}_2Th–RuCp(CO)_2$. Calculations on these systems indicate a metal–metal bonding HOMO made up of an occupied transition metal d orbital donating into a vacant actinide 6d acceptor orbital, and is best described as a 'dative' metal–metal bond.[20,40,157]

A density functional theoretical study has examined the question of bonding in the complexes $[(\eta^7\text{-}C_7H_7)_2An]^n$ (Th, Pa, U, Np, Pu, Am).[158] It was found that the 5f δ-symmetry orbitals not only participate in the bonding with e_2'' pπ orbitals of the C_7H_7 rings, but are as important as the symmetry appropriate 6d orbitals in stabilizing the ligand-based fragment orbitals. The 5f percentage in frontier e_2'' molecular orbitals increases across the series, and the contribution of the 6d orbitals gradually decreases across the series. The ground electron configurations, ionization energies, electron affinities, and $An–C_7H_7$ bond energies are strongly affected by these effects.

Although only one valence electron resides in a 5f-localized orbital on uranium in $[U(C_7H_7)_2]^-$, a formal oxidation state of +3 ($5f^3$) was assigned, based on the fact that the HOMO $3e_2''$ molecular orbitals (occupied by four electrons) are nearly 50% 5f in character, and so two of these electrons were assigned to the metal. EPR and electron-nuclear double resonance (ENDOR) studies of $[(C_7H_7)_2U]^-$ suggest that the complex could be treated as $5f^1$, with a ground-state molecular orbital comprised of both $5f_\pi$ and $5f_\sigma$ orbitals.[114]

The role of actinide virtual 6d orbitals and relativistic corrections in describing metal–ligand bonding has been extended to sophisticated calculations on trivalent alkyl complexes $AnMe_3$ (An = U, Np, Pu)[159] and pentavalent uranium imido complexes $(R_2N)_3U{=}NR$.[160] The calculations on $AnMe_3$ (An = U, Np, Pu) were carried out at the complete active space (CAS)-SCF level including relativistic core potentials, and indicate that the experimentally determined pyramidal geometry is more stable than a planar geometry in AnL_3 complexes owing to involvement of 6d character in the An–C bonding orbitals upon bending. The relativistic discrete variational-local density functional (DV-LDF) calculations on $(NR_2)_3U{=}NR$ complexes also point to the importance of 6d orbital participation and indicate the presence of U=NR multiple bonding. These calculations have been used to reassign the gas-phase PES of $[(Me_3Si)_2N]_3U{=}N(SiMe_3)$.[161]

Electronic structure calculations, including relativistic core potentials and the spin-orbit coupling, have been carried out on the C_{28}, Pa@C_{28}, and U@C_{28} species.[162] The ground state of C_{28} is described well by Hartree-Fock (*see Hartree–Fock Theory*) wave functions, and the computed electron affinity

and ionization potential are similar to those of C_{60}. Strong metal-cage binding is found for Pa@C_{28} and U@C_{28}, similar to that in $U(C_8H_8)_2$. The ground electronic states depend on the order of the lowest energy cage π^* and metal 5f orbitals, with $(\pi^*)^1$ and $(\pi^*)^1(5f)^1$ found to be the ground electronic configurations for the Pa and U complexes, respectively. The uranium fullerene is calculated to be diamagnetic.

1 INTRODUCTION

The alkali metals lithium (symbol Li), sodium (Na), potassium (K), rubidium (Rb), and cesium (Cs) constitute Group 1 of the Periodic Table, each having an outer electronic configuration s^1. (The sixth member, francium (Fr), has been little investigated (and will not be discussed here) since all of its isotopes are radioactive (the longest-lived, ${}^{223}_{87}Fr$, has a half-life of only 21 min) and are found only in certain natural decay series and as products of nuclear reactions). The group has been much studied as it best illustrates the effects of increasing atomic size and mass on chemical and physical properties (*see* ***Periodic Table: Trends in the Properties of the Elements***). Thus, all of these elements are metals which show a regular gradation in physical properties as the group is descended. They are the most electropositive metals known, and their chemistry is dominated by the +1 oxidation state, M^+ (*see* ***Coordination & Organometallic Chemistry: Principles***). However, other ionic, atomic, and molecular forms of the elements have been much studied both experimentally and theoretically; notably, alkalide anions M^-, atoms and diatomic gas-phase molecules, and atoms and clustered species (M_n, $M_n{}^{x+}$, $M_n{}^{x-}$) trapped and isolated in materials such as graphite and zeolites (*see* ***Intercalation Chemistry***; ***Zeolites***).

Lithium, sodium, and potassium, and their compounds, are of considerable biochemical and industrial importance.[1–3] Lithium salts can control manic-depressive psychoses,[4,5] the Na^+/K^+ concentration ratio is crucial to nerve impulse transmission, and potassium formulations dominate the plant fertilizer market. Lithium and its salts are used in the production of high-strength and low-density alloys, of lubricating greases, of toughened glass, and in porcelain and ceramics production. Organolithium reagents (e.g. *n*-butyllithium) are of increasing importance as reagents in synthetic organic chemistry[6] (*see* ***Alkali Metals: Organometallic Chemistry***) and as anionic polymerization initiators to produce, for example, styrene–butadiene copolymers for car tyres (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***).[7] Sodium chloride is of particular importance, being more used for inorganic chemical manufacture than any other material. In the future, lithium (especially) and sodium are likely to assume even more commercial importance: lithium metal as a source of tritium (from the ^7Li + neutron reaction) for nuclear fusion processes and as a nuclear reactor coolant, and both elements as likely components of energy storage systems for off-peak electricity and of batteries for electric cars.[8]

2 THE ELEMENTS

2.1 History, Abundance, and Production

Although compounds of sodium and potassium were known in ancient times, it was not until Humphrey Davy's famous electrolytic experiments in 1807 on molten caustic soda and potash that the metals themselves were first isolated.[9] Lithium was first recognized as an alkali metal in various silicate and mica minerals in 1817 (by Arfvedson, who thus named it from the Greek word for stone) and first isolated, again by Davy, in 1818. The discovery of cesium (1860) and rubidium (1861) had to await the development of atomic spectroscopy (by Bunsen and Kirchoff); their names reflect the colors of their dominant spectral lines (Latin; caesius, sky blue, and rubidus, deep-red).

The terrestrial (Earth's crust, oceans, atmosphere) and cosmological abundances[10] of the elements fall into two clear sets. Sodium (Earth, ≈23 000 ppm by mass; Universe, ≈20 ppm) and potassium (≈17 000 ppm; ≈3 ppm) are relatively abundant, and indeed they constitute the seventh and eighth most abundant elements in the Earth's crust. The most important sodium-containing minerals are the chloride (rock salt), carbonate, nitrate (saltpetre), and borate (borax); in addition, there are vast supplies of sodium chloride in oceanic waters (≈30 $kg\,m^{-3}$). Major sources of potassium are the chloride KCl (sylvite) and the mixed-metal chloride $KCl{\cdot}MgCl_2{\cdot}6H_2O$ (carnallite). In contrast, the other three metals are relatively scarce, abundances on Earth and in the Universe being ≈20 and 0.006 ppm respectively for Li, ≈70 and 0.01 ppm for Rb, and ≈2 and 0.008 ppm for Cs. Lithium occurs mainly in silicates such as spodumene ($LiAlSi_2O_6$).

Commercial production of lithium[1] and sodium is by electrolysis of their fused chlorides. For the former, spodumene is washed with H_2SO_4 at 250 °C and water-leached to give $Li_2SO_4{\cdot}H_2O$; successive treatment with Na_2CO_3 and HCl affords insoluble Li_2CO_3 and LiCl. Alternatively,

the ore is heated with CaO to give LiOH which is then converted to the chloride. Fused low-melting eutectics such as LiCl + KCl (450 °C) and NaCl + $CaCl_2$ (505 °C) are used in the electrolysis process, which employs a carbon anode and a steel cathode. The other three metals are also extracted from their chlorides; small quantities of RbCl and CsCl are obtained as by-products of lithium mineral processing. In their cases, however, the molten metal chlorides are treated with the vapor of a reactive metal (Na vapor at 850 °C or Ca vapor at 750 °C) in a countercurrent fractionating tower.

2.2 Uses of the Metals and Their Compounds

Although Rb and Cs, and their compounds, are so far mainly of academic interest, Li, Na (especially), and K, and their compounds, have considerable commercial value. Lithium metal itself[1] is used in the manufacture of alloys with magnesium and aluminum; these combine toughness with low density and so are employed in the construction of armor plate and aircraft/aerospace components (*see* ***Alloys***). Until recently, the major use of sodium was also in alloy manufacture, specifically of the Pb/Na alloy needed for the production of tetraethyllead, the antiknock additive (*see* ***Lead: Organometallic Chemistry***). However, the market here is declining on account of the environmental problems caused by lead emissions. Molten Na (and, to a lesser but increasing extent, molten Li) is employed also as a heat-exchange coolant around nuclear reactors; properties such as a low-melting point and low viscosity but a high heat capacity are valuable in this respect, although there are many technical problems such as melt containment, corrosion, and reactions with the atmosphere and with the reactor walls.[11]

The major bulk-produced lithium salts are the stearate, used to thicken and gel oils to provide lubricating greases; the carbonate, used as a flux in porcelain and enamel production, as an additive to bauxite in aluminum production (where it lowers the fusion temperature of the electrolyte and raises the melt conductivity), and as a source of Li^+ ions to replace larger Na^+ ions in the production of toughened glass; and the hydroxide, which is used to absorb carbon dioxide from enclosed spaces such as submarines. More 'specialty' lithium compounds find use in organic syntheses; for example, lithium aluminum hydride as a reducing agent and various organolithium compounds (particularly n-butyllithium) as selective proton abstractor reagents and as anionic polymerization initiators.[1,6,7,12,13] Most industrial-scale compounds are derived from sodium chloride, annual world consumption of which is of the order of 170 million tonnes. Salt itself has major uses in road clearance and in animal feeds, but most of it is converted by large-scale processes to products such as sodium hydroxide, chlorine, and sodium carbonate (which, taken together, constitute the chloralkali industry). The major potassium salt is also the chloride, used to formulate most potassic plant fertilizers. Other less employed, but still important, potassium compounds include the hydroxide, used mainly to produce phosphates for liquid detergents; the carbonate, used in fluorescent lamps and in optical lenses; the bromide, which is the normal source of bromine gas for organic syntheses; and the superoxide (KO_2), which is used in breathing masks in mines and space vehicles since it reacts with traces of moisture in the breath to generate oxygen.

A more unusual use of the alkali metals and their compounds, but one of high industrial importance, is as promoters of various catalysts.[14] For example, addition of Li^+, Na^+, or K^+ to MgO or CaO catalysts for the oxidative coupling of CH_4 to give valuable C_2 products (ethane, ethylene) improves the yields greatly; spectroscopic investigations have implied that $[M^+O^-]$ active sites are produced on the catalyst surface and that these sites abstract H from CH_4 to give $\cdot CH_3$ radicals, which then couple.[15–17] Similarly, catalysts for various transformations of syngas (H_2/CO mixtures) can be promoted by alkali metals, for example, doping of a Cu/ZnO catalyst with Cs doubles methanol yields from H_2/CO mixtures, an effect attributed partly to formation of surface formate (CsCHO)[18,19] (*see* ***Oxide Catalysts in Solid-state Chemistry*** and *see Synthesis Gas*).

Sodium and potassium are among the 25 or so elements now thought to be essential for animal life.[4,20] They perform electrophysiological functions based on the fact that the Na^+:K^+ concentration ratio is different in the fluids inside and outside cells. Because of these concentration gradients across cell membranes, a potential difference is set up and this is responsible for the transmission of nerve impulses. Lithium also is of biochemical importance, but as a drug in the treatment of manic-depressive psychosis; in the United Kingdom, for example, about 1 in every 1500 people take prescribed gram quantities of Li_2CO_3 daily. The inorganic pharmacology of lithium has been reviewed recently[5,21] but it seems likely that its prime role is to affect the mobilization of calcium into and out of cells by inhibiting certain enzymes in inositol phosphate pathways (*see* ***Metal-based Drugs***; ***Metal-based Imaging Agents***).

A future bulk use of lithium and sodium might well be as components of batteries, particularly for off-peak electricity storage and in electric cars. The latter use will be prompted by legislation; for example, in California alone, by the year 2003, 10% of all new cars (over 200 000) must be emission-free.[8] However, development of such batteries will be a major challenge. Those produced to date give limited range (having to be recharged frequently) and poor acceleration, and they are expensive, requiring complicated installation engineering. For example, sodium/sulfur batteries use a liquid sodium anode, a sulfur cathode, and a solid electrolyte of β-alumina (Al_2O_3), but the snag is that they operate at 300 °C.[22] Similarly, Li/FeS_x batteries employ Li and FeS_x electrodes with a molten electrolyte of LiCl/KCl at 400 °C.[23,24] Clearly, it would be preferable to avoid molten/liquid systems which require elevated temperatures and which pose severe containment

problems. However, development of solid-only cells has been hampered by the scarcity of low-temperature solid electrolytes with good ion conductivity (*see* ***Ionic Conductors***). Materials of promise in this regard include solid $LiAlCl_4$ (with Li_xTiS_2 and Li_xCoO_2 intercalated electrodes),[25] solid solutions based on lithium titanium phosphate,[26] and LiI·4MeOH which has the highest conductivity so far observed for Li^+ (due to mobile complexed cations in the solid-state structure, $Li(MeOH)_4{}^+{\cdot}I^-$).[27]

2.3 Atomic, Physical, and Chemical Properties

Fundamental atomic and physical properties of the alkali metals are given in Tables 1, 2, and 3. The elements are characterized by having electron configurations each with a single s orbital electron outside a noble gas core (see Table 1). Sodium and cesium are mononuclidic so that their relative atomic masses are known extremely accurately; in effect, the same can be written for potassium and rubidium since their isotopes (of which there are three and two, respectively) have extremely long half-lives. Lithium occurs naturally as ^6Li (7% abundance) and ^7Li (93%); its other three isotopes are radioactive, with very short half-lives. At least one isotope of each element has a nuclear spin (I) and hence, potentially, useful information can be gleaned from NMR studies: ^6Li, $I = 1$; ^7Li, $I = 3/2$; ^{23}Na, $I = 3/2$; ^{39}K (93%), $I = 3/2$; ^{87}Rb (28%), $I = 3/2$; ^{133}Cs, $I = 7/2$. In practice, ^7Li NMR spectroscopy has found most use; for example, in elucidating solution structures and solution equilibria for many lithium compounds and in monitoring concentrations and mobilities of lithium ions in vivo.[28–32]

The radii of the metals increase progressively with increasing atomic number, and these elements are the largest in their respective periods. Such features lead to relatively small first ionization energies for the atoms, and the chemistry is dominated by this fact. Thus the elements are highly reactive metals and form M^+ ions in the vast majority of their compounds. The very high second ionization energies prohibit formation of M^{2+} species. However, although the electron affinities (or ‘electron attachment energies’) are only

Table 1 Atomic and related properties of the alkali metals

Metal	Electronic configuration	Atomic number	Relative atomic mass	Metal radius (Å)	Ionization energies ($kJ\,mol^{-1}$) 1st	2nd	Electron affinity ($kJ\,mol^{-1}$)	Electronegativity (Pauling scale)
Li	$[He]2s^1$	3	6.941	1.52	520.1	7296	59.8	0.98

Rb	2.99	1.49	–	293	2.28	67.5
Cs	3.02	1.70	9.9	264	2.28	68.0

mildly exothermic, M^- ions can be produced for all the alkali metals (lithium excepted) under carefully controlled conditions (see Section 2.4).

The bonding in alkali metal compounds is held to be essentially ionic, involving electrostatic attractions between 'bare' or solvated M^+ ions and associated anions. This reflects the ease of formation of M^+ ions and the relative weakness of any covalent bonds formed: the valence orbitals available to these atoms are diffuse, leading to poor overlap. This ionic character is predictable also from the low electronegativities of the alkali metals (cf. approximate electronegativity values for typical nonmetals: C 2.5, N 3.0, O 3.5, F 4.0). On this basis, the degree of covalency would be highest for lithium (Li^+ is the smallest, most polarizing cation of the group). However, it is now generally agreed that the bonding even in, say, lithium–carbon bonds is essentially electrostatic in nature.[33,34]

Turning to the properties of the metals themselves (Table 2), all are soft and low-melting materials, Li to Rb being silvery white in color and Cs golden yellow. Their densities are extremely low (Li has the lowest density of any solid at room temperature), although they show very high electrical conductivity. Such properties reflect the fact that, with only one available valence electron per atom, the metallic-binding energy is very low within rather open body-centered cubic lattices. Indeed, such binding energies decrease as the group is descended, and this is apparent in decreasing values for enthalpies of fusion and vaporization. The vapors themselves consist of covalently bonded M_2 diatomic molecules and, mainly, single M atoms. Within the former, the M–M bond energy is expectedly greatest when $M = Li$, since Li has the smallest covalent radius. When vaporized, the elements all have characteristic flame colors: Li crimson, Na yellow, K violet, Rb red–violet, and Cs blue. These arise because of the ready excitation of the single s^1 outer electron and they form the basis of the analytical determination of element concentrations by atomic absorption spectroscopy.

The high reactivities of the alkali metals are reflected in very positive electrode potentials (Table 3, shown as oxidation potentials in aqueous media). The exceptionally high value for lithium appears at first sight anomalous given that, being the smallest atom, it has the highest ionization energy. However, Li^+ is the smallest of the Group 1 cations, and hence is the most heavily and most strongly solvated. Although only four H_2O molecules are bonded directly to each Li^+, over 20 others are affected and form a secondary solvation sphere to give a total solvation number of ca. 25. Hence Li^+ has the most exothermic hydration energy, and the ${Li^+}_{aq}$ ion is the largest and the least mobile of the hydrated alkali metal cations. As related in Section 4, which is concerned with complexes of alkali metal compounds, such features are general ones and pertain to a diversity of polar solvents.

2.4 Solutions of Alkali Metals: Solvated Electrons, Alkalides, and Electrides

In common with certain other metals (e.g. the alkaline earths Ca, Sr, and Ba and the lanthanides Eu and Yb) the alkali metals will dissolve in liquid ammonia and in certain other solvents such as organic ethers, organic amines, and HMPA (*see* ***Ammonia & N-donor Ligands***). However, the solubility is greatest in liquid ammonia and it is dramatic; for example, at $-50\,°C$, 1 mole of Cs (132.9 g) will dissolve in only 2.34 mole of NH_3 (39.8 g). Discovery of this phenomenon is usually attributed to Wehl in 1863, but it now seems likely that these solutions were first prepared by Davy as early as 1808. The solutions have remarkable properties, particularly regarding color, electrical conductivity, and magnetic susceptibility. Dilute solutions are blue owing to an intense absorption at a wavelength of around 1500 nm and tailing into the visible. The position of this absorption, and hence the blue color, is independent of the metal present, so indicating the presence of a species common to all such solutions. At higher concentrations, the color changes to a metallic bronze. The solutions conduct electricity and the current carrier is plainly highly mobile since the conductivity of dilute solutions is considerably higher (7 or 8×) than that of fully ionized salts in water. On concentration, the conductivity first decreases gradually to a minimum at about 0.05 M, but then increases very markedly until, at around 1 M, it is comparable to that of the metal itself. Magnetic susceptibility measurements reveal that dilute solutions are paramagnetic to the extent of one free electron per metal atom. Concentration first leads to a decrease in susceptibility, and indeed solutions of minimal conductivity are also diamagnetic; however, further concentration restores some paramagnetism.

The above findings have been fully reviewed.[35,36] There is a widespread consensus as to their interpretation and it is one which tallies with the low lattice enthalpies of the alkali metals, their low ionization energies, and the high solvation energies of M^+ ions. Thus, in dilute solutions the M atoms ionize to give M^+ cations (which are solvated by NH_3 molecules) and electrons (equation 1). These electrons occupy cavities of around 3.3 Å diameter in the liquid 'lattice', such cavities being produced by displacement of 2 or 3 NH_3 molecules which occurs because of repulsion between each electron and the electrons within these solvent molecules. This cavity concept can explain why solutions are of considerably lower density than that of liquid ammonia itself. The blue color of dilute solutions is due to wavefunction transitions undergone by these solvated (yet quasi-free) electrons. The presence of such relatively mobile species explains also the high conductivities and paramagnetism of dilute solutions. At higher concentrations, solvated electrons begin to pair up and they are removed by formation of solvated alkalide anions (equation 2). Both processes lead to reductions in paramagnetism and

conductivity.

$$\underset{\text{(dispersed)}}{M(s)} \rightleftharpoons M(NH_3) \rightleftharpoons M^+(NH_3) + e^-(NH_3) \quad (1)$$

$$M(NH_3) + e^-(NH_3) \rightleftharpoons M^-(NH_3) \quad (2)$$

Liquid ammonia solutions of the alkali metals have found use as strong and selective reducing agents in diverse areas of chemistry. Such solutions are quite stable providing the ammonia is pure and anhydrous, and especially providing that no transition metal ions are present. Such ions catalyze decomposition to metal amide (equation 3). Synthetic uses in inorganic chemistry include the generation of transition metal species in unusually low-oxidation states (see Section 3.5) and of clustered polyanions of main group elements, for example, Sn_9^{4-}, Pb_7^{4-}, As_5^{3-}, and Sb_7^{3-}. A recent use with considerable scope has been the reduction of transition metal salts to give small (2–15 nm diameter) metal particles.[37] However, probably the most widespread application of these alkali metal solutions has been as reducing agents in organic synthesis[6,38] since they will frequently effect reductions that are otherwise impossible. The reagents have been especially valuable in peptide synthesis.[39] Among these alkali metal reagents, sodium naphthalenide is commonly used as a one-electron donor in these organic reduction reactions. However, two-electron transfer via two-step has been proposed in organic reactions involving K^+ (18-crown-6)K^-.[40,41]

$$e^-\cdot NH_3 + e^-\cdot NH_3 \longrightarrow H_2 + NH_2^- \quad (3)$$

$$2M(s) \rightleftharpoons M^+(solv) + M^-(solv) \quad (4)$$

As mentioned above, solutions of the alkali metals (except Li) contain solvated M^- anions as well as solvated M^+ cations and solvated electrons;[35] indeed, there is some evidence to suggest that the reducing abilities of such solutions are due largely to the presence of these anions. Alkalide containing Li^- has not been observed in solution or in the solid state, which is due to the strong solvation/complexation of Li^+.[42] Isolation of stable solids containing these alkalide anions has depended on driving the equilibrium shown in equation (4) to the right and then on protecting the anion from the polarizing effects of the cation. Both aims have been realized by using two-dimensional and three-dimensional macrocyclic ethers (crowns and cryptands, respectively; see Section 4.3). The cryptands are particularly effective in encapsulating M^+ cations. For example, addition of Na metal to a solution of $N[(CH_2CH_2O)_2CH_2CH_2]_3N$ (called *2,2,2-crypt*) in $EtNH_2$ allows isolation of golden yellow crystals with a metallic luster, $[Na(2,2,2\text{-crypt})]^+\cdot Na^-$. In the crystal, each Na^- ion sits over an open face where the captured Na^+ is visible through the crypt molecule. The anion has an apparent radius of around 2.2 Å, cf. 1.02 Å for six-coordinate Na^+ and 1.54 Å for the covalent radius of Na. Similar crystalline alkalides are preparable for the heavier Group 1 metals, for example, $[Cs(18\text{-crown-}6)]^+\cdot Cs^-$, and mixed-metal species are also known, for example, $[Rb(15\text{-crown-}5)]^+\cdot Na^-$. Recently, structures of alkalides contain mixed-sandwich complexes of alkali metal cations with 18-crown-6, 15-crown-5, and 12-crown-4 have been determined.[43] An unusual barium azacryptand sodide $Ba^{2+}(H_5Azacryptand[2.2.2]^-)Na^-\cdot 2MeNH_2$ has been synthesized and structurally characterized by X-ray crystallography and ^{23}Na MAS NMR.[44] Novel dimer of $(Na_2)^{2-}$ has been found in the crystal lattice with internuclear distance of 4.17 Å, 1.3 Å shorter than the average diameter (5.5 Å) of Na^-. Dimers of K^- and Rb^- and chains of Rb^- and Cs^- have also been observed.[45] Solid-state NMR spectra of the homo-metallic systems reveal separate resonances for M^+ and M^-, confirming that they behave as independent entities. Solution NMR spectra also give sharp signals for M^-, indicating that the anion is essentially unsolvated.

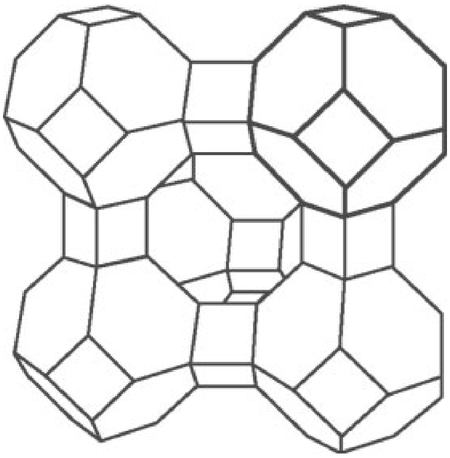
It is also possible to prepare crystalline electrides in which a trapped electron acts in effect as the anion. The bulk of the ‘excess’ electron density in electrides resides in the ‘X-ray empty’ cavities and in the interconnecting channels. Structures of electrides $[Li(2,1,1\text{-crypt})]^+\cdot e^-$ $[K(2,2,2\text{-crypt})]^+\cdot e^-$, $[Rb(2,2,2\text{-crypt})]^+\cdot e^-$, $[Cs(18\text{-crown-}6)_2]^+\cdot e^-$, $[Cs(15\text{-crown-}5)_2]^+\cdot e^-$ and mixed-sandwich electride $[Cs(18\text{-crown-}6)(15\text{-crown-}5)^+e^-]_6\cdot$18-crown-6 are known.[46–48] Silica-zeolites with pore diameters of ∼7 Å have been used to prepare silica-based electrides.[49] The potassium species contains weakly bound electron pairs which appear to be delocalized, whereas the cesium species have optical and magnetic properties indicative of electron localization in cavities with little interaction between the electrons or between them and the cation. The structural model of the stable cesium electride synthesized by intercalating cesium in zeolite ITQ-4 has been confirmed by the atomic pair distribution function (PDF) analysis.[50] The synthetic methods, structures, spectroscopic properties, and magnetic behavior of some electrides have been reviewed.[51] Theoretical study on structural and electronic properties of inorganic electrides has also been addressed recently.[52]

2.5 Metal Atoms and Clusters Trapped in Zeolites and Graphite

The section above described how alkali metal species such as solvated M^+ ions and M^- ions can be formed and isolated within the ‘lattices’ of certain liquid solvents. It is also possible to obtain single alkali metal atoms (M) and clusters (usually cationic ones, $(M)_n^{x+}$) in various solid ‘hosts’ such as zeolites and graphite. There is considerable interest in clustered species since they are especially relevant to the question of what has been called the ‘*metal/nonmetal transition*’, that is, how many atoms need to be gathered together before metallic (rather than molecular, nonmetallic) properties become apparent? The few electron alkali elements lend themselves to state-of-the-art

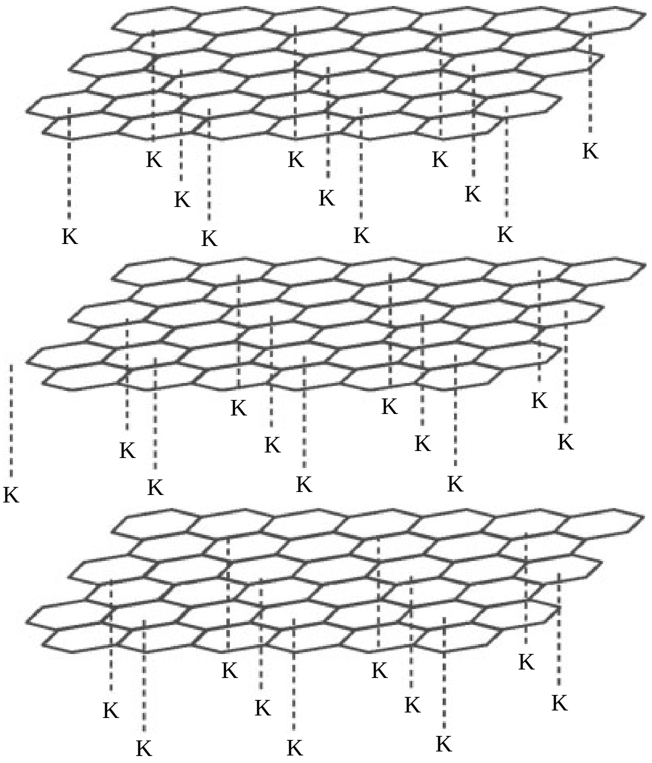
quantum mechanical calculations which probe this question, and this area has been reviewed recently.[53]

Zeolites (e.g. Zeolite A, (**1**)) are a class of aluminosilicates which are built up from corner-sharing SiO_4 and $A1O_4$ tetrahedra arranged in three-dimensional networks and which provide channels and cavities of molecular dimensions (*see* ***Zeolites***). Electroneutrality is maintained by the presence of metal (usually alkali metal) cations. Clustered cationic species such as Na_3^{2+}, Na_4^{3+}, Na_5^{4+}, Na_6^{5+}, K_3^{2+}, and K_4^{3+}, as well as neutral alkali metal particles, $(M)_n$, can be formed within such 'hosts' by a variety of methods including high-vacuum deposition of metal atoms,[54] treatment of the zeolite with an alkali metal azide (which decomposes to give the metal),[55] and reduction of the cations already present in zeolites with solutions containing solvated electrons.[56] Species produced (which are frequently paramagnetic) have been studied by ESR spectroscopy and by metal NMR spectroscopy.[57] K^- and Rb^- in metal-loaded zeolites have been prepared and studied by ^{87}Rb NMR.[58]



(**1**)

Alkali metals can also be inserted ('intercalated') into various forms of elemental carbon, particularly of graphite.[59] This allotrope has a lamellar structure containing flat cojoined hexagons of carbon atoms which form flat layers. Such layers, separated by 3.35 Å, are not superimposed but alternate, usually in an ABAB pattern, and alkali metal atoms can be placed in the gaps simply by treating finely divided graphite with weighed quantities of alkali metals (K, Rb, Cs) in an evacuated vessel. Species produced are commonly of general formula C_xM with $x = 8$, 24, 36, 48, and 60. In C_8K, all the layers (now 5.43 Å apart) are separated by layers of K atoms (see (**2**)), whereas in the other species M atoms are found only in each nth interlamellar spacing. Quite typically, lithium behaves differently, giving intercalates such as C_6Li, $C_{12}Li$, $C_{18}Li$, and others of uncertain and variable composition such as $C_{15-25}Li$ and $C_{19-33}Li$. All such materials are colored (e.g. C_8M bronze, $C_{24}M$ blue) and have high conductivity due to fairly ready exchange of electrons between graphite and the metal. Interest in them centers mainly on this latter property. In this context, it has recently been found[60] that fullerenes such as C_{60} (isolated from soot extracts) can also be doped by alkali metal vaporization to give films such as $C_{60}K_3$ and $C_{60}Rb_3$ which have superconductivity transition temperatures of around 20 K (*see* ***Carbon: Fullerenes***).



(**2**)

3 COMPOUNDS

3.1 Introduction

It is apparent from the ionization energy and electronegativity data given in Section 2.3 (Table 1) that the chemistry of alkali metal compounds is, with few exceptions, the chemistry of the +1 state. This is, of course, an approximation since total charge separation is unknown, but it is generally believed to be a fairly accurate one in the case of the alkali metals. The matter has been a source of past debate,[33,34,61] especially in the case of lithium where the high-charge density associated with the small lithium cation can lead to appreciable degrees of polarization of anions. The most modern calculations estimate that this effect accounts for ≈10% of bonding at the most, even with the most polarizable, least electronegative anions. In the lithium alkyls, for example, the high volatilities, low-melting points, and alkane and arene solubilities often cited in support of covalent bonding are in fact determined by the strength of

bonding between the aggregated molecular units in these compounds. They say nothing of the bonding of the metal within the aggregates. These compounds and their heavier congeners are fully discussed in ***Alkali Metals: Organometallic Chemistry***. Other failings of the ionic bond model will be discussed as they arise. Limits of space preclude a fully comprehensive treatment of alkali metal compounds but all chemical principles and classes of compound to which the identity of the metal is relevant will be covered, with appropriate citations to sources of further information.

3.2 Binary Compounds

3.2.1 Hydrides

The alkali metal hydrides may be formed by direct combination of the elements. All adopt the fcc structure. The hydride anion is small and thus lattice energies are high, especially for LiH with the smallest cation.[62] Evidence for the existence of H^- in these species came from the observation of a large increase in conductivity on melting, and the production of hydrogen at the anode upon electrolysis. All react as strong bases and reducing agents. The reaction of LiH with H_2O has been used as a convenient H_2 source, but reactivity increases down the group such that RbH and CsH ignite spontaneously in dry air. The apparent ionic radius of H^- varies with the cation, since the electron density around the single proton nucleus is easily polarized (r^- in LiH = 1.37 Å, in RbH = 1.54 Å). The hydrides find most use in the form of complexes such as Li^+ $AlH_4{}^-$, useful as selective reducing agents. For further details, *see **Hydrogen: Inorganic Chemistry***.

The interstitial hydride $[Li_8(H)\{N(2\text{-pyridyl})Ph\}_6]^+$ $[Li(Me_2Al^tBu_2)_2]^-$ has been reported.[63] Similar hydride compound $[Li_7(H)\{N(2\text{-pyridyl})Ph\}]_6$ has also been obtained by further treatment of the above reaction mixture with THF. Recently, main-group polyhedral clusters with the $Li_8(H)$ moieties has been synthesized by the reaction of a bicyclic 1,3,4,6,7,8-hexahydro-2*H*-pyrimida[1,2-a]pyridimine (hpp) in tandem with $ZnMe_2$ and ^{t}BuLi. The product is an ion-separated compound $[Li_8(H)(hpp)_6]^+$ $[Zn^tBu3]^-$, which has been structurally characterized by X-ray crystallography. It has shown that the hydride is enclosed by an unusual $(Li^+)_8$ cubic cage whose six faces are straddled by the six pyridylamide moieties.[64]

'Inverse Sodium Hydride', a crystalline salt that contains the reverse H^+ and Na^- formed by reversible encapsulation of H^+ in 3^6adamanzane (Adz), has been synthesized and characterized.[65] Theoretical studies of the analogous $Me_3N^-H^+\cdots Na^-$ suggest that the species is indeed metastable with respect to deprotonation in solvents having dielectric constants below ∼2.[66]

Table 4 Lattice energies and enthalpies of formation for the alkali metal halides

Compound	Lattice energy (kJ mol^{-1})	$\Delta H_f{}^\circ$ (kJ mol^{-1})
LiF	1036	−147.22
LiCl	853	−97.66
LiBr	807	−83.94

CsI	604	−82.84

3.2.2 Halides

These, the classic 'ionic compounds', provide an oft-used example of periodic trends (*see **Periodic Table: Trends in the Properties of the Elements***). All are high melting, colorless crystalline solids. Table 4 shows their enthalpies of formation and lattice energies. There is a steady decrease in lattice energies moving down both Group 1 and Group 17, clearly demonstrating the influence of ion sizes. Size is also important in dictating crystal packing arrangements[67] (*see **Halides: Solid-state Chemistry***). The comparable sizes of Cs^+ and Cl^- result in the bcc structure (often termed '*CsCl structure*') which maximizes the coordination number of each ion at 8, whereas a greater size mismatch as in LiCl allows the structure to be determined by closest packing of halide ions in a cubic close-packed lattice with the metal occupying the octahedral holes, so giving a mutual coordination number of 6. From this hard-sphere ionic bond model, limiting values of cation/anion radius ratios may be calculated geometrically. The successes and failures of this model are presented in Table 5. Failures in the hard-sphere ionic bond model have been ascribed to polarization effects, resulting in deformation of the ions. The overpreponderance of the fcc lattice has been attributed to the fact that this geometry maximizes any covalent contributions from p orbitals on the metals. A molecular orbital approach to bonding, treating the lattice as an infinite 'molecule', would seem more appropriate where covalent contributions were thought to be important.

Trends in enthalpies of formation (Table 4) are not as regular as those of lattice energy. For fluorides, lattice energies dominate ΔH_f; therefore the smallest cation gives the most stable fluoride. For the other halides, the ease of production

Table 5 Ion radius ratios and predicted and found coordination numbers for the alkali metal halides

Compound	r^+/r^- (Pauling radii)	Predicted CN	Experimental CN
LiF	0.44	6	6
LiCl	0.33	4	6
LiBr	0.31	4	6
LiI	0.28	4	6

RbCl	0.82	8	6
RbBr	0.76	8	6
RbI	0.68	6	6
CsF	1.24	8	6
CsCl	0.93	8	8
CsBr	0.87	8	8
CsI	0.78	8	8

of gaseous cations from the metal becomes the main variant parameter; therefore the easily sublimed (low lattice energy of the metal), least electronegative Cs produces the more stable chlorides, bromides, and iodides. All may be produced by neutralization of aqueous alkali hydroxide or carbonate with the appropriate hydrohalic acid. NaCl (and KCl) are, of course, available directly from rock-salt deposits or by evaporation from sea waters.

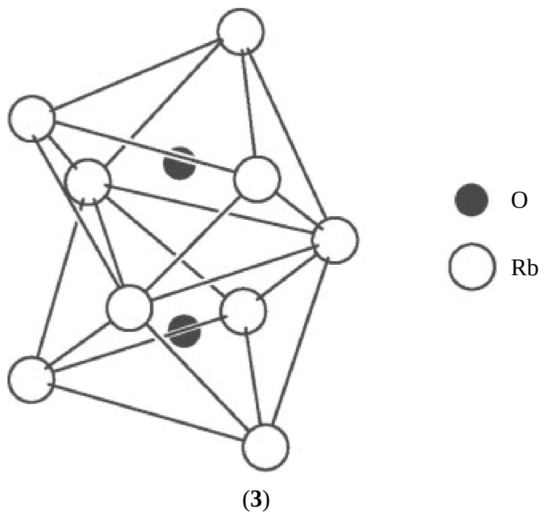
Solubilities are hindered by large lattice energies and helped by energy gained in solvent–cation binding. Thus, LiF is only sparingly soluble in water (very high lattice energy) while the other alkali halides become progressively more soluble with increasing size (lower lattice energy) and greater solvation (more room to bind more solvent molecules). In all cases, highly polar, small molecules (like H_2O and NH_3) are most efficient, but LiCl will dissolve in THF, and LiBr and LiI in alcohols, SO_2, and so on. This chemistry is fundamentally the coordination chemistry of the cations, and will be covered more fully later (see Section 4.4.2). Reactions in solution are generally those of the solvent-separated anions, not strongly dependent on alkali cation, and are dealt with as reactions of the halogens (*see* ***Fluorine: Inorganic Chemistry*** and ***Chlorine, Bromine, Iodine, & Astatine: Inorganic Chemistry***).

Unusual and interesting reactions of alkali halides have been seen in argon matrices by IR spectroscopy. For example, codeposition of CsF with SOF_2 results in the novel $Cs^+[SOF_3]^-$. An interesting new area of research is emerging in the study of 'nanocrystals' such as $Na_{14}Cl_{13}$, a tiny fragment of the rock-salt lattice, whose properties are dominated by surface effects.[68]

Solubility and Raman spectroscopic studies of molten mixtures of $ZrCl_4$-CsCl, $ThCl_4$-MCl (M = Li, Na, K or Cs), and ZrF_4-KF has been considered useful in the electrorefining of Zr and Th metal which would be an alternative and less-expensive process than the batch-type metallothermic Kroll process.[69–71]

3.2.3 *Chalcogenides*

A variety of oxides of the alkali metals are known, illustrating the varying catenation and oxidation states of oxygen. Also, they provide some of the rare examples of compounds where the metals are not, formally at least, +1 cations. All the metals form stable salts of O^{2-}, the most stable being Li_2O, the major product of burning Li in air. All have the antifluorite structure except Cs_2O which has the layered anti-$CdCl_2$ structure. Peroxide salts M_2O_2 are most readily prepared for Li and Na but careful oxidation of K, Rb, and Cs allows isolation of their ${O_2}^{2-}$ salts. The paramagnetic superoxides $M^+{O_2}^-$ are the major combustion products of K, Rb, and Cs, while being unstable for Li and only accessible with difficulty for Na. This is a good example of the alkali metal affecting the route of a reaction by its size/coordinating ability. Among the more unusual oxides are the poorly characterized sesquioxides 'M_2O_3' and the red 'ozonides' $M^+{O_3}^-$, also stable only with large cations. Interestingly, while the solid lithium ammoniate $[Li(NH_3)_4]^+[O_3]^-$ is isolable, removal of the ammonia causes the coordinative demands of the lithium ion to 'rip apart' ${O_3}^-$, possibly due to the high-charge density on Li^+. Some interesting suboxides exist for the larger metals, originally thought to be impure solid solutions of metal and metal monooxide, but now fully characterized in the cases of Rb_6O, Rb_9O_2, and Cs_7O. For example, Rb_9O_2 consists of two Rb_6 octahedra sharing a common face (**3**), each octahedron having a central O atom. Short Rb–Rb distances imply metal–metal bonding. All these species have excess electrons (e.g. Rb_9O_2 is better represented as $(Rb^+)_9{\cdot}(O^{2-})_2{\cdot}5e^-$) and hence they have metallic properties and also show air, moisture, and temperature



(**3**)

sensitivity.[72] More coverage may be found in ***Oxides: Solid-state Chemistry*** and ***Oxygen: Inorganic Chemistry***.

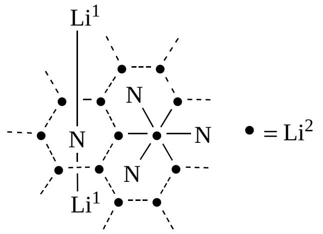
All alkali sulfides are preparable by reaction of the metal–ammonia solution with sulfur. Exact stoichiometry is important to prevent formation of polysulfides.[73] Sulfur will support combustion of the metals, but products are impure. All the sulfides M_2S adopt the antifluorite structure and are susceptible to hydrolysis, giving them the characteristic odor of H_2S. Hydrolysis is not necessarily complete, however, and alkali sulfide structures containing coordinated water are known. Reaction of the sulfides with further sulfur produces the polysulfides M_2S_x ($x = 2–6$). As in the oxides, higher catenation is favored by larger cations. The polysulfides are low-melting yellow to red solids. The sodium polysulfides Na_2S_x ($x = 2–5$) have significance in their potential use in battery systems.[22] The chemistry and structure of the dianions in these systems will be dealt with in ***Chalcogenides: Solid-state Chemistry*** and ***Sulfur: Inorganic Chemistry***.

The selenides and tellurides are similar to the sulfides, being preparable from ammonia solutions of the alkali metals. They are water-soluble yet partially hydrolyzed like the sulfides, but are more susceptible to oxidation back to the element. Not every member of the class M_xSe_y/Te_y has been fully investigated, but the many that have promise few surprises (*see* ***Selenium: Inorganic Chemistry*** and ***Tellurium: Inorganic Chemistry***). The polonides are similar, and also have their own article (*see* ***Polonium: Inorganic Chemistry***).

3.2.4 Nitrides, Phosphides, Arsenides, Antimonides, and Bismuthides

The most stable of the nitrides, Li_3N, will form spontaneously from the elements at room temperature. The red crystalline solid reacts with water to give LiOH and NH_3, and will combust in air. It is handled in an inert atmosphere. The structure is unique, having two lithiums forming the apices of a hexagonal bipyramid at 1.94 Å and the remaining six in a hexagonal array at 2.11 Å. These hexagons pack in layers bridged by the apical lithiums (**4**). The lithium ions seem to be mobile in the lattice, making Li_3N an ionic conductor.[1] Among the alkali metal nitrides, only Li_3N has been well characterized. The preparation of the heavier alkali metal nitrides has not been successful. However, the preparation of Na_3N has been developed recently.[74] The anti-ReO_3 type structure of Na_3N has also been determined and it has shown that the nitrogen atom is surrounded by six sodium atoms to form an octahedron with a Na-N bond distance of 2.37 Å. The coordination number of the nitrogen atom changes from eight (in Li_3N) to six (in Na_3N) because the sodium atom has a larger radius than the lithium atom.[75] Convincing evidence for other pure alkali nitrides M_3N is absent, but binary compounds of nitrogen are, however, known for all alkali metals in the form of azides $M^+N_3^-$. These hygroscopic, ionic salts are amongst the most stable of the azides, being fusible with minimal decomposition. They may be prepared from aqueous solutions of HN_3 by neutralization with metal hydroxide or carbonate, though direct industrial routes to NaN_3 have been developed (e.g. equation 5). Most azides of other elements are made from NaN_3, some finding use as explosives and detonators.

$$3N_2O + 4Na + NH_3 \longrightarrow NaN_3 + 3NaOH + 2N_2 \qquad (5)$$



(**4**)

For phosphides, a wide variety of stoichiometries are preparable, from simple K_3P to Rb_2P_5 to Cs_4P_6, NaP_5, Na_3P_{11}, Na_3P_{21}, Li_2P_{16}, Li_3P_{21}, and so on containing complex catenating anions.[76] The alkali metals play little part in the chemistry, so the reader is referred to ***Phosphides: Solid-state Chemistry*** for further information.

For the heavier elements As, Sb, and Bi, further diversity in structure and stoichiometry is found. The ionic bond model becomes less useful as these species may be thought of as intermetallics, possessing metallic luster, and conduction or semiconduction properties. Typical examples include Na_3Bi and NaBi, which becomes superconducting at low temperatures (<2.5 K). Further details will be found in the relevant article for each element, As, Sb, and Bi. Zintl anions of these elements are also known.[77]

3.2.5 Carbides

The alkali metals form only ionic carbides, mostly simple ionic salts of acetylene, M_2C_2, which liberate acetylene on reaction with moisture. There has been much recent interest[78] in permetalated and hypermetalated hydrocarbon species, or ‘methanides’. Most studied in this respect has been lithium, presumably because of its volatility and amenability to calculation. Mass spectrometric and calculational evidence has been presented for CLi_6, CLi_3, and C_2Li_4, but real samples of CLi_4, C_3Li_4, and C_5Li_4 are preparable. All are pyrophoric powders. The heavier metals form another class of ‘carbide’, the graphite intercalation compounds, but as the electron has not been totally freed from the metal, these were considered in the previous section.

3.2.6 Silicides, Germanides, Stannides, and Plumbides

Germanium, tin, and lead give alloy-type binaries of the alkali metals of variable stoichiometry, but when dissolved in ammonia with the alkali metals they produce colored Zintl-type anions (*see* ***Zintl Compounds***) in solution which can be

isolated as crystals with appropriate complexants for the alkali metal. Apart from crystallizing from the molecular solvents, several clusters can be isolated from the solid-state reactions in which direct synthesis of the elements is performed.[79] Silicon has not yet been shown to share this behavior in solution but several alkali silicide phases are known,[80] with widely variable catenation patterns reminiscent of the sulfides and phosphides, for example, Li_7Si_2, NaSi, $Li_{12}Si_7$, and so on. The latter contains Si_5^{6-} rings and Si_4^{12-} trigonal planar 'stars'.[81] Silicon- and alkali-rich alloy-like phases also exist, for example, Na_8Si_{46}, $Li_{22}Si_5$. The rarity of isostructural compounds with different alkali metals underlines the folly of ignoring the alkali cations in compounds of this type.

A series of alkali tetrelides $M_{12}Tt_{17}$ (M = alkali metals; Tt = tetrels = group 14 elements), which contain the anionic clusters of Tt_4^{4-} and Tt_9^{4-} with the naked cations, have been prepared by direct synthesis from the corresponding elements[79–84] in solid state. Ge_9^{4-} was the first deltahedral cluster of the tetrels in solid state being isolated and structurally characterized although the Tt_4^{4-} has been made few decades ago. Single-crystal X-ray structure determination revealed that the unit cell of $Rb_{12}Si_{17}$ contains isolated clusters of Si_4^{4-} and Si_9^{4-}.[82] The Zintl anions Tt_4^{4-} and Tt_9^{4-} isolated from these alkalide tetrelides adopt tetrahedral and deltahedral geometry, respectively.[79–84]

Some other Zintl anions (*see* ***Zintl Compounds***) of Sn_9^{4-}, Pb_9^{4-} such as $[K_4Sn_9(18\text{-crown-}6)_3]$·ethylenediamine, $[Li(NH_3)_4]_4[Pb_9]NH_3$, $[K(18\text{-crown-}6)]_4[Pb_9]$·en.·tol, are known.[85–87] The interesting linear, trimer, and tetramer of rubidium Ge_9 clusters $[Ge_9{=}Ge_9{=}Ge_9]^{6-}$ and $[Ge_9{=}Ge_9{=}Ge_9{=}Ge_9]^{8-}$ have been synthesized and characterized recently.[88,89]

3.2.7 *Borides and Others*

Best known are the MB_6 borides, for example, NaB_6, comprising an interconnected cubic lattice of B_6 octahedra with the metal atom at the center of each cube in a CsCl-like arrangement. Phases M_3B have also been reported, more saltlike in nature with little covalent B–B bonding. The exact composition of 'NaB_6' was found to be 'NaB_{15}'. Recently, the actual phase composition has been found to be Na_3B_{20},[90,91] and its structural framework consists of interconnected boron atom icosahedra and additional interstitial boron atoms.[92] So far, the exact compositions and crystal structures of four alkali metal borides Li_2B_6,[93] Li_3B_{14}, Na_3B_{20},[90,91] and Na_2B_{29}[92] have been found. Other alkali metal borides such as potassium, rubidium, or cesium borides have not yet been obtained. Further information is given in ***Borides: Solid-state Chemistry***.

Few distinct points arise from discussion of the chemistry of compounds of the alkali metals with the other metallic elements. Most are alloy- or amalgam-like in nature. Whether they deserve the title 'compounds' has been the subject of debate.[94]

The recent advances in the cluster chemistry of triels (particularly Ga, In, and Tl) generally recognize the alkali trielides as traditional Zintl polyanions or nonclassical Zintl clusters in which an extra electron is present. The alkali metals form binary and ternary network compounds with indium and gallium, which are composed of fused clusters or cluster fragments. In contrast, thallium forms individual cluster anions.[95–97] The alkali metal cations play a decisive role in the structure by filling up spaces efficiently and keeping the cluster apart.[98] Examples of trielide clusters include anions of Ga_{11}^{7-}, In_{11}^{7-}, In_4^{8-}, Tl_4^{8-}, Tl_5^{7-}, Tl_6^{6-}, Tl_{11}^{7-}, and so on.[99,100] These isolated anionic clusters display different structures, such as a pentacapped trigonal prism in Cs_8Ga_{11}, K_8In_{11}, and Rb_8In_{11},[99] a three-dimensional indium network built of layers of In_{12} icosahedra and zigzag chains in KNa_3In_9,[101] and an arachno 12-vertex polyhedra 'drums' and closo icosahedra in $K_3Na_{26}In_{48}$.[102]

3.3 Oxoacid Salts

The vast majority of the chemistry of alkali metal salts of oxoanions shows little dependency on the identity of the cation. Much of the chemistry has been comprehensively covered before,[73] and receives further up-to-date coverage in the articles on the relevant element. However, a few important examples and general points are included here.

3.3.1 *Borates*

Alkali borates occur in a few very large Salt-like deposits. A great many phases exist, which may be formulated in equivalents of metal ion, boron oxide, and H_2O, but this says nothing of structure. The identity of the metal (often an alkali metal) clearly is one of the determining factors in the occurrence of a given phase, but these complex matters have their own article (*see* ***Borates: Solid-state Chemistry***). Most common is borax, $Na_2B_4O_7{\cdot}10H_2O$, more informatively written as $Na_2[B_4O_5(OH)_4]{\cdot}8H_2O$, which is used as an alkaline buffer, in glass manufacture, and in fire retardants. Its reaction with hydrogen peroxide forms 'sodium perborate', $Na_2[B_2(O_2)_2(OH)_4]{\cdot}6H_2O$, used as a bleach in washing powders. This use is declining with lower-washing temperatures and the growing use of liquid detergents.

Mixed-alkali metal polyborates $CsLiB_6O_{10}$ has been found as a promising nonlinear optical material.[103]

3.3.2 *Carbonates and Silicates*

Most alkali carbonates form a wide variety of hydrates, for example, $Na_2CO_3(H_2O)_x$ ($x = 1, 7, 10$). The decahydrate has pairs of sodiums octahedrally surrounded by water ligands, with no metal–anion close contacts. The paired octahedra share an edge to give $[Na_2(H_2O)_{10}]^{2+}[CO_3]^{2-}$. In contrast, the monohydrate has two independent sodiums

coordinated to 5 and 4 carbonate oxygens, respectively. Further variety in structure and stoichiometry is found when carbonic acid acts monobasically to give the 'bicarbonates', for example, $NaHCO_3$, which also form a variety of hydrates, as well as mixed carbonate/bicarbonate systems, notably the major natural carbonate 'trona' $Na_2CO_3{\cdot}NaHCO_3{\cdot}2H_2O$. Similar behavior is found for other alkali metals and indeed mixed-metal phases are common, for example, $K_2CO_3{\cdot}Na_2CO_3{\cdot}6H_2O$, $KLiCO_3$, and so on. Lithium forms no bicarbonates. Its carbonate is rather insoluble in water, and is easily prepared anhydrous. All the carbonates are susceptible to thermolysis (equation 6). The temperature required for this reaction increases with increasing cation size. This periodic trend is shared with other oxoanion salts since the lattice energy of the product oxide is the dominant factor.

$$M_2CO_3 \xrightarrow{\Delta} M_2O + CO_2 \qquad (6)$$

It will be seen in the article ***Zeolites*** that the chemistry of the metal ion is often unimportant in their complex structures. Consequently, there is little to discuss in terms of periodic trends and differences. It should be noted, however, that sodium silicate is important for its use as a builder in washing powders.

3.3.3 Oxoacid Salts of Nitrogen, Phosphorus, Arsenic, Antimony, and Bismuth

All alkali metals form nitrates MNO_3 and nitrites MNO_2. The former decompose to the latter with strong heating in the absence of O_2. This tendency is greatest for the smaller metal ions, following a group trend. All are hygroscopic and crystalline hydrates are common.

The nitrates are prepared by neutralization of nitric acid with the appropriate hydroxide. In some cases, metathesis reactions have been commercially exploited (equation 7). Through manipulation of the differing aqueous solubility/temperature relationships of the various salts in the equilibrium mixture, KNO_3 is isolable.

$$NaNO_3 + KCl \rightleftharpoons KNO_3 + NaCl \qquad (7)$$

The nitrites are preparable thermally as mentioned above, or by reaction of nitrogen oxides with metal hydroxide or carbonate (e.g. equation 8). The nitrites are all water-soluble but with a smaller tendency to hydrate formation than the nitrates. $NaNO_2$ is used as an oxidant and a nitrogen source in the production of azo dyes, and so on. It has also found wide use in curing meats, although recent concern has been expressed over the safety of the products of the reactions of NO_2^- with the organic compounds in foods. Salts of other nitrogen oxoacids exist, for example, $Na_4N_2O_4$ and Na_3NO_4, and these receive coverage in ***Nitrogen: Inorganic Chemistry***.

$$Na_2CO_3 + NO + NO_2 \longrightarrow 2NaNO_2 + CO_2 \qquad (8)$$

Phosphorus has an even wider range of oxoacid chemistry, and a commensurately wide range of phosphates, phosphites, polyphosphates, hypophosphites, and so on of the alkali metals are preparable. Sodium and potassium are the most common cations used, largely because of their availability and low cost. The cation often has little effect on the properties and applications, which are covered in ***Phosphates: Solid-state Chemistry***. Most form a variety of crystalline hydrates, which have been well covered in previous treatments[73] and need not be repeated here. True to form, lithium is the exception, forming no stable hydrates with phosphorus oxoanions.

A variety of alkali–arsenic oxides has been isolated, including Na_2HAsO_4, NaH_2AsO_4, RbH_2AsO_4, $LiAsO_3$, $KAsO_3$, $NaAsO_2$, $NaAsO_3$, Na_3AsO_3, and Na_3AsO_4. Some find use as wood preservatives, bacteriocides, and herbicides. Hydrates are common. Many are salts of the poorly characterized arsenious acid $As(OH)_3$,[104] but salts of arsenic acid, H_3AsO_4, are also known. They are good oxidizing agents. Structures are complex, with polymeric anions being common (cf. phosphates). The identity of the metal can affect the catenation mode of the anions, for example, $LiAsO_3$ has a dimeric repeat-unit in its infinite chains of AsO_4 tetrahedra, while $NaAsO_3$ has a tetrameric repeat-unit, and $KAsO_3$ has a cyclic trimeric anion $As_3O_9^{3-}$.

There is a greater tendency to salts of Sb^V over Sb^{III}. $NaSb(OH)_6$, $NaSbO_3$, $LiSbO_3$, and Li_3SbO_4 are all known. Polyanion motifs are again common. While $Bi(OH)_3$ forms no anions, being basic, Bi^v oxoanions are rare and very strongly oxidizing. However, $NaBiO_3$, prepared from Bi_2O_3 and Na_2O_2, is sold as a powerful oxidant, and has an ilmenite structure. Hydrates are also known.

3.3.4 Oxoacid Salts of the Chalcogens

The chemistry of polonium may be discounted because of the short half-life and extreme rarity of the element. Tellurates are mostly salts of telluric acid, $Te(OH)_6$, and are not similar to the sulfates. Selenates are more similar, forming compounds such as $Na_2SeO_4(10H_2O)$ exactly like sulfur, but the chemistry is not so extensive as to define the role (if any) of the alkali metal in the compound. The extensive oxo chemistry of sulfur, however, allows such comparisons to be drawn. For example, both $RbHSO_3$ and $CsHSO_3$ are isolable, while the salts of the smaller cations produce the disulfites $M_2S_2O_5$. The full variety is too rich to explore here (*see* ***Sulfur: Inorganic Chemistry***) but the great industrial importance of Na_2SO_4 in the paper and cardboard industry should be noted.

3.3.5 Oxyhalides

Those oxyhalide anions that find use are most often used as alkali metal salts. A particular metal is often chosen to optimize physical properties; for example, $LiClO_4$ is used as an oxidant in rocket propellants because the light metal

maximizes energy density, while the larger ion in $KClO_3$ gives the nonhygroscopic properties that are desired for use in safety matches and pyrotechnic displays. The metal has little chemical effect on the anions; indeed, a structure determination on $NaClO_3$ was used to define the precise geometry of the isolated ClO_3^- anion.[105]

Periodic trends are apparent, again due to size effects in crystal packing. The very soluble $LiClO_4$ crystallizes from water as a trihydrate with each lithium surrounded by face-sharing octahedra of water molecules which weakly hydrogen-bond to the poorly coordinating perchlorate ions.[106] In $CsClO_4$, however, the sparingly soluble salt crystallizes anhydrous from aqueous solution in a $BaSO_4$-type structure. Further examples may be found in the relevant chapters on halogen chemistry.

3.4 Some Salts of Other Inorganic Acids

3.4.1 Hydroxides

The alkali hydroxides are the strongest bases accessible in aqueous solution, since the alkali metals are the most electropositive elements in the Periodic Table. NaOH and KOH are made and used on a massive scale industrially, as well as being ubiquitous laboratory reagents. They are able to deprotonate even weak carbon acids such as cyclopentadiene when poorly donating anhydrous reaction media are employed (the reaction produces water which can then solvate the excess hydroxide, thereby providing a driving force). All are hygroscopic to varying degrees, and form numerous hydrates. Lithium hydroxide has the lowest tendency to hydrate, since the small hydroxide ion can pack efficiently with the lithium cations (cf. perchlorates). It forms a stable, nondeliquescent monohydrate that can be easily dehydrated by vacuum or heat. It is also the weakest base in the gas phase, where it exists predominantly as ring dimers. Base strength increases down the group, as the hold of the metal on the hydroxide becomes weaker. In aqueous solution, of course, there is little difference between the basicity of the alkali hydroxides due to the effects of solvent leveling.

All the hydroxides absorb CO_2 from the air to form carbonates. Similarly, formates may be prepared by heating solid hydroxides with carbon monoxide (e.g. equation 9).

$$NaOH + CO \xrightarrow{180\,^\circ C} HCO_2Na \qquad (9)$$

The hydroxides are formed by electrolysis of aqueous brines as part of the chloralkali process. The metal formed at the cathode immediately reacts with water to produce the hydroxide and hydrogen gas.

3.4.2 Amides

The metal–ammonia solutions discussed in Section 2.4 are metastable. Their decomposition, catalyzed by transition metal ions, yields the ionic salts $M^+NH_2^-$. They may also be formed by passing ammonia gas over the heated molten metals. They are only sparingly soluble in ammonia, and decompose on contact with moisture. $NaNH_2$ (sodamide) has historically been widely used as a very strong base in anhydrous media in organic synthesis. It also serves as a source of the NH_2^- nucleophile. Where this second mode of reactivity is undesired, it has largely been superseded by the stronger, more soluble, less nucleophilic dialkylamide bases, such as lithium diisopropylamide (LDA) (see Section 5). The sodium and potassium counterparts of LDA was found to be a better reagent over the metallation of diphenylmethane.[107,108] Structurally, the alkali amides behave as simple ionic salts. All have high-temperature modifications where the anions are freely rotating pseudospheres. NaCl-type lattices are found for high-temperature potassium, rubidium, and cesium amides. The low-temperature forms are distorted close-packed lattices due to the asymmetry of the NH_2^- anions.[109]

By using a combination of gas-phase synthesis and millimeter/submillimeter-wave spectroscopy, $LiNH_2$ was found to be a monomeric unsolvated planar molecule. The lithium amide $\{[H_2NCH_2CH_2N(H)Li]_\infty\}$ has a polymeric ladder structure with two types of $(NLi)_2$ ring which alternate throughout its infinite length.[110]

Superbases react readily with organic substrates to give heavy metal derivatives of the substrate function as exceptional strong proton abstraction reagents in organic synthesis. The lithium amide-alkoxide complex is composed of four LiNLiO units, whereas the bimetallic lithium/heavier alkali metal mixed amide-alkoxide complexes are constructed from $Li_xM_yN_aO_b$ units $(x + y = a + b)$. The trimetallic Li-Na-K amide-alkoxide compounds consist of a twelve-vertex $Li_2Na_2K_2N_4O_2$ cage as in $[\{RN(H)_2(Bu^tO)[LiNaK{\cdot}(TMEDA)_2]_2\}]$ has been reported.[111]

3.4.3 Alkali Pseudohalides

The salts of hydrazoic acid, $M^+N_3^-$, have already been discussed in Section 3.2.4, but a variety of other alkali pseudohalides exist. The most important of these are the cyanides M^+CN^-, preparable by neutralization of HCN with the appropriate alkali base. NaCN and KCN reached such industrial importance that alternative bulk syntheses have been developed (e.g. equation 10). This Castner process fed the gold extraction industry and continued to feed the electroplating and nylon synthesis markets until cheaper routes directly to HCN were found. In cases where the alkali cyanides are still required, the simple neutralization route is now most economic.

$$Na + NH_3 \xrightarrow{-1/2H_2} NaNH_2 \xrightarrow[+C \atop -H_2]{600\,^\circ C} \frac{1}{2}Na_2CN_2 \xrightarrow[+C]{800\,^\circ C} NaCN \qquad (10)$$

Structurally, the alkali cyanides are truly pseudohalides, all except LiCN adopting either NaCl or CsCl structures at normal temperatures. The required high symmetry is produced by rapid solid-state fluxionality in which the $C{\equiv}N^-$ dumbbell ions rotate to sweep out a sphere of radius intermediate between those of Cl^- and Br^-. Low-temperature phases exist[112] where this fluxionality is not present, for example, CsCN. Once again, lithium is the exception, exhibiting a fully ordered but loosely packed structure related to zinc blende in which each lithium has three N contacts and one C contact. A preference for N coordination is rare among those compounds where it is possible to distinguish between C and N. The highly polarizing cation seems to distort the anion, its C≡N bond length being 1.15 Å in LiCN but 1.05 Å in NaCN. The variety of possible bonding modes of C≡N (linear, bent, η^2, η^1, μ^2, etc.) in less aggregated forms of M^+ CN^- has been the subject of calculational[113] and gas-phase and matrix IR investigation, but solid-state data at present are limited to a few crown complexes and complex transition metal cyano anions.

Other alkali pseudohalides may be prepared from the cyanides. Mild oxidation of M^+CN^- in solution with lead oxides produces M^+OCN^-. The heavier chalcogens may be directly combined (e.g. equation 11).

$$KCN + S \xrightarrow{\Delta} KNCS \quad (11)$$

Potassium thiocyanate, like others in the series, a soluble and hygroscopic ionic salt, finds use in photographic developers. KNCSe may be similarly prepared.[114] The $TeCN^-$ anion is only isolable with very large organic cations, and so no solid alkali tellurocyanate is known. Metastable solutions of M^+TeCN^- may, however, be prepared.

3.5 Salts of Some Important Complex Anions

Aside from the compounds that fall into the well-defined categories above, there are of course a multitude of alkali salts of complex anions of different types, many of which are unknown as the free acids. A selection of the more important and unusual is included here.

Sodium borohydride, prepared as in equation (12), is reaching the status of a bulk inorganic commodity. This industrial preparation was developed to supersede the less economic, but more convenient, direct route (equation 13). Lithium borohydride may be prepared similarly (equation 14). Both sodium and lithium borohydrides have been much used as reducing agents. $NaBH_4$ requires polyethers for efficient dissolution, while $LiBH_4$ is quite soluble in THF. $NaBH_4$ is the more selective reagent, able to reduce ketones to alcohols in the presence of nitriles, nitro groups, alkenes, and so on. This difference in reactivity underlines the fact that as soon as highly ionizing, strongly solvating media (such as H_2O) are excluded, the alkali metal 'salts' are much more associated in solution, and hence the identity of the cation has a much greater effect on the reactivity of the compound. The nature of the structural origins of such differences will be discussed in Section 4. Apart from specialty uses in organic (and inorganic) syntheses, $NaBH_4$ is widely used in the bleaching of wood pulp and in chemical plating of metals such as nickel on to nonmetal surfaces.

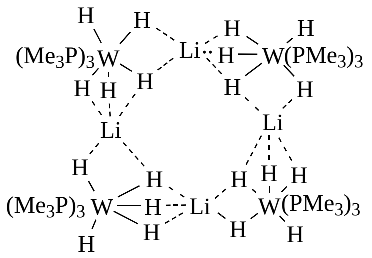
$$Na_2B_4O_7 + 7SiO_2 + 16Na + 8H_2 \xrightarrow{500\,^\circ C} 4NaBH_4 + 7Na_2SiO_3 \quad (12)$$

$$4NaH + BCl_3 \longrightarrow NaBH_4 + 3NaCl \quad (13)$$

$$4LiH + BF_3{\cdot}OEt_2 \longrightarrow LiBH_4 + 3LiF + Et_2O \quad (14)$$

The heavier congeners $M^+EX_4{}^-$ (E = Al, Ga, In) are progressively more reactive. The most common, $LiAlH_4$, has been widely used as a reducing agent and hydrogenating agent. It is a more potent reductant than the borohydrides and is more soluble and hence more reactive in ethers. This greater reactivity makes $LiAlH_4$ less selective than borohydrides and makes handling under an inert nitrogen atmosphere advisable. It is much used as a rigorous drying agent in laboratory solvent distillations, especially of ethers. The bonding in $LiAlH_4$ may have appreciable covalent character since the crystal packing is not a simple close-packed arrangement[115] and contains some short Li–H distances [4Li–H = 1.88–2.00 Å, 1Li–H = 2.16 Å, cf. $(Li^+H^-)_\infty$ = 2.04 Å].

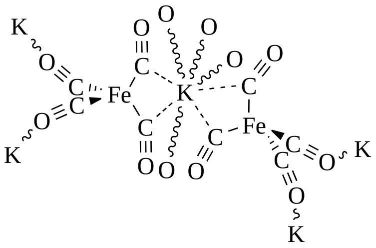
Complex hydrides are known for transition metals also. Evidence has been presented[115] suggesting substantial covalency in the W–H–Li bonds of $[W(PMe_3)_3H_5Li]_4$ (**5**).



(**5**)

A further interesting class of molecules are the alkali salts of transition metal carbonylates. Reduction of neutral metal carbonyls with alkali metals in liquid ammonia produces materials such as $Na_2Fe(CO)_4$. These form valuable synthons in inorganic chemistry, and hence have received much study in their own right. Reactions and spectroscopic properties are often highly dependent on alkali cation and donor-solvent present.[116] This shows how an alkali metal can be closely involved in directing the chemistry of a 'salt'. Structurally, the metal has an important rôle. The $K_2Fe(CO)_4$ salt is known and crystallographically characterized without external donors. The K sits between carbonyls (see (**6**)) and direct metal–metal interaction cannot be ruled out. The less unusual terminal contacts to O of other units complete the coordination of the cation. The anion is distorted in this arrangement, but

when crypt ligands (see Section 4.3) are introduced to shield the anion from the alkali metal a regular tetrahedral form is resumed.[117] HMPA solutions of sodium can reduce these complexes even further, so that formally M^{3-} transition metals are formed. However, in these highly shock-sensitive and pyrophoric materials the electrons are almost certainly spread on to the carbonyl ligands and perhaps on to the alkali metals themselves.[118] The extreme reducing power of HMPA/Na solutions stems from the presence of 'sodide' $Na(HMPA)_x^-$ anions. Typical examples of these 'superreduced' species include $Na_3Re(CO)_4$ and $Na_3V(CO)_5$.



(**6**)

4 COORDINATION COMPOUNDS

4.1 Introduction

All alkali metal-containing materials have close contacts from the metal to another atom, or group of atoms, and to this extent all compounds may be termed '*coordination compounds*'. However, the term is usually reserved for those compounds containing a metal coordinated to a neutral ligand, normally (but not necessarily) one containing organic functions. The coordination chemistry of the alkali metals has in the past been viewed as a rather poor area of research. Their unipositive charge and relatively large size gave the metals a rather poor coordinating ability. Consequently, aqueous coordination chemistry often gave only hydrates, with a few examples of salicylates and diketonates, rendered stable by the chelate effect. However, interest and systematic study has blossomed over the last 20 years, largely because of two phenomena. The first was the Nobel prize-winning discovery of the crown ethers and their development into the field of 'molecular recognition', making use of the 'macrocyclic effect' in overcoming the low charge density of the heavier alkali metals. The second is the increased investigation of nonaqueous alkali metal chemistry, triggered largely by the growing importance of lithium in organic synthesis. Few ligands are superior to water in their ability to coordinate to alkali metals, but by excluding H_2O and limiting the supply of available Lewis base donor molecules, a rich structural chemistry has developed, challenging that of the transition metals in its diversity.

4.2 General Principles

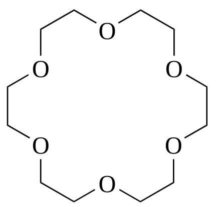
The coordinating ability of the alkali metals generally decreases with charge density in the sequence Li > Na > K > Rb > Cs but 'molecular recognition' arguments may sometimes dictate a different order (see Section 4.3). The predominance of ionic bonding removes the directional constraints often seen in transition metal complexes, and therefore geometries vary widely, depending upon the minimization of interligand repulsions and the maximization of contacts from metal to electronegative center. For the larger metals, extensive polymerization often ensues where it is not hindered by the use of chelating ligands (most notably in the case of crowns and crypts) or very bulky ligands. However, in some cases this tendency to polymerize may be limited by judicious choice of appropriate ligands and synthetic route. The smallness of lithium in comparison to most anions makes this tendency to limited oligomerization most prevalent for that metal (exemplified in the hexameric, molecular nature of $(n\text{BuLi})_6$, cf. $(n\text{BuNa})_\infty$; *see* ***Alkali Metals: Organometallic Chemistry***). Molecular aggregates containing up to 20 lithium cations have been prepared,[119] but dimers are most common, and solid-state monomers are comparatively rare in the absence of highly chelating ligands.[120]

Coordination numbers are so dependent on ligand geometry that the concept of 'preferred' coordination number is of limited use. For example, lithium may be said to prefer 4 coordination, but examples of 1 to 12 coordination are known. Low formal coordination numbers are often accompanied by secondary interactions with other sources of electron density, such as C–H bonds and arene π-systems. There are even examples of C–H activation caused by a low-coordinate sodium cation.[121] Of course, there is a trend towards higher preferred coordination for the heavier group members (6 for Na, K; 8 for Rb, Cs).

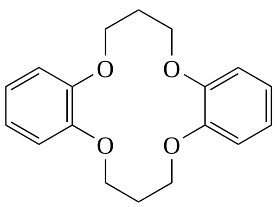
4.3 Macrocyclic Complexes

The serendipitous discovery by Pedersen of the 'crown' ether ligands[122] sparked the development of what is now a systematically and intensively investigated, and well-reviewed,[123,124] field. The crowns are cyclic polyether molecules containing a variable number of oxygen atoms (commonly 4, 5, or 6) linked by (normally) ethylene (e.g. 18-crown-6, (**7**)) or 1,2-dibenzo bridges (e.g. dibenzo-14-crown-4, (**8**)). These ligands wrap around the metal, and can displace water ligands due to the entropically dominated 'macrocyclic effect'. The resultant 'organic sheath' around the cation confers solubility in organic solvents which leads to uses in phase transfer catalysis. The coordination of the cation by the crown weakens its interaction with the anion, sometimes to the point of total separation. The substantially increased nucleophilicity of the anion then leads to much more rapid reaction (the 'naked anion effect'). The discovery of the crown ethers also sparked the development of research into

'molecular recognition', since the crown ether 'host' could 'recognize' specific alkali metal (and other) cation 'guests' due to the fixed size of the macrocyclic cavity. The different ionic radii of the M^+ ions induced the selective complexation effects that form the basis of the use of crowns in cation separation, and recently in ion-specific measurement devices.[125] The crown ethers, tribanzo-21-crown-7 and tetrabenzo-24-crown-8, are found to exhibit modest selectivity for Rb^+ and Cs^+ over other alkali metal ion, respectively.[126,127]

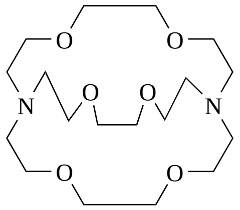


(**7**)



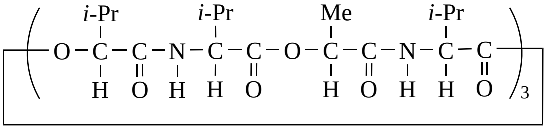
(**8**)

In a crown complex, the metal generally sits slightly above an approximate plane formed by the oxygen donor atoms, with further weak coordinations to water molecules and/or the anion. In some cases a 2:1 crown:metal ratio is preferred, resulting in a sandwich structure. Total encapsulation of the metal was more closely achieved with the synthesis of the cryptands,[128] which are simply bicyclic crowns, rendered so by the introduction of tertiary amine bridgeheads (e.g. 2,2,2-crypt, (**9**)). This leads to a much more strict and inflexible control of macrocyclic cavity size as well as greater encapsulation. Total ion separation is common. Selectivity between K^+ and Na^+ can be as great as 10^5:1. It is noted that the large-size cryptands such as 3,3,2-crypt and 3,3,3-crypt do not show generally better complexation and selectivity for two large cations, Rb^+ and Cs^+, than for the other cations of alkali metals. The poor complexation and low selectivity for these cations are mainly due to the large cavity radius and high flexibility of these cryptands.[129]



(**9**)

This Na^+/K^+ selectivity is of paramount importance since many physiological functions depend upon its maintenance. The selective transport of K^+ across cell membranes is achieved by the natural antibiotic valinomycin (**10**), which contains a crownlike cycle of ether oxygens, but also a number of amide linkages. The cycle would seem too large to bind K^+ as effectively as valinomycin is known to do, but Nature is ingenious: the amide units engage in reversible, intramolecular hydrogen bonding to 'sew-up' the cycle in a 'tennis-ball seam' arrangement, having the combined effects of making the cavity smaller, making it three-dimensional (cryptand-like) and presenting the hydrophobic isopropyl groups to the outside of the molecule and so allowing good transport through lipids. It is this flexibility which makes valinomycin effective; its avidity and selectivity generated by its three-dimensionality is accompanied by the facile complexation and decomplexation kinetics that are essential for efficient transport. While the cryptands possess the former characteristics, the reliance on inflexible covalent linkages to achieve them make the ion uptake and (especially) release kinetics unsuitable for a transport function. The synthetic answer came with the development of the lariat ethers,[130] which are crown ethers with additional Lewis base donor side-arms that mimic the natural system by giving reversible three-dimensional incarceration of the alkali metal ion upon complexation.



(**10**)

Another class of macrocyclic molecules for binding with alkali metal cations is calix[*n*]arene ($n = 4,6,8$) and its derivatives. They are made up of phenol and methylene units which provide a rigid arrangement of various number of oxygen donor atoms for metal complexation. Some of them are proved to display exceptional selectivity for K^+ and Cs^+.[131] Further details of this developing field will be found in ***Macrocyclic Ligands***.

A new type of macrocyclic complex with the arrangement of Lewis acidic and Lewis basic sites opposite to that encountered in conventional crown ether complexes described above is named inverse crown ethers. They are formed by eight-membered $[MNM'N]_2$ rings (M = Li, Na, K; M′ = Mg, Zn; N = HMDS, TMP) with peroxide or oxide ions occupying the core of the ring. The core atoms are introduced into the cyclic rings by deliberately exposing the reaction mixture to molecular oxygen. Apart from occupying by oxygen atoms or anions, the core atoms can also be placed by other anion species such as arene anions. This type of inverse crowns contains no core oxygen atoms anion.[132]

4.4 Other Complexes

4.4.1 Introduction

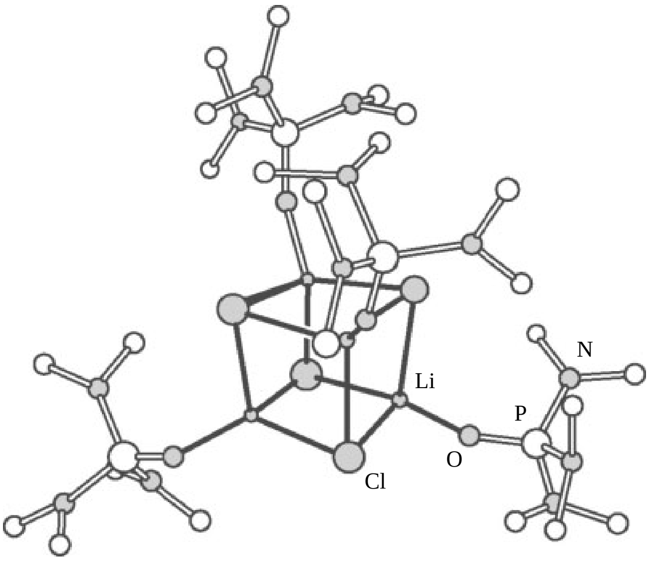
It was said in the preceding section that highly chelating ligands can exclude water from the coordination sphere of

alkali metals. In those cases where highly chelating ligands are not present (i.e. most inorganic cases), hydrates predominate. Inorganic hydrates were dealt with in Section 3, and organic cases will be covered in Section 5, so it remains here to discuss the nonaqueous inorganic coordination chemistry of the alkali metals.

There are broadly two routes to coordination complexes of alkali inorganics. The first is dissolution of the salt in an excess of the coordinating ligand. This is often kinetically unfavorable, since it requires rupture of a very large number of bonds. The second is to form the desired salt in situ in the presence of a stoichiometric amount of donor from a reactive metal source, either a metal hydride, organyl, or the metal itself, for example, equations (15) and (16). The second of these routes has found more general success.[133]

$$C_4H_9Cl + C_4H_9^-M^+ + xL \longrightarrow C_8H_{18} + (M^+Cl^-\cdot L_x)_y \qquad (15)$$

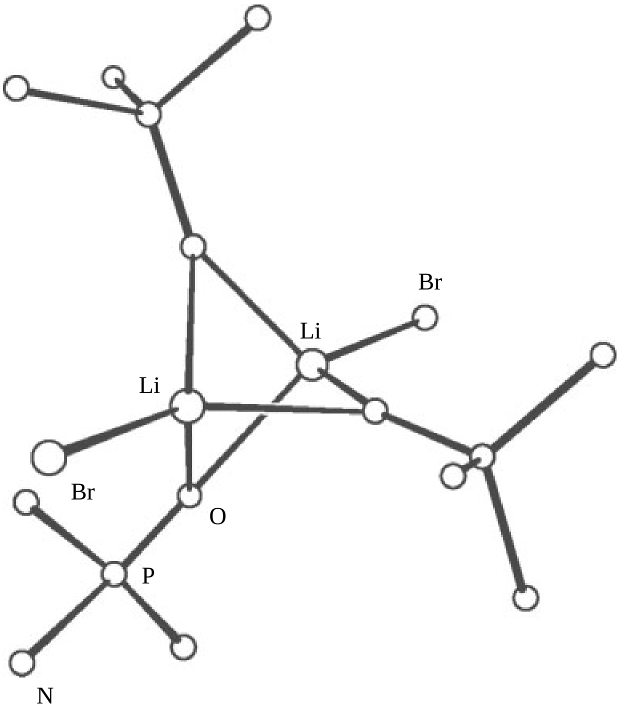
$$NH_4^+NCS^- + M + xL \longrightarrow \frac{1}{2}H_2 + NH_3 + (M^+NCS^-\cdot L_x)_y \qquad (16)$$



(**11**)

4.4.2 *Alkali Halide Complexes*

It has not yet proved possible to isolate a solid complex of lithium fluoride, since its lattice energy is too high to make complex formation thermodynamically feasible. There are a considerable number of complexes of lithium chloride, from the fully ion-separated $Li(en)_2{}^+\cdot Cl^-$, prepared by dissolution of $(Li^+Cl^-)_\infty$ in a vast excess of the bidentate ligand,[134] through contacted monomeric (4-*t*-Bu-py)$_3$LiCl, prepared in a similar manner,[135] to more aggregated species that might be considered as fragments of the LiCl lattice. Interestingly, all of these 'intercepted lattice' species were prepared by the in situ generation and complexation route. Examples are $Li_4Cl_4\cdot(PMDETA)_3$ and $[Li_6Cl_6\cdot(TMEDA)_4]_\infty$. In these cases, multidentate amine donors were employed to limit association. The bulky and very powerfully donating monodentate base HMPA also traps a fragment of the LiCl lattice in the cubanelike complex (LiCl·HMPA)$_4$ (**11**).[136]



(**12**)

The greater size mismatch between Li^+ and Br^- makes aggregation less pronounced in LiBr complexes. Simple ring dimers, for example, (LiBr·TMEDA)$_2$, are common. The complex LiBr·PMDETA is dimeric in the solid state with 5-coordinate lithium, but in benzene solution this rather asymmetric dimer is in equilibrium with a monomeric form.[137] An unusual 'dimeric' LiBr complex which may be considered as two monomers of LiBr connected only by bridging HMPA ligands is also known.[138] This complex, $[LiBr\cdot(HMPA)_{1.5}]_2$ (**12**), was synthesized by the in situ 'ammonium salt route'.[133] A LiBr complex with another, rather weaker, monodentate pyridine donor in the same ligand:salt ratio results in a more aggregated structure, $[(2,6\text{-}Me_2C_5H_3N)_6Li_4Br_4]$, and is a product of dissolution in excess donor.[139] A 4-runged 'step ladder' arrangement results because the internal lithiums are solvated giving a pseudotetrahedral 4-coordination at each point, in contrast to the near-planar ladders obtained in the case of lithium amides and phosphides (see Section 5).

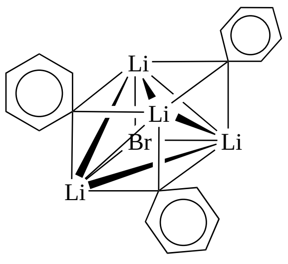
Iodides show still less propensity to aggregate. Ion-separated species (e.g. Li^+ $(Ph_3PO)_4I^-\cdot Ph_3PO$) are common, and dimers are the highest oligomeric unit found as yet. The dimeric (LiI·TMEDA)$_2$ prepared by an in situ route contrasts with the ion-separated $Li^+(TMEDA)_2I^-$ prepared by dissolution.[140]

There are considerably less data for the complexes of the heavier alkali metals. Because the cations are

larger, they are better able to make effective contact with a larger number of anions than an equivalent lithium salt. Oligomeric complexes with the lighter halogen anions are therefore rare. With chelating ligands, some ion-separated complexes are known (e.g. $(Ph_2P(O)CH_2P(O)Ph_2)_3Na^+Br^-\cdot 3H_2O$), and for heavier halogens a dimer $(NaI\cdot PMDETA)_2$ and a polymer $(NaI\cdot diglyme)_\infty$, that contains an unusual bridging mode for the diglyme ligand,[141] have been isolated.

These are some examples of simple complexes, but when the alkali halides interact with other systems, further variety results. Reactions often produce alkali halides which become incorporated into the structure of the desired product. For example, it is sometimes difficult to produce halide-free organolithiums from the standard synthesis (equation 17). So-called '*mixed aggregates*' sometimes result,[142] as shown by the crystallographically characterized phenyllithium–lithium bromide aggregate (**13**) crystallized from ether. Since the presence of alkali halide in a reaction medium can affect structure, it can also affect reactivity, as demonstrated in lithium amide chemistry. Stereoselectivity of enolization has been shown to be dramatically affected by added salts.[143] Mixed aggregates such as the LDA–LiCl structure (**14**) may be responsible.[144] A further 'added salt effect' is seen in the interaction of lithium salts with large biomolecules, for example, [(Gly-Gly-Gly)·LiBr]. Addition of the salt disrupts hydrogen-bonding networks and results in much greater solubility in organic solvents.[145]

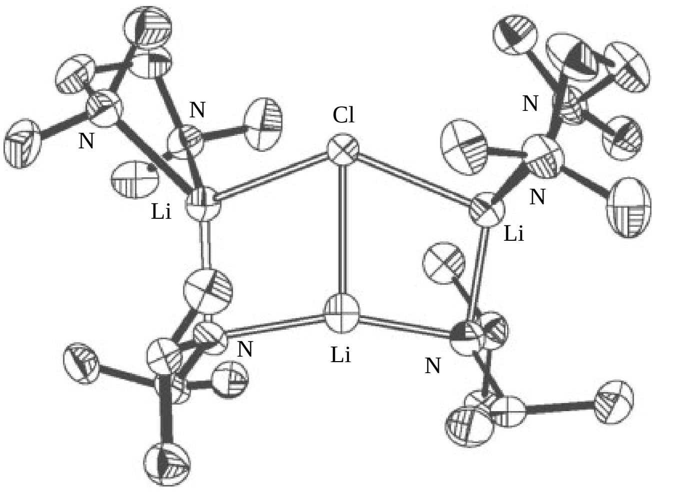
$$RX + 2Li \longrightarrow RLi + LiX \qquad (17)$$



(**13**)

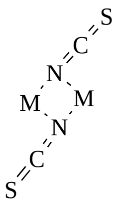
4.4.3 *Complexes of Other Inorganic Anions*

The largest contiguous group of nonmacrocyclic, molecular complexes is provided by the alkali thiocyanates. The HMPA complex of lithium thiocyanate crystallizes as an unusual asymmetric dimer. The sodium complex of the same stoichiometry exists in a more normal symmetric dimer arrangement, while the potassium thiocyanate complex adopts an unprecedented trimeric arrangement.[146] The thiocyanate prefers a terminal, N-bonding mode in all these complexes, although solution evidence exists for a μ^2 N-bridging mode in the complex LiNCS·TMEDA, dimeric in solution. In

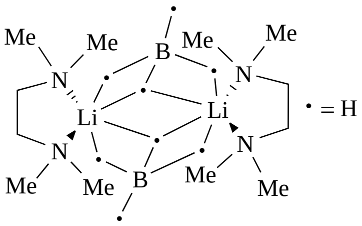


(**14**)

the solid, a polymeric linear structure is obtained, held by weaker Li···S coordinations. A recent paper discussed the first μ^2 N-bridge alkali thiocyanate complex,[147] but even here the bridge is highly asymmetric (see (**15**)) and the compound could be viewed as a loosely held dimer of (TMPDA)LiNCS monomers, where NCS approaches a linear Li···N···C geometry.



(**15**)



(**16**)

Nonmacrocyclic complexes of other alkali pseudohalides are rare indeed, though many other inorganic anions are found in alkali metal complexes. Oxoanion salts, such as $LiNO_3$, are found to form complexes. The binding mode of the anion in such cases would be expected to be highly dependent on the nature of the base employed, and this is found to be the case. In dissolution syntheses, 2-methyl- and 3,5-dimethylpyridine gave polymeric $LiNO_3\cdot(L)_2$ and monomeric $LiNO_3\cdot(L)_3$ complexes, respectively. In the polymer, links were through bridging *bis* η^1 nitrate oxygens, while the monomer contained only one nitrate–Li contact.[148]

Complex hydrides give a variety of interesting structures. For $LiBH_4$ derivatives, a monomeric example crystallized from THF[149] shows three μ B–H–Li bridges and a very short B–Li distance of 2.19 Å (cf. C–Li, 2.36 Å in the analogous $(\mu\text{-H})_3C$ environment of solid $(MeLi)_\infty$). However, when TMEDA is used as the donor in the parent borohydride, a dimeric complex (**16**) results, containing four μ^2 and two μ^3 B–H–Li contacts.[150] A tetrameric complex with μ^4

B–H(Na)$_3$ bonds was obtained from a diethyl ether solution of $NaBHMe_3$. This could also be considered as a lattice fragment of sodium hydride where each metal is coordinated by one Lewis base (Et_2O), and each hydride coordinates one Lewis acid (Me_3B).[151]

This list of examples could contain complexes obtained from a very wide variety of alkali metal compounds where lattice energy considerations make complex formation thermodynamically favorable. The in situ preparative routes even make trapping of kinetic, as opposed to thermodynamic, products feasible. Furthermore, complexation can stabilize a compound unknown in the uncomplexed state. (For example, it was stated in Section 3.2.3 that the heavier alkali metals favor higher catenation in sulfides. Consequently, Li_2S_2 is the most highly catenated parent lithium sulfide known, but the complex $Li_2S_6{\cdot}(TMEDA)_2$ is preparable by a number of routes.[152]) While there are many such complexes not covered here, and doubtless many more to be discovered, no further major structural or bonding trends in this section remain to be discussed at this still comparatively early stage in the development of alkali metal coordination chemistry.

5 METAL-ORGANICS

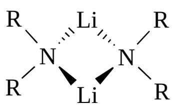
Those compounds with metal–carbon bonds that fit the strict definition of the term 'organometallic' deservedly have their own article in this encyclopedia (*see* ***Alkali Metals: Organometallic Chemistry***), but a large and important class of compounds exists that contain organic groups bound to noncarbon central anions that give the compounds a 'molecular' character distinct from the latticelike behavior of most of the inorganic salts discussed previously. This class, which for the purist may be described as 'metal-organics' rather than organometallics, is briefly discussed here.

5.1 Alkali Metal Organoamides[153,154]

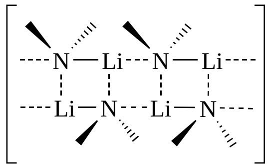
5.1.1 Amidolithiums

The term 'amidolithium' is the unambiguous name for the compounds RR′NLi (R, R′ = alkyl, aryl, silyl, etc.) more often termed '*lithium amides*'. They derive their importance from the near-ubiquity of their bulkier members lithium diisopropylamide (LDA), lithium tetramethylpiperidide (LTMP), and lithium hexamethyldisilazide (LHMDS) in organic synthesis.[6] Using such powerful but nonnucleophilic bases, many useful reactions may be performed, notably the enolization of ketones and esters, which can proceed both regio- and stereoselectively under kinetic control at low temperatures.[155]

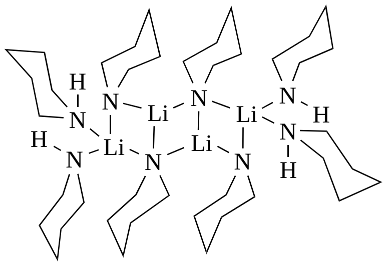
Amidolithiums have the same ionic bonds and tendencies to aggregation as other lithium salts. The primary unit is normally the planar ring dimer $(LiNRR')_2$. Groups R and R′ project orthogonally from the Li_2N_2 ring plane (**17**), thus preventing vertical association. However, when the R groups are small and restricted, lateral association (laddering, (**18**)) of rings results.[153,154] Polymerization in this way can lead to amorphous materials, as for piperididolithium, $(C_5H_{10}NLi)_\infty$, but a soluble, oligomeric precursor (**19**) to infinite laddering has been isolated in this case.[156] Lithiation of the terminal piperidine ligands would result in completion of the ladder structure. A bend is discernible in this ladder structure of (**19**), which in hexamethyleneiminolithium (**20**) has increased so that both ends of the ladder meet in a six-membered cycle.[153] The original Li_2N_2 dimers may still be discerned as being connected by the shortest Li–N bond lengths.



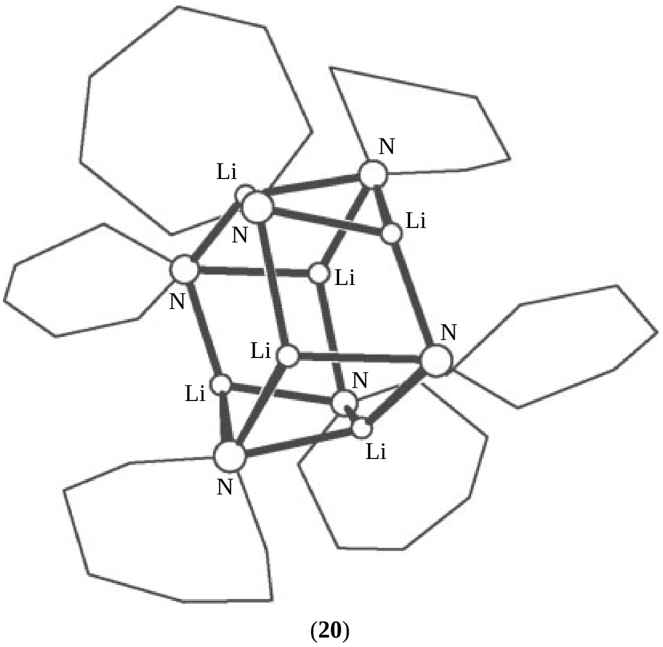
(**17**)



(**18**)



(**19**)



(**20**)

When R and R′ are large and/or floppy, this laddering is less favorable. In the exceptionally bulky case of $[LiN(SiMe_3)(2,6\text{-}i\text{-}Pr_2C_6H_3)]_2$, a simple dimer is most stable,[157] but normally ring size increases in order to distance the N^- centers from each other and symmetrize charge distribution around Li. Thus, LTMP forms a cyclic tetramer, virtually linear at lithium, while LHMDS forms a trimer.[153] LDA exists in nondonating solution as cyclic oligomers and normally precipitates as an amorphous polymer, but crystallizes from hexane/TMEDA as a polymeric helix.[158]

The effect of solvation by Lewis base donor solvents is to reduce this complexity. THF, the most widely used solvent for these bases, forms bis-solvated dimeric complexes with most amidolithiums, since this smallest Li_2N_2 ring provides maximum room for the additional donor molecules. Chelating donors may even produce monomers, but ion separation is found in the solid state only when the anion is stabilized by electron-accepting heteroatoms.[159]

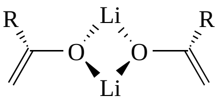
5.1.2 Amides of the Other Alkali Metals

The longer bond lengths of the heavier alkali amides remove the constringent aggregation patterns of lithium chemistry.[154] Variety abounds, and too few data exist to draw convincing generalizations about uncomplexed amide geometries. Above it was noted that LiHMDS was trimeric in the solid state; NaHMDS is an infinite chain polymer, but KHMDS is a dimer.[160] Other ‘rule’ violations include the stacked amide structures of $(Me_2NNa)_{10}\cdot(TMEDA)_4$ and $(Me_2NNa)_{12}\cdot(TMEDA)_4$.[161] However, in these and most other known structures, the M_2N_2 subunit dominates in both complexed and uncomplexed amides.

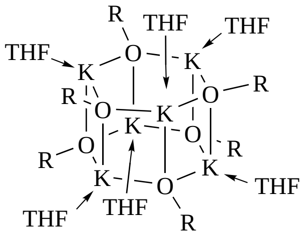
The heavier alkali amides have yet to find widespread use in synthesis owing to the inferior selectivity imparted by their greater reactivity. However, in situ mixtures of heavy alkali alkoxides and lithium amides are finding increasing use as very strong bases.[6,155] The nature of the reactive species is as yet unclear.

5.2 Alkali Metal Enolates

These form a class of compounds which has received much study because of their part in the important C–C bond-forming aldol reaction.[162] The primary structural units are again rings but here association is vertical (stacking) rather than lateral, since the organic groups can align themselves in the same plane (approximately) as the $(LiO)_x$ rings (see (**21**)). The uncomplexed lithium enolate of pinacolone is a stack of two trimers but shrinks to a stack of two dimers when solvated by THF. The sodium enolate of pinacolone crystallizes with one unenolized ketone per metal; therefore it also forms a four-metal stack of two bis-solvated dimers. In contrast, the THF complex of potassium pinacolonate (**22**) can accommodate donor molecules while maintaining the higher aggregation



(**21**)



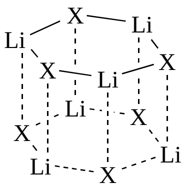
(**22**) R = *t*-BuC(=CH_2)−

state due to the longer K–O bonds.[163] Similar aggregated species have been observed in solution.[162]

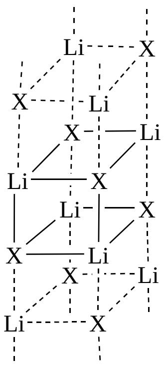
Mixed-metal enolate has also been found. The core of the lithium sodium enolate of pinacolone forms an ‘open stack’ structure in which two edges of the face-sharing cubes are absent.[164]

5.3 Others

Of the vast plethora of alkali-organic structures,[61,165] a few groups deserve special mention, even if they have yet to find the widespread synthetic significance of the above two classes.

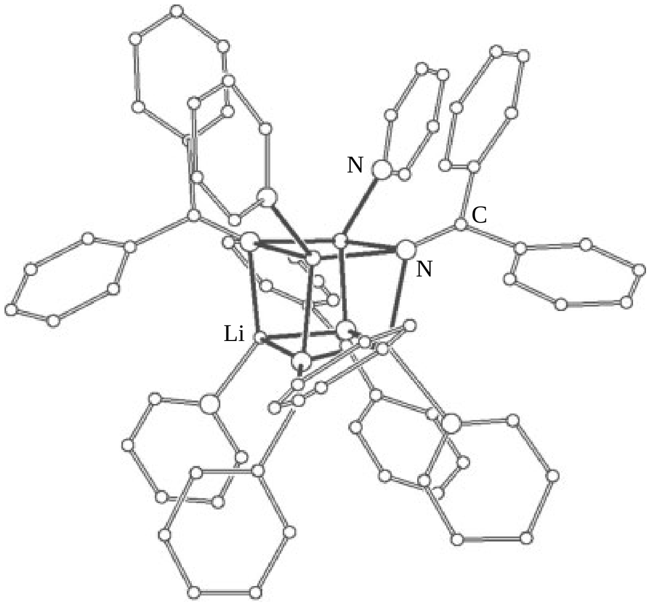


(**23**)



(**24**)

The imidoalkalis, RR′C=NM, are important because it was in the attempt to explain their structures that the widely applicable stacking principle was developed.[153,154] The uncomplexed lithium cases, for example, LiN=C(*t*-Bu)$_2$, form hexameric structures, that is, double stacks of trimers (**23**). Further stacking is precluded by the bulky R groups. If both of these are flat, for example, Ph, infinite stacking (**24**) results in precipitation of amorphous powders. One such material, $(LiN{=}CPh_2)_\infty$, can be broken down by pyridine to a double stack of solvated dimers (**25**). For bulky donors (e.g. HMPA) and imines, only the simple dimer can form, for example, $(t\text{-}Bu_2C{=}NLi\cdot HMPA)_2$. No uncomplexed heavier imidoalkali has yet been prepared crystalline, except as a constituent of mixed-metal species $Li_4Na_2(N{=}CRR')_6$. These have the same stoichiometry as the double-stacked trimers in which each lithium attains three coordination, but the structure



(**25**)

changes to a triple stack of dimers with the introduction of sodium. The smaller ring size gives more room for the ligands to stack, while giving the Na^+ ions the opportunity of four coordination in the center of the triple stack.[154]

Even larger stacks have been observed with the sterically undemanding acetylide ligands in $(t\text{-BuC}{\equiv}\text{CLi})_{12}\cdot(\text{THF})_4$. These aggregation tendencies are also apparent in simple alkoxides, for example, NaO-*t*-Bu exists as a mixture of nonameric and hexameric aggregates in the solid state.[166] Alkoxides such as this are often used in syntheses of high nuclearity mixed-metal clusters.[167] Lithium alkoxides have a wide range of applications such as precursor materials for chemical vapor deposition, ceramics and sol-gel processes, and as reagents in organic synthesis. The structure of unsolvated lithium *tert*-butoxide has only been confirmed as hexamer in 2002.[168] However, the unusual octameric structure has also been revealed recently. It has sections resembling both a cubane and a cyclic hexamer.[169] It was found that both hexamer and octamer coexist in the solution of lithium tert-butoxide. For the heavier alkali metal alkoxides, they adopt various forms of aggregates such as Cs(*o*-2,6-*i*-PrC_6H_3) in which the two-dimensional infinite-sheet structure is uncommon.[170] For the heterometallic alkoxides, mixed lithium-heavier alkali metal alkoxides are found to be highly aggregated cage structures, for example, $[(t\text{-BuO})_8Li_4M_4]$ contains a sixteen-vertex $O_8Li_4M_4$ cage structure comprising of one ${M^+}_4$ plane and two $(O_4Li_2)^{2-}$ dianions.[171]

Phosphides $RR'P^-M^+$ are found to follow laddering principles in common with the amides,[172] while thiolates RS^-M^+ give more variety, and depart from the behavior of their lighter congeners. Crystalline one-dimensional chains, stepped ladders[173] (a polymeric equivalent of the monosolvated double stack of dimers) and even high nuclearity clusters are found. In $Li_{14}(SCH_2Ph)_{12}S(TMEDA)$, the cluster forms around a central S^{2-} ion.[174]

Bonding to anions centered on the heavier p-block elements tends to give either polymers or highly solvated monomers or dimers. The nature of bonding between organotin- and lead anions and alkali metals has recently come under study. These bonds are found to be both weak and predominantly ionic.[175]

Most of the above relates to anions with one center of charge. Structural and chemical diversity takes on a further dimension with the alkali complexes of multiply centered organic anions such as carboxylates (the lithium salts are important as automotive greases), diketonates, sulfonates, and so on.[61,165] One such complex was recently shown to be the first example of a lithium amide containing water in its coordination sphere.[176] Study of others has shown how the coordination chemistry of the metal can profoundly affect the anion, causing rearrangements and extrusions.[121,177] The breadth and speed of current developments means that events will soon overtake this brief account.

1 INTRODUCTION

Organolithium compounds have been more widely used than compounds of the heavier alkali metals. Smith has published an extensive review that focuses on the organometallic chemistry of sodium, potassium, rubidium, and cesium.[1] An important textbook that covers the general aspects of organoalkali metal chemistry was written by Elschenbroich and Salzer.[2] These publications, along with this article in the first edition of this encyclopedia,[3] were used as foundational sources for this overview of the organometallic chemistry of the alkali metals.

Organolithium complexes, like the organomagnesium Grignard reagents, are important reactants in organic synthesis (*see* ***Beryllium & Magnesium: Organometallic Chemistry***). The similarity in structure, bonding, and reactivity of organolithium and -magnesium compounds exemplifies the common chemistry exhibited by representative elements having a diagonal placement within the periodic table (*see* ***Periodic Table: Historical Aspects*** and ***Periodic Table: Trends in the Properties of the Elements***).

Additional aspects of the chemistry of lithium that have facilitated research are (1) the ability to acquire lithium NMR data, and (2) the possibility of performing high-level theoretical calculations of organolithium compounds (*see* ***Molecular Orbital Theory***). Lithium exists naturally as two isotopes, ^{6}Li (7.4% natural abundance) having a nuclear spin of 1, and ^{7}Li (92.6% natural abundance) having a nuclear spin of 3/2, both of which are NMR active. Organolithium compounds enriched in ^{6}Li have also been prepared and studied by NMR. Lithium NMR data are used to determine structural and bonding information about organolithium compounds, and variable-temperature NMR studies are specifically useful in elucidating dynamic exchange processes that occur with these molecules (*see* ***Stability Constants & their Determination***). Lithium chemical shift values are used to distinguish contact ion paring from solvent-separated ion paring and also the degree of covalency in Li–C bonds (increased covalency shifts lithium resonances to lower field). The magnitude of $J_{\text{Li–C}}$ coupling is used as a more direct measure of the degree of Li–C bond covalency. UV-Visible spectrophotometry also provides important information about ion paring in solutions of organolithium compounds.

Theoretical calculations of organolithium species have received considerable attention. The low atomic number of lithium is suitable for the most sophisticated molecular orbital methods. Although much debate exists over the degree of covalency within lithium – carbon-bonding interactions, the presence of some covalent character in Li–C bonds of alkyllithium compounds is widely accepted.

The bonding interactions within organoalkali metal complexes of the heavier alkali metals are generally considered to be strongly electrostatic or ionic in nature. This is supported by a large collection of evidence, consisting primarily of solution NMR data, single-crystal X-ray analyses, and gas-phase computational studies.

2 GENERAL ASPECTS OF THE CHEMISTRY OF ORGANOALKALI METAL COMPOUNDS

2.1 Synthesis

Organoalkali metal compounds must be synthesized and handled under inert atmosphere conditions because of their high sensitivity to air and moisture. Many of the organolithium compounds are soluble in hydrocarbons, but organometallic compounds of the heavier group 1 metals generally require more polar solvents. In general, a synthetic route is chosen based on the typical yield, expense of reagents, and the relative solubilities of all products formed in the reaction. The following are examples of general methods for synthesizing organoalkali metal compounds.

2.1.1 Direct Synthesis

The direct reaction of an organic halide with an alkali metal is one of the most important methods for synthesizing organolithium compounds. The reaction of two equivalents of the alkali metal with one equivalent of the organohalide produces the organoalkali metal compound and metal halide

(equation 1).

$$2M + RX \longrightarrow RM + MX \qquad (1)$$

This route is useful for the synthesis of organolithium compounds, but is often hindered with the more reactive and heavier alkali metals because of the tendency toward Wurtz coupling (equation 2).

$$RM + RX \longrightarrow R\text{–}R + MX \qquad (2)$$

The formation of the metal halide as a by-product limits the use of this method for the synthesis of reagents intended for further reactions. The relative solubilities of the organoalkali metal compounds and the metal halides formed in these reactions do not generally allow for easy separations.

The assay of organoalkali metal reagent solutions can be performed using hydrolysis (equation 3), followed by simple acid–base titration (equation 4).

$$RM + H_2O \longrightarrow RH + MOH \qquad (3)$$

$$MOH + HCl \longrightarrow MCl + H_2O \qquad (4)$$

2.1.2 Metallation

There are three general types of metallation reactions (metal–hydrogen exchange) that are commonly used to synthesize organoalkali metal compounds from organic molecules: Direct reaction with an alkali metal, reaction with an alkali metal hydride, or reaction with an organo- or amido-alkali metal. Since these reactions involve acid/base equilibria, they are dependent on both the C–H acidity of the organic molecule and the basicity of the alkali metal source.

The direct reaction of an organic molecule with an alkali metal produces an organoalkali metal compound and hydrogen gas (equation 5).

$$2M + 2RH \longrightarrow 2RM + H_2 \qquad (5)$$

This synthetic route can be useful for organic molecules with exceptionally acidic protons, such as acetylenes or cyclopentadienes. These reactions often require the alkali metal to be present as very small particles. Sodium 'sand' can be formed by refluxing in THF with minor agitation to break up the sodium into tiny particles. Reactions with potassium may require a 'mirror' that can be formed by dissolving potassium metal in liquid ammonia followed by evaporation of the ammonia from the reaction vessel. Ultrasound has also been used to aid in the formation of organolithium compounds from lithium metal.[4–7]

Like the reaction shown in equation (5), the reaction of an alkali metal hydride with an organic molecule also produces an organoalkali metal compound and hydrogen gas (equation 6).

$$2M + 2RH \longrightarrow 2RM + H_2 \qquad (6)$$

Relatively acidic organic molecules will react directly with alkali metal hydrides. Crown ethers, strong amines, or ether donors are often used in reactions with the heavier alkali metal hydrides to give more soluble organometallic products. This synthetic route has become increasingly less common due to the generally low solubility of organoalkali metal products and marginal purity of alkali metal hydrides.

The reaction of an organo- or amido-alkali metal reagent with an acidic organic molecule produces an organoalkali metal compound and the amine or organic compound (equation 7).

$$RM + R'H \longrightarrow R'M + RH \qquad (7)$$

Methyl lithium and butyl lithium are widely used for the synthesis of other organolithium compounds. For example, lithium cyclopentadienides are generally prepared by the reaction of the cyclopentadiene with butyl lithium. In contrast, the amido-alkali metal compounds are becoming increasingly important in the synthesis of organoalkali metal compounds with the heavier alkali metals. For example, 1,2,4-tris(trimethylsilyl)-1,3-cyclopentadiene reacts with potassium bis(trimethylsilyl)amide to form potassium 1,2,4-tris(trimethylsilyl)cyclopentadienide.[8]

2.1.3 Transmetallation

Organoalkali metal compounds can be formed from the reaction of an organometallic compound with an alkali metal (equation 8) or organoalkali metal compound (equation 9). This reaction generally works for transferring an organic ligand from a less electropositive metal to a more electropositive metal. Typically, organometallic compounds of Bi, Cd, Hg, Pb, Sb, Si, Sb, and Zn are used for this type of transfer to an alkali metal. This can be useful for preparing organoalkali metal compounds when working with organic ligands that are highly functionalized. It is also effective when halide contamination of the organoalkali metal compounds would be a problem for subsequent reactions.

$$M + RM' \longrightarrow RM + M' \qquad (8)$$

$$RM + R'M' \longrightarrow R'M + RM' \qquad (9)$$

By reacting directly with the alkali metal, organomercury compounds are commonly used to synthesize organoalkali metal compounds of the heavier alkali metals. This route has been used to make various alkyl compounds, such as butyl[9] and trimethylsilylmethyl[10] derivatives (equation 10).

$$HgR_2 + 2M \longrightarrow 2MR + Hg \qquad (10)$$

Since organolithium compounds are often more readily available, transmetallation can also be useful for preparing an organometallic compound of the heavier group 1 metals from

an organolithium compound. In fact, the reaction of a heavier alkali metal alkoxide with an organolithium compound is the most widely used method for preparing organoalkali metal compounds of the heavier alkali metals (equation 11). For example, 1,3-bis(trimethylsilyl)allyl potassium was prepared by the reaction of 1,3-bis(trimethylsilyl)allyl lithium with potassium *t*-butoxide (equation 12).[11] This reaction was effected in hexanes with additional TMEDA. The allyl potassium compound is insoluble and can be isolated by filtration in high yield. In general, these reactions are performed in hydrocarbon solvents with some ether present. The alkoxide is generally chosen for easy separation following the reaction. Organostannanes can be reacted with phenyllithium to give tetraphenyl tin and a different organolithium compound[12] (equations 13 and 14).

$$\mathrm{LiR + MOR' \longrightarrow MR + LiOR'} \quad (\mathrm{M = Na, K, Rb, Cs}) \qquad (11)$$

$$\mathrm{Li[C_3H_3(SiMe_3)_2] + KOC(CH_3)_3 \longrightarrow K[C_3H_3(SiMe_3)_2] + LiOC(CH_3)_3} \qquad (12)$$

$$\mathrm{4PhLi + (H_2C{=}CH)_4Sn \longrightarrow Ph_4Sn + 4H_2C{=}CHLi} \qquad (13)$$

$$\mathrm{Ph_3SnCH_2AsPh_2 + PhLi \longrightarrow Ph_4SnCH_2AsPh_2 + Ph_2AsCH_2Li} \qquad (14)$$

2.1.4 *Carbometallation*

The electropositive nature of alkali metals allows for insertions into alkali metal–carbon bonds. Thus, the reaction of an organoalkali metal reagent with an unsaturated organic molecule produces a more complex organoalkali metal compound. In particular, organolithium compounds will react in this way with conjugated dienes, even under mild conditions. For example, 1,3-butadiene reacts with *tert*-butyl lithium to give an allyl lithium compound[3] (equation 15).

$$\mathrm{(CH_3)_3CLi + H_2C{=}CH{-}CH{=}CH_2 \longrightarrow (\mathit{Z}\ and\ \mathit{E})\text{-}(CH_3)_3C{-}CH_2CH{=}CHCH_2Li} \qquad (15)$$

2.1.5 *Thermolysis and Thermal Rearrangements*

Organolithium compounds can be converted to other organolithium compounds under high temperatures. For example, dilithiomethane is produced from methyl lithium when heated between 223 and 226 °C.[13]

2.2 Structure

The structures of organolithium compounds have been extensively studied, and there are a number of reviews available.[14–16] A recent review of the structures of organoalkali metal compounds of the heavier group 1 metals has also been made available.[1] Specific details of the structures formed by various types of organoalkali metal compounds both in solution and in the solid state will be discussed in following sections.

2.3 Reactivity

In general, the reactivity of the alkali metals and the reactivity of the organometallic compounds of these metals increase as we go down the group or column. Organoalkali metal compounds are similar to, but more reactive than Grignard reagents. For example, the carbanions of organoalkali metal compounds have been widely used as nucleophiles in reactions with various 'electrophilic' organic compounds. Organolithium compounds have been particularly useful in this way for the formation of new carbon–carbon bonds. Organoalkali metal compounds are both air- and moisture-sensitive and are sometimes pyrophoric. In addition, organoalkali metal compounds will react as Brønsted bases with protic reagents.

There are a couple of other general features of the reactivity of organoalkali metal compounds worth mentioning. (1) Most organoalkali metal compounds form complexes with crown ethers, provided the 'crown' is an appropriate size for the particular alkali metal (*see* ***Alkali Metals: Inorganic Chemistry***). (2) In general, the thermal stability of organoalkali metal compounds decreases as their size and reactivity increases. Both α- and β-eliminations are usual pathways of thermal decomposition for group 1 organometallic compounds.

3 ALKYL, ALKENYL, ALKYNYL, AND ARYL COMPOUNDS

3.1 Alkylalkali Metal Compounds

In recent years, considerable attention has been given to organoalkali metal compounds containing bulky silicon-substituted alkyl groups. The use of these ligands has provided compounds that differ dramatically in structure and reactivity from compounds with smaller alkyl groups. Organometallic compounds with bulky silicon-substituted alkyl groups have been reviewed.[17]

3.1.1 *Synthesis*

Most alkyllithium compounds are prepared by the direct synthesis method shown in equation (1). For example, lithium metal reacts with bromomethane in ether to form methyl lithium and lithium bromide (equation 16).[2]

$$\mathrm{2Li + CH_3Br \longrightarrow LiCH_3 + LiBr} \qquad (16)$$

The heavier alkylalkali metal compounds can be prepared from a transmetallation reaction with an alkyllithium

compound. For example, methyl potassium is formed from the reaction of methyl lithium with potassium *t*-butoxide (equation 17).[18]

$$\text{MeLi} + t\text{BuOK} \longrightarrow \text{MeK} + t\text{BuOLi} \qquad (17)$$

Organoalkali metal compounds of the heavier alkali metals with more highly substituted alkyl groups can be formed from the reaction of an alkane with the appropriate methyl derivative (MMe; M = Na,[19] K,[20] Rb,[21] and Cs[21]) (equation 18).

$$\text{RH} + \text{MMe} \longrightarrow \text{RM} + \text{MeH}(\text{R} = \text{C(SiMe}_3)_3) \qquad (18)$$

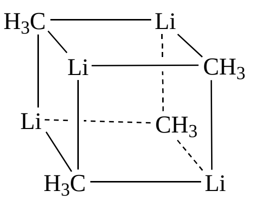
Alkylalkali metal compounds are also commonly formed from reactions with organomercury compounds. Solvent-free $LiC(SiMe_3)_3$ has been prepared by the reaction of an organomercuryhalide with butyl lithium in hexanes (equation 19).[17]

$$2\text{BuLi} + \text{BrHgR} \longrightarrow \text{LiR} + \text{LiBr} + \text{HgBu}_2 \qquad (\text{R} = \text{C(SiMe}_3)_3) \ (19)$$

3.1.2 *Structures*

In solutions, the extent of the oligomerization or the degree of association of alkylalkali metal compounds is dependent on several factors: the size of the metal, the steric bulk of the alkyl substituent, the concentration of the compound, the identity of the solvent, the presence of additional bases, and the temperature of the solution. More information is available on the structures of organolithium compounds than the heavier alkali metal compounds since they are widely used as reagents in organic synthesis and because of the availability of ^{6}Li NMR data.

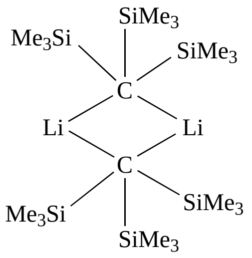
In the solid state[22,23] and in the gas phase,[24–26] methyl lithium exists as a tetramer. The tetramer of methyllithium in the solid state can be viewed as a distorted cube of carbon and lithium atoms (Li–C, 2.36 Å; Li···Li, 2.68 Å) (**1**).



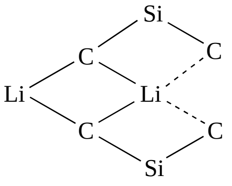
(**1**)

Structurally similar tetramers are maintained in solutions with electronic donors (THF or TMEDA).[27,28] For example, the same core structure exists for the methyllithium TMEDA adduct. Ab initio methods have been used to study the aggregation of various methyl lithium oligomers in the presence of various donor ligands.[29] The heavier alkali metal (M = K, Rb, Cs) methyl compounds have more ionic bonding and crystallize in a nickel arsenide-type lattice.[30] *Tert*-butyllithium also exists as a tetramer in the gas phase[26] and in hexanes or benzene.[31,32] Aggregation energies and conformer preferences have been investigated for *tert*-butyllithium using density functional theory.[33]

The synthesis, structures, and reactions of silicon-substituted alkyl derivatives of metals from groups 1, 2, and 3 have been recently reviewed.[17] A diverse range of structures has been discovered with the alkali metals. More recently, some additional structures and an important discussion of structural trends observed among the silicon-substituted alkyl derivatives of the alkali metals have also been published.[34] Tris(trimethylsilyl)methyl lithium forms a solvent-free dimer, as well as several 'ate' complexes in the presence of bases (THF or TMEDA). In the alkyl-bridged dimer of tris(trimethylsilyl)methyl lithium (**2**), there are interactions between the C–H bonds of the silyl ligand and the lithium atoms (**3**) (Li to C distances of 254.1(7) and 246.6(6) pm).[17]



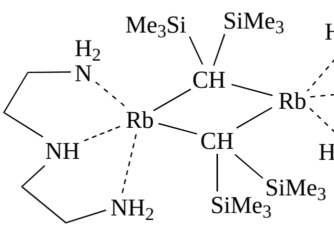
(**2**)



(**3**)

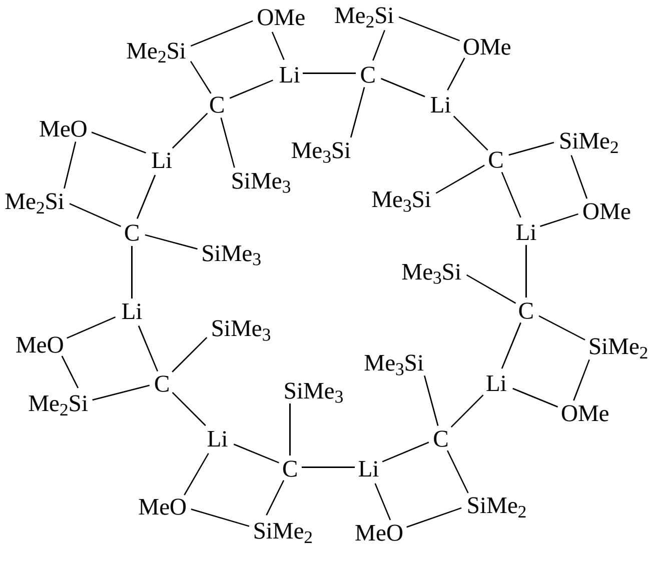
Silicon-substituted alkyl derivatives of the heavier alkali metals are increasingly being used in the synthesis of other organometallic compounds because of their solubility. Perhaps, it is this enhanced solubility that has allowed for the structural characterization of many of these compounds in recent years. Tris(trimethylsilyl)methyl potassium and rubidium both crystallize as solvent-free compounds from ether solution. The potassium derivative consists of infinite, linear chains of alternating potassium cations and alkyl anions (average K–C = 309.7(11) pm).[17,20] There are weak interactions between the chains, potassium to six methyl groups (three on each side), allowing the potassium to be eight-coordinate (K···C range from 318.7 to 331.1 pm).[17,20]

The solvent-free bis(trimethylsilyl)methyl sodium and bis(trimethylsilyl)methyl lithium are isostructural and crystallize as polymeric chains of alternating cations and anions.[35,36] The potassium compound also crystallizes as an infinite polymer chain of alternating cations and anions with one thf molecule on each potassium cation.[37] Bis(trimethylsilyl)methyl cesium crystallizes as a polymeric chain with one TMEDA ligand coordinated to each cesium cation.[38] The PMDTA adduct of the rubidium derivative (**4**) crystallizes as an alkyl-bridged dimer (Rb–C–Rb, 104.7(2); Rb–C, 336.1(10), 348.5(8)) with terminal PMDTA ligands.[37]

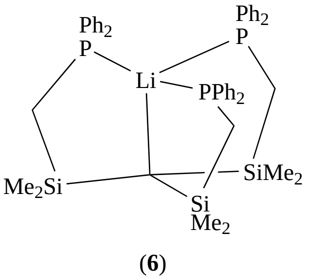


(**4**)

The unusual bis-silyl methyl ligand, $(CH(SiMe_3)(SiMe_2OMe)^-)$, forms a cyclo octamer with lithium (**5**).[39] The bis(trimethylsilyl)dimethylphenylsilylmethyl ligand forms monomeric compounds with lithium and sodium in the presence of additional electron donors (TMEDA, diethyl ether, and THF).[34] In each structure, there are additional interactions between the metal ions and carbons from the phenyl rings. The tris(dimethylphenylsilyl)methyl compounds of sodium, potassium, rubidium, and cesium crystallize in polymeric chains. Each of these compounds also has intra- and intermolecular phenyl-metal cation interactions.[34] The monomeric $[LiC(SiMe_2CH_2PPh_2)_3]$ forms as a base-free compound even in the presence of a large excess of electron donors (such as TMEN) (**6**).[40]



(**5**)



(**6**)

3.1.3 Reactivity

Two exchange processes have been elucidated for 2-methylbutyllithium in solution. A slow intra-oligomer exchange gives inversion of configuration at the C_α bonded to lithium. A more rapid inter-oligomer exchange of Li–C bonds is also observed. Menthyllithium is configurationally rigid to at least 50 °C in hydrocarbon solutions, but only to below 0 °C in ether. Chiral cyclopropylmetal compounds of lithium, sodium, or potassium are configurationally stable as prepared. However, the presence of THF leads to rapid racemization as solvent-separated ion pairs are formed. Mixtures of $(MeLi)_4$ and $(EtLi)_4$ give mixed RLi oligomers via inter-oligomer exchange of Li–R bonds. Carbenoids, such as BuCHBrLi, are configurationally stable at −120 °C.[41]

Alkyllithium reagents can be converted to acylsilanes by reaction of RLi with CO and Me_3SiCl (equation 20).[42]

$$\mathrm{RLi + CO + Me_3SiCl} \xrightarrow[-110\,^\circ\mathrm{C}]{\mathrm{THF/Et_2O/C_5H_{12}}} \mathrm{RC(O)SiMe_3} \qquad (20)$$

3.2 Alkenylalkali Metal Compounds

3.2.1 Synthesis

For synthetic application, the formation of substituted alkenylalkali metal compounds with high regio- and stereoselectivity is desirable. Alkenyl halides react with organolithium reagents by metal-halide exchange to give alkenyllithium compounds. The halides of choice include bromide and iodide; alkenyl chlorides favor α-hydrogen metallation. Low-reaction temperatures permit retention of the stereochemistry of the original alkenyl halide in the alkenyllithium product (equation 21). Vinylsodium and – potassium can be prepared from direct reaction of the metals with vinyl bromide or vinyl chloride respectively.

$$(E)\text{-}\mathrm{RHC{=}CHBr} + 2t\text{-}\mathrm{BuLi} \xrightarrow[-120\,^\circ\mathrm{C}]{\mathrm{THF/Et_2O/C_5H_{12}}} (E)\text{-}\mathrm{RHC{=}CHLi} + t\text{-}\mathrm{BuH} + \mathrm{Me_2C{=}CH_2} \qquad (21)$$

Alkenyllithium compounds can also be prepared by metallation of alkenes, particularly when alkenyl hydrogens are rendered acidic by an α-substituent (equation 22). Transmetallation of alkenyl stannanes with organolithium reagents gives alkenyllithium compounds with retention of alkene stereochemistry (equation 23). Tin–lithium transmetallation has been used to prepare 1,4-dilithio-1,3-butadiene.[43] Monosubstituted alkenyllithium compounds RHC=CHLi, can also be prepared from the corresponding diorganotelluride, RHC=CHTeBu, by reaction with butyllithium in

THF.[44]

$$\mathrm{RHC{=}C(SO_2Ph)H + MeLi \longrightarrow RHC{=}C(Li)(SO_2Ph)} \quad (22)$$

$$(E)\text{-}\mathrm{Me_3SiHC{=}CHSnR_3 + BuLi \xrightarrow{\text{low temp.}} } (E)\text{-}\mathrm{Me_3SiHC{=}CHLi} \quad (23)$$

3.2.2 *Structures and Reactivity*

Vinyllithium is tetrameric in THF solution. Alkenyllithium compounds containing α-hydrogen or – alkyl substituents do not isomerize readily; however, the presence of donor solvents promotes (Z)-to-(E) isomerization. Those compounds containing α-aryl substituents isomerize readily. The configurational stabilities of HDC=C(Li)X, where X is CN or CO_2Me, and RHC=C(Li)Y, where Y is OR′ or Me_3Si, have been investigated.[45,46]

Lithio-enynes of the type (Z)-RHC=C(Li)C≡CHR′ are configurationally stable at temperatures below −120 °C, and the lithio-diene, (Z,Z)-BuHC=C(Li)CHC=CHBu, is configurationally stable at temperatures below −78 °C.[47] X-ray structural determinations of alkenylalkali metal compounds are particularly sparse.

3.3 Alkali Metal Acetylene Compounds

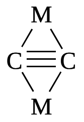
3.3.1 *Synthesis*

The high acidity of the C–H bonds in acetylene compounds allows for the synthesis of alkali metal acetylene compounds by direct reaction with the metals.

3.3.2 *Structures*

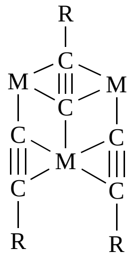
The heavier alkali metal compounds of the formula MC≡C–CH_3 (M = Na, K, Rb, Cs) have been studied by X-ray powder diffraction and are found to be isostructural, crystallizing with a tetragonal unit cells.[48–51] The heavier alkali metals prefer a double π-bridged structure (**7**) rather than a linear σ-bonding structure (**8**). The metal–carbon distances are similar for both carbon atoms in the acetylides, M–C≡C–H and M–C≡C–CH_3. The polymer-sheet structure (**9**) has increasing symmetry in π-bonding between layers with an increase in the size of the metal. Lithium acetylides typically crystallize with more linear structures. For example, the single-crystal X-ray structure of $[(Ph\text{–}C{\equiv}C\text{–}Li)tmpda]_2$ shows a preference for 'end-on' bonding rather than 'side-on' bonding (**10**).[52]

The differences in bonding preferences in lithium acetylides may be confused by the competition from coordinating solvents. In the absence of solvent interactions, as in the crystal structure of Li–C≡C–$SiMe_2$–C_6H_4–OMe, nearly symmetric π-interactions are observed.[53] Computational

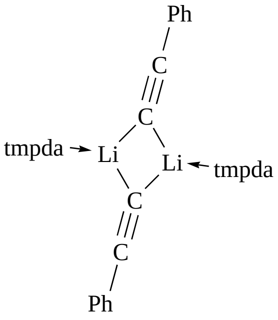


(**7**)

(**8**)



(**9**)



(**10**)

studies suggest that these interactions are weak in alkali metal acetylide compounds (only 0.73 kcal mol^{-1} for Li–C≡C–R), and the strength apparently decreases with increasing size (0.07 kcal mol^{-1} for Cs).[53]

3.4 Arylalkali Metal Compounds

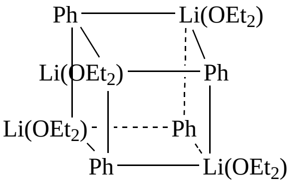
3.4.1 *Synthesis*

Orthometallation of substituted arenes has been reviewed.[54,55] The ortho-directing ability of substituents in (η^6-arene)$Cr(CO)_3$ complexes decreases as F > CONHR > NHCOR > CH_2NR_2 ≈ OMe ≫ CH_2OMe.[56] Heavier alkali metal arenes can be formed from the reaction of phenyl lithium with sodium or potassium alkoxides.

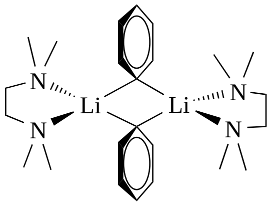
3.4.2 *Structures and Reactivity*

The degree of oligomerization of various aryllithium compounds in the presence of donor species has been determined by NMR (^{13}C and ^{7}Li).[57,58] X-ray structures of $[PhLi{\cdot}OEt_2]_4$ (**11**),[59] $[PhLi{\cdot}TMEDA]_2$ (**12**),[60] and PhLi·PMDTA (**13**)[61] illustrate the diversity of structures of aryllithium compounds containing donor ligands. Recently, the utility of aryllithium compounds in aryl–aryl coupling has been demonstrated to produce a range of unusual substituted biaryls.[62]

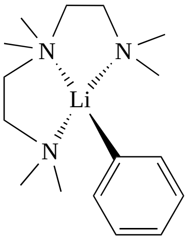
The solvent-free phenyl derivatives of the heavier alkali metals have not been structurally characterized. Phenyl sodium dimers crystallize in the presence of donors such as, PMDTA and TMEDA.[18] Using the bulky mesityl-substituted derivatives, a solvent-free arylsodium compound has been characterized $[Na(C_6H_3Mes_2\text{-}2,6)]_2$.[63]



(**11**)



(**12**)



(**13**)

4 ALLYL, PENTADIENYL, AND BENZYL COMPOUNDS

4.1 Allylalkali Metal Compounds

4.1.1 Synthesis

The direct reaction of allyl halides and alkali metals leads to extensive coupling of the allyl fragments, so other synthetic routes must be used for the preparation of allylalkali metal compounds. The metallation of appropriate alkenes is an effective route to allyl compounds. A wide variety of metalating agents have been used, including lithium amides, alkyllithium reagents, Me_3SiCH_2K, and Me_2SiCH_2Cs. Transmetallation of allylstannanes or -mercury compounds gives convenient routes to halide-free allylalkali metal compounds (equations 24–26).[64] The thermal ring-opening of the cyclopropylithium species can also be used to prepare allyllithium complexes (equation 27).

$$(H_2C{=}CHCH_2)_2Hg + 2M \longrightarrow 2(H_2C{=}CHCH_2)M + Hg \qquad (24)$$

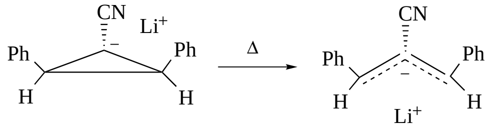
$$M = \text{Li–Cs}$$

$$4(H_2C{=}CHCH_2)Li \xleftarrow[\text{-Sn}]{\text{4Li}} (H_2C{=}CHCH_2)_4Sn\ 4$$

$$\xrightarrow[\text{-}R_4Sn]{\text{4RLi}} (H_2C{=}CHCH_2)Li \qquad (25)$$

$$R'_3SnCH_2CR{=}CH_2 \xrightarrow[\text{-}R'_3SnR'']{\text{MeLi or } Me_3SiCH_2M} [CH_2CRCH_2, M] \qquad (26)$$

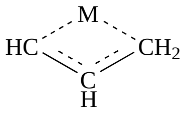
$$M = \text{K or Cs};\ R'' = \text{Me or } CH_2SiMe_3$$



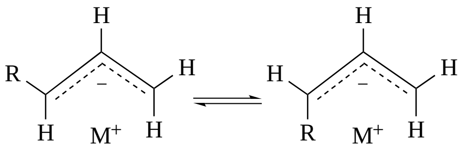
(27)

4.1.2 Structural Studies

The preferred structure of allylalkali metal compounds of lithium through cesium as predicted from ab initio calculations is one having a symmetrical bridging geometry (**14**) with mainly electrostatic bonding between the allyl anion and the metal cation.[65] Allyllithium in ether solution appears to be highly oligomerized, while in THF solution it exists as an unsymmetrical, rapidly equilibrating dimer.[66] However, allylmetal complexes of sodium or potassium have symmetric and presumably monomeric structures in THF solution, like (**14**).[66]



(**14**)



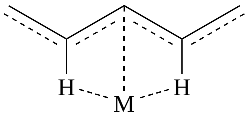
(**15*E***) (**15*Z***)

Allylalkali metal compounds exhibit dynamic isomerizations and bond rotations in solution. In THF solution, allylalkali metal complexes undergo C–C bond rotations with activation energies normally in the range of 45–75 kJ mol^{-1}. 1-Alkylallylalkali metal compounds usually exist as a dynamic mixture of (E) and (Z) isomers (**15**), with a thermodynamic preference for the (Z) configuration. The rates of isomerization of *trans*-neopentylallyl metal complexes in THF solution decreases in the sequence Li > Na > K.[67] Numerous studies of the structures and dynamic properties of allyllithium compounds have been reported.[68–72]

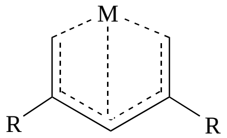
4.2 Pentadienylalkali Metal Compounds

Pentadienyl carbanions are analogous to allyl anions with an extended delocalization of charge. Reaction of 1,3- or 1,4-pentadienes and alkali metals in THF in the presence of a base, such as NMe_3 or TMEDA, affords crystalline pentadienylalkali metal complexes. A contact ion pair structure is predicted for these compounds by theoretical calculations and is consistent with solution structural data obtained by NMR. The pentadienyl anion usually interacts with the cation as an η^3- or η^5-ligand depending on the structural orientation of the backbone carbon atoms of the pentadienyl anion (W-, S-, or U-shaped skeletal structures). A η^3 contact ion pair structure having a ‘W-shaped’ pentadienyl ligand is shown (**16**). 2,4-Disubstituted

pentadienyl complexes favor the η^5 'U-shaped' structure (**17**). This structure has been confirmed by X-ray diffraction for 2,4-dimethylpentadienylpotassium·TMEDA.[73] The potassium ion is coordinated to a chelating TMEDA ligand, and the K–C contact distances to the five pentadienyl skeletal carbon atoms range from 3.152(7) to 3.219(8) Å. In THF solution, 1,3,5-triphenylpentadienyllithium exists in one W-shaped and two S-shaped conformations.



(**16**)



(**17**)

4.3 Benzylalkali Metal Compounds

4.3.1 Synthesis

As with preparing allyl complexes, direct reaction of benzyl halides and alkali metals is not a generally useful route to benzylalkali metal compounds due to R–R coupling. Benzylalkali metal compounds can be prepared by (1) addition of organometallic reagents to arylalkenes, (2) cleavage of benzyl ethers (equation 28), (3) transmetallation (equations 29–31), and (4) metallation of methyl substituted aromatics. α,α-Bis(trimethylsilyl)benzyl potassium can be prepared by metallation with a mixture of butyllithium and potassium 3-methyl-3-pentanolate in THF.[73]

$$\mathrm{PhCR'R''OMe} + 2 \longrightarrow \mathrm{KPhCR'R''^{-}K^{+}} + \mathrm{KOMe} \quad (28)$$

$$\mathrm{ArCH_2SnBu_3} + \mathrm{BuLi}/t\text{-}\mathrm{BuOM} \longrightarrow \mathrm{ArCH_2{}^{-}M^{+}} + \mathrm{Bu_4Sn} \quad (29)$$

$$\mathrm{(PhCH_2)_2Hg} + 2\mathrm{Li}\ 2 \longrightarrow \mathrm{PhCH_2Li} + \mathrm{Hg} \quad (30)$$

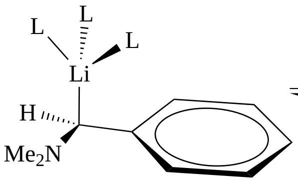
$$\mathrm{PhCH_2Li} + \mathrm{MOR} \longrightarrow \mathrm{PhCH_2M} + \mathrm{LiOR} \quad (31)$$

$$\mathrm{M} = \mathrm{Na\text{–}Cs}$$

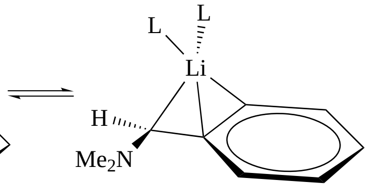
4.3.2 Structural Studies

Benzylalkali metal compounds exist as aggregate structures in most solutions. NMR and UV-visible spectrophotometry are useful techniques for elucidating these solution-phase structures. Benzyllithium is dimeric in benzene solution; the carbanion charge is probably more delocalized in THF solution. NMR studies of a THF solution of α-(dimethylamino)benzyllithium reveals a dynamic equilibrium between the η^1- and η^3-structures (**18**) and (**19**). The monohapto isomer (**18**) is preferred thermodynamically.[74] The effects of various donor ligands on this type of dynamic behavior in solution is continually being studied.[75,76]

The crystal structure of α,α-Bis(trimethylsilyl)benzyl potassium consists of a linear coordination polymer with



(**18**)



(**19**)

alternating benzyl and potassium ions.[73] In this structure, the potassium is primarily η^3-coordinated to the benzyl ligand with interactions to a lesser extent with a neighboring aromatic ring. There are numerous agostic interactions, both between the potassium ions and trimethylsilyl groups and between neighboring chains.

5 CYCLOPENTADIENYL AND RELATED COMPOUNDS

5.1 Synthesis

The relatively strong Brønsted acidity of cyclopentadienes, indenes, and fluorenes, permits the formation of alkali metal compounds of the conjugate bases of these organic molecules by direct reaction with the metal. The effect of substituents on the rate of formation of 9-R-fluorenyllithium compounds in THF solution and on the degree of ion pairing in solutions of these species has been determined.[77–79] Potassium derivatives are commonly prepared by the reaction of the cyclopentadiene with potassium bis(trimethylsilyl)amide.[8] Fluorenyl and indenyl compounds with the heavier alkali metals, Rb and Cs, are also prepared by reaction with the metal bis(trimethylsilyl)amide.[80,81] The cyclopentadienyl ring in alkali metal compounds can also be coordinated to other metals.[82]

5.2 Structural Studies

CpLi exists in ethers as a contact ion pair, in which the lithium ion is located above the cyclopentadienyl ring. The crystal structure of CpLi(12-crown-4) reveals analogous structural features. This complex has a sandwich-type structure in which the lithium ion is coordinated to the four oxygen atoms of the crown ether on one side and to the Cp ring on the other. Several X-ray structures of alkali metal cyclopentadienyl compounds containing silyl substitution of the Cp ligand have been reported.[83,84] The structures of fluorenyl alkali metal complexes (Li–Cs) stabilized by diglyme have also been reported.[85] The crown-ether-stabilized compounds of cyclopentadienyl, indenyl, and fluorenyl with the heavier metals, Rb and Cs, have also been reported.[80] A common structural feature is the η^5 coordination of

the Cp ring to the metal ion, although ion pair structures having uncoordinated substituted Cp anions are observed with chelating donors, such as polyethers or crown ethers.

6 HYDROCARBON RADICAL ANION AND DIANION COMPOUNDS

6.1 Synthesis and Reactivity

Many unsaturated hydrocarbons, especially aromatic compounds, react with alkali metals by electron transfer to form paramagnetic radical anions or diamagnetic dianions. Such species are usually highly colored and have sufficient stability to be studied because the added electron density is delocalized in the LUMO of the hydrocarbon. ESR spectroscopy is useful for characterizing these radical anion species.[86–88] Compounds containing these anions are usually soluble in ether solvents, although crown ethers can affect the solubility of these salts in hydrocarbon solvents. Cyclooctatetraene reacts with potassium to give a radical monoanion and eventually reacts further to form the aromatic dianion (abbreviated K_2COT). Silyl substituents appear to facilitate reduction by alkali metals. The hexasubstituted benzene $(Me_3Si)_6C_6$ reacts with lithium in THF to give the dianionic salt $[(Me_3Si)_6C_6][Li(THF)]_2$.[89,90]

The reactivity of hydrocarbon anion or dianion compounds of the alkali metals with respect to alkylation, electron transfer, and protonation has been studied.[91] These species have also been used as reagents in the preparation of organoalkali metal compounds.[92,93]

6.2 Structural Studies

In the solution phase, aromatic radical anions of alkali metals exist as free ions, ion pairs, or as oligomers. Aromatic dianion salts probably form relatively tight ion pairs or oligomers. Solid-state structures of several aromatic radical anion or dianion alkali metal compounds have been determined.[94] In the dianion $Naph_2^-$ $[Li{\cdot}TMEDA]_2^+$, a lithium ion is located over each six-membered ring on opposite sides of a nearly planar naphthalene dianion. The X-ray structure of $(C_8H_8)_2^-$, $2K^+{\cdot}3THF$ reveals a planar dianion bonded on either side as an η^8-ligand to the two potassium ions. The K–C distances range from 2.936 to 2.983 Å.[95] In $[(Me_3Si)_6C_6][Li(THF)]_2$, both lithium ions are located on the same side of the dianion, which has adopted a boat-shaped ring conformation. This structure is maintained in solution. The related salt $[1,2,4,5\text{-}(Me_3Si)_4C_6H_2][Li(DME)]_2$ is structurally different in that the ring of the dianion is essentially planar, and the lithium ions are located on opposite sides of the aromatic ring.[89,90]

Glossary

Curie: that amount of radioactivity which has the identical disintegration rate as 1 g of ^{226}Ra, specifically 3.70×10^{10} s^{-1}
Quasiaromatic: compound with resonance stability incurred by coordination of a metal cation with the bidentate ligand derived from deprotonation of a β-diketone

1 INTRODUCTION

An alkaline earth is an oxide of an element in group 2 of the periodic table. In their pure forms, these elements collectively are referred to as the alkaline earth metals. These metals, like their neighbors the alkali metals (group 1 elements, *see* ***Alkali Metals: Inorganic Chemistry***), are strong reducing agents and are, therefore, not observed uncompounded in Nature. The group 2 elements readily give up their two valence electrons, present in an s atomic orbital subshell, and thus portray a chemistry dominated by dications.

In previous arrangements of the *Periodic Table* (*see* ***Periodic Table: Trends in the Properties of the Elements***), the elements beryllium, magnesium, calcium, strontium, barium, and radium were referred to as members of Group IIa, or 2A. As inclusion of the word 'metal' in their title implies, these elements are both malleable and extrudable; however, they are rather brittle. They are electrical conductors. When pure, all except the lightest, beryllium, react with atmospheric O_2 and/or H_2O to form a protective coating of metal oxide, which acts as a surface barrier to inhibit bulk oxidation. In the specific case of calcium, this coating is primarily composed of the nitride.

The inorganic chemistry of the group 2 elements can be categorized succinctly into a rather limited focus. The overwhelming preponderance of the +2 oxidation state rules the chemistry of these elements. This ubiquitous observation, coupled with the severely limited energetic accessibility of other oxidation states, has dictated the development of the area. These elements are comparable in much of their chemistry, diverging most in aspects dependent on atomic size rather than electronic charge. It is in this regard that the greatest diversity is displayed in these congeners. The span encompasses a quite broad range (Be, 111 pm; Ra, 223 pm) and thereby influences some of the observed trends. This effect emerges most noticeably in the realm of coordination chemistry.

All six elements are found in Nature. Radium has no stable isotopes (*see Isotopes & Isotope Labeling*); however, ^{226}Ra has a half-life of 1600 years. Its decay mode is by α (4.780 MeV) and γ emission. As a consequence of this radioactive nature (*see Radioactive Decay*), its chemistry remains relatively unexplored. In several arenas, rather comprehensive studies have examined various properties of all of the lighter group 2 elements. Efforts have been made to extend all given comparisons to radium; however, in some instances this has proven rather difficult.

One significant deviation from the influence of ionic chemistry for the group 2 elements is beryllium. Although the chemistry of this lightest element of the group exhibits indications of the presence of some covalent bonding (*see Covalent Bonds*), it does not overwhelm the dominating trend toward ionic behavior. There are several well-understood reasons for the uniqueness of beryllium. Its comparatively large charge/size ratio, relatively high *Electronegativity* and low z nature combine to produce this observed effect. The first of these items may be adequately explained by proper application of *Fajans' Rules*. The second of these is manifested by the comparatively small resultant electronegativity difference between Be and other atoms entering into a bonding arrangement, thus inhibiting bond polarity and promoting covalency. The final factor is a controlling variable of the number of atomic orbitals potentially available to accommodate bonding electrons (*see* ***Electronic Structure of Main-group Compounds***). One consequence of its location early in the periodic table is the limitation on this number of orbitals to four (one s and three p), and the concomitant delegation to be, in the primary examples, four coordinate. Such restraints are removed for the other group 2 elements and, as we shall discover below, coordination numbers (*see* ***Coordination Numbers & Geometries***) of 6, 8, 10, and, in certain instances, even 12, commonly are observed for these elements.

2 THE ELEMENTS

The date, location, and credited scientist of discovery, comparable information for initial pure isolation, and historical derivation of the name of each of the group 2 elements are summarized in Table 1. The principal ore found in Nature, the industrial preparation and purification, and the principal contemporary uses are outlined in Table 2. Several important properties of each element are listed in Table 3. These properties can be broken down into the categories of general information (name, symbol,

Table 1 Historical information

Element	Discovery Year	Discoverers	1st pure isolation	Isolators	Named after
Beryllium	1797	Vauquelin (Paris)	1828	Wöhler (Berlin) Bussy (Paris)	Beryllos (Greek: beryl)
Magnesium	1755	Black (Edinburgh)	1808	Davy (London)	Magnesia (Greek: Thessaly district)
Calcium	1808	Davy (London)	1808	Davy (London)	Calx (Latin: lime)
Strontium	1790	Crawford (Edinburgh)	1808	Davy (London)	Strontian, Scotland
Barium	1774	Scheele	1808	Davy (London)	Barys (Greek: heavy)
Radium	1898	Curie (Paris)	1910	Curie (Paris)	Radius (Latin: ray)

Table 2 Industrial information

Element	Principle ore	Industrial preparation/purification	Principal uses
Beryllium	Beryl ($Be_3Al_2Si_6O_{18}$)	Electrolysis of fused $BeCl_2$ or reduction of BeF_2 with magnesium	Alloy with copper Highly X-ray permeable Nuclear reflector/moderator
Magnesium	Dolomite ([Mg,Ca]CO_3)	Electrolysis of fused $MgCl_2$ (obtained from brines)	Lightweight structures (alloys) Sacrificial electrodes Flares, pyrotechnics, incendiary bombs
Calcium	Limestone ($CaCO_3$)	Electrolysis of fused $CaCl_2/CaF_2$	Reductant in preparation of Zr, Th, U, RE Plaster (as CaO)
Strontium	Celestite ($SrSO_4$)	Reduction of SrO with Al or electrolysis of $SrCl_2$/KCl	Fireworks (red) Glass manufacturing
Barium	Baryte ($BaSO_4$)	Reduction of BaO with Al or electrolysis of $BaCl_2$	Petroleum drilling fluids (as $BaSO_4$) Pesticide (as $BaCO_3$)
Radium	Uraniums	Separation	Luminous paint Cancer therapy } (both decreasing)

Table 3 Properties of the elements

	Beryllium	Magnesium	Calcium	Strontium	Barium	Radium
Symbol	Be	Mg	Ca	Sr	Ba	Ra

Coefficient of linear thermal expansion (K^{-1} × 10^{-6})	11.5	26.1	22	23	19	20.2
Thermal n^0 cross section (barn)	0.0092	0.063	0.43	1.2	1.3	20

atomic number, and relative atomic mass), chemical (radii, electronegativity, and reduction potential), physical (melting point, boiling point, density, ΔH_{vap}, $\Delta H^0{}_{f(gas)}$, electrical resistivity, thermal conductivity, mass magnetic susceptibility, and coefficient of linear thermal expansion), nuclear (number of isotopes, thermal n^0 cross section, and NMR (see below)), environmental (abundance), and electronic (first, second, and third *Ionization Potential*, and *Electron Affinity*). Several excellent compilations of more exhaustive data have been assembled.[1–12]

2.1 Radium

The known inorganic chemistry of radium does not differ significantly from that of barium.[13] The isotopes of radium are compiled in Table 4. The chloride, bromide, and nitrate salts of Ra are all water soluble. For example, $RaCl_2$ (24.5 g/100 mL H_2O at 25 °C) has a comparable solubility to $BaCl_2$ (30.7 g). This slight difference is the primary mode of separation of Ra from Ba. Barium sulfate frequently plays the role of a carrier for Ra. The solubility of $RaSO_4$ (2.1×10^{-4} g/100 mL H_2O at 25 °C) is perhaps the lowest of any of the group 2 elements. Other aqueous insoluble salts of Ra include $CO_3{}^{2-}$ and $CrO_4{}^{2-}$.

Owing to the difficulty in separating Ba and Ra cleanly, Hahn erroneously attributed Ra radioactivity to Ba and thereby passed over the discovery of nuclear fission (*see Binding Energy of Nuclei*). His sample of $BaSO_4$ was not the pure Ba compound, and the unknown Ra contaminant led to his observation and incorrect conclusion.

Table 4 Isotopes of radium

Mass	Mode of decay	Half-life	Source
213	α	2.7 min	Th + p; Pb + C^{6+}
219	α	$\sim 10^{-3}$ s	Daughter Th^{223}
220	α	∼0.03 s	Daughter Th^{224}
221	α	30 s	Daughter Th^{225}
222	α	38 s	Daughter Th^{226}
223 (AcX)	α	11.435 day	Natural; descendant U^{235}
224 (ThX)	α	3.64 day	Natural; descendant Th^{232}
225	β^-	14.8 day	Daughter Th^{229}
226	α	1622 year	Natural; descendant U^{238}
227	β^-	41.2 min	$Ra^{226}(n, \gamma)$
228 (MsTh$_1$)	β^-	6.7 year	Natural; descendant Th^{232}
229	β^-	∼1 min	Daughter Th^{233}
230	β^-	1 h	Th + d

3 NUCLEAR MAGNETIC RESONANCE

The gaining of widespread acceptance for the great utility of magnetic resonance imaging in the medical community has served to bring the field of NMR out of the research laboratory and into contact with the everyday lives of many citizens. Although the most widely exploited nuclei remain ^1H, ^{13}C, and ^{31}P, the inorganic chemist has available a much wider variety of potential choices. Each of the group 2 elements, except Ra, has an isotope that possesses the requisite properties for NMR observation. These are presented in Table 5, together with

Table 5 Nuclear magnetic resonance

Nuclide	^{9}Be	^{25}Mg	^{43}Ca	^{87}Sr	^{137}Ba	^{13}C
Abundance (%)	100	10.00	0.135	7.00	11.23	1.10
Nuclear spin	3/2	5/2	7/2	9/2	3/2	1/2
Frequency	14.053	6.1195	6.728	4.333	11.113	25.144
Sensitivity ($\times 10^{-3}$)	13.9	2.67	6.40	2.69	0.776	15.9
Receptivity	78.8	1.54	0.0527	1.07	4.41	1.00
Quadrupole moment ($\times 10^{-28}$)	0.052	0.22	0.05	0.36	0.28	0

comparative data for ^{13}C. This will allow the reader to place these rather esoteric nuclei in their proper perspective with respect to a commonly employed organic analytical technique. It is noteworthy that all of the group 2 elements except for ^{43}Ca have a higher receptivity than ^{13}C, several of them significantly ($^{137}Ba > 4\times$) and one of them overwhelmingly ($^{9}Be > 78\times$) larger than the corresponding relative assignment of $^{13}C \equiv 1.00$. In all probability, the development of techniques based on these nuclei have been hampered, to date, by the high odd-halves (>1/2) spin associated with all of the nuclides of interest. This impedance may be diminished, however, by the recent elegant work employing a double rotating solid-state probe for NMR that reduces the quadrupole moment contribution to line-broadening.[14] The applicability of this technique to mineralogy, geology, and catalyst identification should be widespread.

4 BIOLOGICAL ROLES

In a comparable manner to the discrimination found for the group 1 elements ([Na^+] is higher outside cells and [K^+] is higher inside cells) the observation is that [Mg^{2+}] is higher inside animal cells and [Ca^{2+}] is higher in the body fluids outside the cells.[15] Complexes between ATP and Mg^{2+} are one component of phosphohydrolase and phosphotransferase enzymes (*see Enzyme*) involved in the release of energy from ATP. In animals, the utilization of Mg^{2+} plays a major role in nerve fiber impulse transmission. In animal teeth (enamel (fluoroapatite, $[3\{Ca_3(PO_4)_2\}\cdot CaF_2]$)) and bones (apatite, $Ca_3(PO_4)_2$), the key contribution of Ca^{2+} to the structural formation of biological systems is manifested. Additionally, Ca^{2+} plays a role in the clotting of blood and the mechanism of muscle contraction that maintains a consistent heart rhythm (*see* ***Calcium-binding Proteins***).[16] The composition of green plant *Chlorophyll* is centered around Mg^{2+}. This nitrogen-based macrocyclic ligand-containing molecule is a derivative of the tetrapyrrole porphine, a highly conjugated heterocyclic tetradentate alkaloid. During plant photosynthesis, it is this ligand that participates in one-electron redox reactions, not the metal. The apparent function of the Mg^{2+} is predominantly structural in origin. The two-dimensional rigidity imparted to the ring system reduces thermal vibration energy loss, and thus increases the percent conversion. Additionally, the role of a five-coordinate species formed by the inclusion of hydrogen bonds from water is integral in the stacking of units into the three-dimensional antenna arrays required for absorption of light (680–700 nm).[17] Although, in principle, any nonredox-active metal of the proper ionic radius could fulfill this role, in Nature only Mg^{2+} has been observed to perform this seminal contribution to the biological systems.

The total mass per element in a human of average mass (70 kg), the oral toxic intake, and the daily dietary intake for the group 2 elements are summarized in Table 6. These numbers reflect the total concentrations of the elements in all forms; however, it is primarily as the divalent *Cation* that they are found. In this capacity, they also serve an essential function by their contribution to specific ionic equilibria in living cells. Both calcium and magnesium have been classified as essential bulk elements, falling into the subcategory of macrominerals. Although one report claims that omission of either strontium or barium from the diet of rats and guinea pigs resulted in depressed growth and reduced calcification of bones and teeth, this hint at the essential role of the heavier group 2 elements has neither been confirmed nor rejected in the past four decades.[15] It is relatively well understood that both Sr and Ba show some stimulatory action, are relatively nontoxic (see Table 6 for Ba), and will mimic (spare) Ca in most biological systems. To date, no essential or stimulatory function has been found for Be.[18] The obvious toxicity due to the radioactive nature of Ra is discussed elsewhere.

4.1 Beryllium Biochemistry

There has been much confusion about the toxicity of Be.[19] Numerous reports are based on incomplete research and, in a limited number of instances, have been misquoted at great length in the subsequent scientific literature. For example,

Table 6 Biological concentrations for group 2 elements

	Be	Mg	Ca	Sr	Ba	Ra
Mass in human	0.036 mg	19 g	1.00 kg	320 mg	22 mg	31×10^{-9} mg
Oral toxic intake	Close to zero	Nontoxic	Nontoxic	Nontoxic	200 mg	na
Daily dietary intake (mg)	0.01	250–380	600–1400	0.8–5	0.60–1.7	2×10^{-9}

one authoritative work states 'It should be noted that not more than 500 g Be total, in *any chemical form*, should be kept in a laboratory; otherwise, in the event of fire, beryllium compounds could be vaporized or blown about to such an extent as to constitute a hazard to the surrounding area'.[7] Yet, in 1948, after a major fire and explosion in a Lorain, Ohio, beryllium manufacturing facility, which included the ignition of some 2.5 tons of Mg in the BeO processing factory, no firefighters, police, naval reserve personnel (activated for crowd control), or spectators reported any evidence of the symptoms of beryllium diseases.[19]

With the data available at this point, it does not appear that ingestion of beryllium compounds presents a significant health hazard. Likewise, there is no evidence to indicate that simple skin contact with elemental beryllium or its compounds will result in dermatoses. The unequivocal establishment of an immunological basis for Chronic beryllium disease (CBD) located this disorder to be a pulmonary granulomatous process. CBD is a localized response to an insoluble and persistent irritant. Acute pulmonary beryllium disease is caused by airborne particulates of soluble beryllium salts, primarily $BeSO_4$ or BeF_2. This disease is generally limited to the upper respiratory tract. Although there were 30–60 new cases per year during the period 1942–1947, there have been less than 10 total confirmed cases within the past 40 years. In almost each instance, it was a single isolated case resulting from accidental exposure during maintenance work at a manufacturing facility. Thus, although perhaps not as benign as its heavier congeners Mg and Ca, the relative risk posed by Be is rather small. When compared with other inorganic compounds, such as AsH_3, the exposure limits of 25 $\mu g\,m^{-3}$ per 30 min place this threat in perspective.

4.2 Coordination Chemistry

The ionic radii (Table 7) of the group 2 elements follow the predicted trends.[6] The coordination numbers of the elements differ, as expected, from 4 (for Be) to 12 (for Ba) (*see* ***Coordination & Organometallic Chemistry: Principles***).[3] On the whole, all observed geometries are standard (*see* ***Coordination Numbers & Geometries***). The absolute solubilities of typical salts have been summarized (Table 8).[7] The gas-phase bond dissociation energies trail the pattern forecast by examination of electronegativity and orbital overlap differences (Table 9).[8] A wide array of typical reactions could be found for the group 2 elements; a minor sampling of this diverse chemistry is presented here (Table 10).[12]

Table 7 Ionic radius (pm)

Coordination number	Element[a]					
	Be	Mg	Ca	Sr	Ba	Ra
4	27	57				
6	45	72	100	118	135	
8			112	126	142	148
12						170

Table 10 Some typical reactions of group 2 elements

Reaction	Comment
$M + 2H_2O \rightarrow M(OH)_2 + H_2$	Be probably reacts with steam; Mg with hot water, and Ca, Sr, and Ba react rapidly with cold water
$M + 2HX \rightarrow MX_2 + H_2$	All the metals react with acids, liberating hydrogen
$Be + NaOH \rightarrow Na_2[Be(OH)_4] + H_2$	Be is amphoteric
$2M + O_2 \rightarrow 2MO$	Normal oxide formed by all group members with excess oxygen
$Ba + O_2 \rightarrow BaO_2$	Ba also forms the peroxide
$M + H_2 \rightarrow MH_2$	Ionic 'saltlike' hydrides formed at high temperatures by Ca, Sr, and Ba
$3M + N_2 \rightarrow M_3N_2$	All the metals form nitrides at high temperatures
$3M + 2P \rightarrow M_3P_2$	All the metals form phosphides at high temperatures
$M + S \rightarrow MS$	All the metals form sulfides
$M + Se \rightarrow MSe$	All the metals form selenides
$M + Te \rightarrow MTe$	All the metals form tellurides
$M + F_2 \rightarrow MF_2$	All the metals form fluorides
$M + Cl_2 \rightarrow MCl_2$	All the metals form chlorides
$M + Br_2 \rightarrow MBr_2$	All the metals form bromides
$M + I_2 \rightarrow MI_2$	All the metals form iodides
$M + 2NH_3 \rightarrow M(NH_2)_2 + H_2$	All the metals form amides at high temperatures

5 COMPOUNDS OF GROUP 2 ELEMENTS WITH HYDROGEN

The group 2 elements Mg, Ca, Sr, and Ba all react with H_2(g) to form *Hydrides* of the formula MH_2 (e.g. equation 1). The dihydride of beryllium is difficult to prepare and less thermodynamically stable than the dihydrides of the heavier group 2 congeners. Impure BeH_2 (contaminated with various amounts of diethyl ether) was made historically by reducing $BeCl_2$ with lithium aluminum hydride ($LiAlH_4$) (equation 2). Pure samples can be obtained by reducing $BeCl_2$ with lithium borohydride ($LiBH_4$) to give BeB_2H_8 (equation 3), then heating BeB_2H_8 in a sealed tube with triphenylphosphine (PPh_3) (equation 4). Alternatively, it may be prepared by a thermal *β-Hydride Elimination* of isobutene from bis(*t*-Bu)beryllium at temperatures of ~100 °C (equation 5).[20] Additionally, convenient methods for the preparation of MgH_2 are reduction of Mg(anthracene) (equation 6) and exchange between alkyl magnesium compounds and phenylsilyl hydrides (equation 7).[21]

$$Ca(s) + H_2(g) \longrightarrow CaH_2(s) \tag{1}$$

$$2BeCl_2 + LiAlH_4 \longrightarrow 2BeH_2 + LiCl + AlCl_3 \tag{2}$$

$$BeCl_2 + 2LiBH_4 \longrightarrow BeB_2H_8 + 2LiCl \tag{3}$$

$$BeB_2H_8 + 2PPh_3 \xrightarrow{\Delta} BeH_2 + 2Ph_3P{\cdot}BH_3 \tag{4}$$

$$Be(t\text{-}Bu)_2 \xrightarrow{100\,^\circ C} BeH_2 + 2H_2C{=}CMe_2 \tag{5}$$

$$Mg(anthracene) \xrightarrow{H_2} MgH_2 \tag{6}$$

$$MgBu_2 + 2Ph_3SiH \longrightarrow MgH_2 + 2Ph_3SiBu \tag{7}$$

All the metal hydrides are reducing agents and readily are decomposed by water, dilute acids, alcohols, thiols, primary and secondary amines, and other protic compounds, with the evolution of H_2 (equation 8). This specific property has led to wide employment of the compounds as agents for removal of water and other protic impurities from large volumes of organic liquids as one predistillation purification technique.

$$CaH_2 + 2H_2O \longrightarrow Ca(OH)_2 + 2H_2(g) \tag{8}$$

The heavier group 2 dihydrides (CaH_2, SrH_2, and BaH_2) are ionic (*see Ionic Bonds, Ionic Character*), containing the hydride ion (H^-). Beryllium and magnesium dihydrides are covalent and polymeric (*see Polymer*). $(BeH_2)_n$ presents an interesting structural challenge. In the gas phase, it seems probable that several species may be present, comprising polymeric chains and rings. The solid state is polymeric, and the single-crystal X-ray diffraction structure indicates that it consists of chains of beryllium atoms containing hydrogen bridges between them (Figure 1).

Each Be atom is connected to four H atoms, and each H atom is connected to two Be atoms. Since Be has two valence electrons, and H only one, obviously there are insufficient electrons to fulfill the traditional organic two-center, two-electron bonding description. Alternatively, three-center interactions persist, whereby 'banana-shaped' molecular orbitals (a three-center, two-electron bond, *see Three-center Bond*) connect the Be–H–Be atoms, each containing two electrons (see Figure 2 for the molecular orbital scheme (*see Molecular Orbitals*) for this type of *Delocalized*

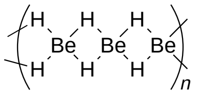

Figure 1 Polymeric structure of BeH_2, containing three-center, two-electron Be–H–Be bridging bonds

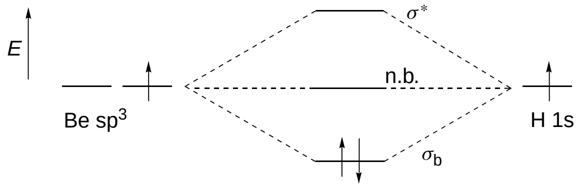

Figure 2 Molecular orbital description of a three-center, two-electron bonding arrangement

Bonding arrangement). This is a primitive example of a *Cluster* compound, where the monomeric molecule BeH_2 (formed with normal bonds) would result in only four electrons in the outer shell of the beryllium atoms.[9] This situation is termed 'electron deficient' (*see Electron Deficient Compound*) and, by entering into a cluster arrangement, each atom shares its electrons with several neighbors and receives a share in their electrons. Clustering is important in the bonding descriptions of metals and the boron hydrides and in the halides of the second and third row transition elements. Typically, when the *Valence Orbitals* are less than one-half full, such clustering interactions may be observed.

6 COMPOUNDS OF GROUP 2 ELEMENTS WITH GROUP 14 ELEMENTS

The broadest representation of this class of compounds is the organomagnesium halides, or *Grignard Reagents*.[22] In detail, the organometallic chemistry of the group 2 elements is covered elsewhere in this Encyclopedia (*see* ***Beryllium & Magnesium: Organometallic Chemistry***). However, there is one important class of *inorganic* compounds formed between the elements of Groups 2 and 14. The carbides of the elements fall within the scope of this section of the work.

Group 2 elements typically form ionic carbides of formula MC_2.[23] When BeO is heated with C at 1900–2000 °C, a brick red colored carbide of formula Be_2C results. This ionic compound adopts the antifluorite structure, that is, like the CaF_2 structure except that the positions of the cations and *Anions* are interchanged. It is unusual because it reacts with water, forming methane, and is thus called a methanide (equation 9).

$$Be_2C\,(s) + 4H_2O\,(l) \longrightarrow 2Be(OH)_2(s) + CH_4(g) \qquad (9)$$

The elements Mg, Ca, Sr, and Ba each form carbides of formula MC_2, either when the metal is heated with carbon in an electric furnace (e.g. equation 10), or when their oxides are heated with carbon (e.g. equation 11). CaC_2 prepared by this manner is a gray colored solid, but is colorless when pure. BeC_2 is made by heating Be with acetylene. On heating, MgC_2 changes into Mg_2C_3. This contains C_3^{4-}, and it reacts with water to form methylacetylene ($CH_3C{\equiv}CH$). The MC_2 carbides all have a distorted sodium chloride type of structure. M^{2+} replaces Na^+ and $C{\equiv}C^{2-}$ replaces Cl^-. The C_2^{2-} ions are elongated, not spherical like Cl^-. Thus, the axis along which the C_2^{2-} ions lie is lengthened, compared with the other two axes, and this results in a tetragonal distortion. At temperatures above 450 °C, the C_2^{2-} ions adopt random positions, rather than being aligned, and the unit cell then becomes cubic instead of tetragonal.

$$Ca + 2C \xrightarrow{1100\,^\circ C} CaC_2 \qquad (10)$$

$$CaO + 3C \xrightarrow{2000\,^\circ C} CaC_2 + CO \qquad (11)$$

Among the carbides of the group 2 elements, calcium carbide is the best known. It reacts with water, liberating acetylene, and thus is called an acetylide (equation 12). At one time, this reaction was the main source of $HC{\equiv}CH$ for oxyacetylene welding. Production of CaC_2 peaked at 7 million tonnes per year in 1960, but declined slightly to 6.2 million tonnes in 1985 because acetylene now is obtained from petrochemical processing.

$$CaC_2(s) + 2H_2O(l) \longrightarrow Ca(OH)_2(s) + C_2H_2(g) \qquad (12)$$

7 COMPOUNDS OF GROUP 2 ELEMENTS WITH NITROGEN

7.1 Liquid Ammonia Solutions of the Elements

The group 2 elements all dissolve in $NH_3(l)$, as do the group 1 elements.[2] Dilute solutions are bright blue in color owing to the spectrum from the solvated electron. These solutions slowly decompose, forming amides and evolving hydrogen; however, the reaction may be accelerated by the presence of transition elements or their compounds (equation 13). Evaporation of the ammonia from solutions of group 1 elements returns the metal, but with group 2 elements, evaporation of the ammonia gives the hexaammoniates of the metals. These slowly decompose to give the bis(amides) (equation 14). Concentrated solutions of the metals in ammonia are bronze colored, owing to the formation of metal clusters.

$$2NH_3 + 2e^- \xrightarrow{[cat]} 2NH_2^- + H_2(g) \qquad (13)$$

$$M(NH_3)_6 \longrightarrow M(NH_2)_2 + 4NH_3 + H_2(g) \qquad (14)$$

7.2 Nitrides of the Elements

The group 2 elements all burn in nitrogen and form ionic nitrides of the formula M_3N_2 (e.g. equation 15). Owing

to the tremendous stability of the N_2 molecule, a large amount of energy is required to convert one dinitrogen molecule with a triple bond into two N^{3-} (nitride ions). The large amount of energy required comes from the substantial quantity of *Lattice Energy* released upon formation of the crystalline solid. The lattice energy is particularly high as a consequence of the high charges on the ions (M^{2+} and N^{3-}). This prevalence of group 2 elements to form nitrides contrasts with the group 1 elements, where Li_3N is the only nitride reported. The very small size of Li^+, resulting in a high lattice energy, explains this observation. These thermodynamic values may be calculated using a *Born–Haber Cycle*. Be_3N_2 is rather volatile, in accord with the greater tendency of Be to covalency, but the other nitrides are involatile. All the nitrides are crystalline solids that decompose on heating and react with water, liberating ammonia and forming either the metal oxide or hydroxide, (e.g. equation 16).

$$3Ca(s) + N_2(g) \longrightarrow Ca_3N_2(s) \quad (15)$$

$$Ca_3N_2 + 6H_2O \longrightarrow 3Ca(OH)_2 + 2NH_3 \quad (16)$$

7.3 Bis[bis(trimethylsilyl)amides] of the Elements

The primary amides of the group 2 elements, $M(NH_2)_2$, are nonmolecular species.[24] When the NH_2^- ligand is replaced by the bulky bis(trimethylsilyl)amido group, however, molecular complexes are formed. A complete set of structures has been obtained for Be through Ba (Table 11). The barium bis(trimethylsilyl)amides form a progression of compounds that illustrate the important relationship between ligand bulk and metal nuclearity.[25] The base-free compound, $[Ba\{N(SiMe_3)_2\}]_2$, exists as a dimer that can accommodate a single THF ligand at each metal center without gross structural change (i.e. $[Ba\{N(SiMe_3)_2\}_2(THF)]_2$). Addition of a second molecule of neutral THF, however, provides enough steric bulk to ensure that the $Ba\{N(SiMe_3)_2\}_2(THF)_2$ adduct crystallizes as a monomer. Remarkably, isostructural dimers of the form $[M\{N(SiMe_3)_2\}_2]_2$ exist for all the metals Mg to Ba. Even though the metal radii in these compounds vary by more than a factor of two (Table 7), the bis(trimethylsilyl)amido ligands adapt to the range of metal–ligand distances without requiring changes in nuclearity.

8 HYDROXIDES, CARBONATES, BICARBONATES, OXIDES, AND PEROXIDES OF GROUP 2 ELEMENTS

The elementary forms, hydroxides, carbonates, bicarbonates, oxides, and peroxides of the group 2 elements all are highly interrelated (equations 17–24) and hence are discussed together (*see* ***Oxides: Solid-state Chemistry*** and ***Chalcogenides: Solid-state Chemistry***).[12]

$$M + 2H_2O \longrightarrow M(OH)_2 + H_2(g) \quad (17)$$

$$M(OH)_2 + CO_2 \longrightarrow MCO_3 + H_2O \quad (18)$$

$$MCO_3 + H_2O + \text{xs } CO_2 \longrightarrow M(HCO_3)_2 \quad (19)$$

$$MCO_3 \xrightarrow{\Delta} MO + CO_2 \quad (20)$$

$$MO + H_2O \longrightarrow M(OH)_2 \quad (21)$$

$$MO + CO_2 \longrightarrow MCO_3 \quad (22)$$

$$MO + \tfrac{1}{2}O_2 \longrightarrow MO_2 \quad (23)$$

$$MO_2 \xrightarrow{\Delta} MO + \tfrac{1}{2}O_2 \quad (24)$$

Table 11 Structural data for group 2 bis[bis(trimethylsilyl)amides] and their adducts[26]

Compound	Central metal coordination number	Nuclearity	Average M–N distance (Å)	Method[a]

$Ba[N(SiMe_3)_2]_2(THF)_2$	4	Monomeric	2.592 (8)	X[25]

[a]E = gas-phase electron diffraction; X = single-crystal X-ray diffraction; t = terminal; μ = bridging.

$Be(OH)_2$ is amphoteric, but the hydroxides of Mg, Ca, Sr, and Ba are basic. The basicity increases from Mg to Ba, and group 2 elements portray the usual trend that basic properties increase on descending a group. Solutions of $Ca(OH)_2$, called lime water, are used to detect carbon dioxide. When $CO_2(g)$ is bubbled through these solutions, they become opaque ('milky'), owing to the formation of a suspension of $CaCO_3$. If additional CO_2 is passed through these cloudy solutions, the turbidity dissipates and soluble calcium bicarbonate is formed from the excess CO_2 (equation 25).

$$Ca(OH)_2(aq) + CO_2(g) \longrightarrow CaCO_3(\downarrow) + H_2O(l) \xrightarrow{\text{excess } CO_2} Ca(HCO_3)_2(aq) \quad (25)$$

The bicarbonates of group 2 elements are stable only in solution. An interesting and aesthetically pleasing consequence of this in Nature greets spelunkers (cavers) to sights of 'cavern columns'. Underground caves, which occur predominately in regions of the planet heavily concentrated with limestone deposits and which are rather somewhat more arid today than in historical times, often have stalactites growing down from the roof, and stalagmites growing up from the floor. Water percolating through the limestone contains some $Ca(HCO_3)_2$ in solution. The soluble bicarbonate slowly decomposes into the insoluble carbonate, thus resulting in the slow growth of the stalactites and stalagmites. The observation of a wide array of colors in these natural structures eminates from trace concentrations of elements of the d-block metals of the periodic table. These transition elements possess electrons that undergo optical transitions between orbitals in the visible region of the electromagnetic spectrum, thereby treating the observer to a 'wonder of the world' (Carlsbad Caverns in New Mexico, USA).[33]

The heavier group 2 elements (Ca, Sr, Ba) have oxidation potentials similar to those of the corresponding group 1 metals, and are rather high in the electrochemical series. They react with cold water quite readily, liberating hydrogen and forming metal hydroxides (e.g. equation 26) (Table 10). The reduction potential of beryllium is much less than those for the rest of the group (Table 3). This indicates that beryllium is much less electropositive (less metallic) than the others, and beryllium does not react with water. There is some doubt whether it reacts with steam to form the oxide (BeO), or fails to react at all (Table 10). Magnesium has an intermediate reduction value, and although it does not react with cold water, it decomposes in hot water (equations 27 and 28). Magnesium forms a protective layer of oxide, so, despite its favorable reduction potential, it does not react readily unless the oxide layer is removed by amalgamation with mercury. In the formation of the oxide film, it resembles the group 13 element aluminum.

$$Ca + 2H_2O \longrightarrow Ca(OH)_2 + H_2(g) \quad (26)$$

$$Mg + 2H_2O \longrightarrow Mg(OH)_2 + H_2(g) \quad (27)$$

Table 12 Desirable properties for furnace liners

1. High melting points (>2500 °C)
2. Low vapor pressures
3. High thermal conductivities
4. Low chemical reactivities
5. Low electrical conductivities

$$Mg + H_2O \longrightarrow MgO + H_2(g) \quad (28)$$

All the elements in group 2 burn in $O_2(g)$ to form oxides (MO). Metallic Be is relatively unreactive in the bulk form, and does not combust below 600 °C, but the powder, as a result of the higher surface area, is significantly more reactive and burns brilliantly. The elements also burn in air, forming a mixture of oxide and nitride. Mg burns with dazzling brilliance in air, evolving substantial amounts of heat (equation 29). This is used to start the *Thermite Reaction* between iron oxide and aluminum, and also to provide light in flash photography using light bulbs, not electronics.

$$Mg + air \longrightarrow MgO + Mg_3N_2 \quad (29)$$

Beryllium oxide usually is prepared by ignition of the metal, but the other metal oxides are predominately obtained by thermal decomposition of the carbonates (MCO_3). Other oxosalts, such as $M(NO_3)_2$ and MSO_4, and also $M(OH)_2$, all decompose to the oxide on heating. The oxosalts are less stable to heat than the corresponding group 1 salts because the metals and their hydroxides are less basic than those of group 2.

Magnesium oxide is not very reactive, especially if it has been ignited at high temperatures, and for this reason it is used as a refractory. BeO also is used as a refractory. They combine a number of properties that make them useful for lining furnaces. These factors are summarized in Table 12. Calcium oxide, SrO, and BaO react exothermically with water, forming hydroxides (e.g. equation 30). Magnesium hydroxide is extremely insoluble in water ($\sim 1 \times 10^{-4}$ g L^{-1} at 20 °C) but the other hydroxides are soluble and the solubility increases as one progresses down the group: $Ca(OH)_2 \approx 2$ g L^{-1}; $Sr(OH)_2 \approx 8$ g L^{-1}; $Ba(OH)_2 \approx 39$ g L^{-1}. Beryllium hydroxide is soluble in solutions containing an excess of OH^-, and therefore is amphoteric (*see Amphoterism*). Magnesium hydroxide is weakly basic, and is widely used to treat acid indigestion in human stomachs. The other group 2 element hydroxides are strong bases.

$$CaO + H_2O \longrightarrow Ca(OH)_2 \quad (30)$$

Beryllium oxide is covalent and has a zinc blende (wurtzite) structure, but all the others are ionic and have a rock salt structure (Figure 3).[23] Attempts to predict the structures (using the ionic sizes and the radius ratio) only are partly successful.

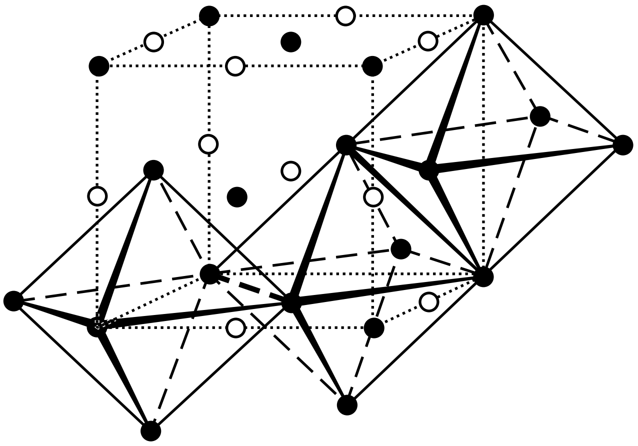

Figure 3 Unit cell of the rock salt structure adopted by MO for the group 2 elements (M ≠ Be), depicting edge-sharing of octahedra

The correct structure is predicted for BeO, MgO, and CaO, but for SrO and BaO the predicted coordination number is eight, although the structures found are six coordinate. Crystals adopt the structure that has the most favorable lattice energy, and the failure of the radius ratio concept in this case leads us to examine the assumptions on which it is based. Ionic radii are not known with great accuracy and they change with different coordination numbers (Table 7). Also, ions are not necessarily spherical, or inelastic (*see* ***Structure & Property Maps for Inorganic Solids***).[24]

As the atoms get larger, the ionization energy decreases and the compounds of the elements also become more basic. Beryllium oxide is insoluble in water but dissolves in acids to give salts, and in alkalis to give beryllates, which on standing precipitate as the hydroxide. Therefore, BeO is amphoteric. Magnesium oxide reacts with water, evolving a substantial quantity of heat and forming $Mg(OH)_2$, which is a weak base. Strontium hydroxide and barium hydroxide are stronger bases. The oxides usually are prepared by thermal decomposition of the carbonates, nitrates, or hydroxides. The increase in basic strength is illustrated by the temperatures at which the carbonates decompose (Table 13).[12] The carbonates all are ionic, but $BeCO_3$ is unusual because it contains the hydrated ion $[Be(H_2O)_4]^{2+}$ rather than Be^{2+}.

Calcium carbonate occurs as two different crystalline forms, calcite and aragonite.[23] Both forms occur naturally as minerals (*see Mineralogy*). Calcite is the more stable: each Ca^{2+} is surrounded by six oxygen atoms from ${CO_3}^{2-}$ ions. Aragonite is a metastable form, and its standard enthalpy of formation is about 5 kJ mol^{-1} higher than that of calcite. In principle, aragonite should decompose to calcite, but a high

Table 13 Decomposition temperatures for MCO_3

Compound	$BeCO_3$	$MgCO_3$	$CaCO_3$	$SrCO_3$	$BaCO_3$
Temperature	<100 °C	540 °C	900 °C	1290 °C	1360 °C

Table 14 Large volume uses of lime

1. In steel making: to remove phosphates and silicates as slag
2. By mixing with SiO_2 and alumina or clay to make cement
3. For making glass
4. In the lime-soda process, which is part of the chlor-alkali industry, converting Na_2CO_3 to NaOH or vice versa
5. For 'softening' water
6. To make CaC_2
7. To make slaked lime [$Ca(OH)_2$] by treatment with water

Activation energy prevents this from happening. Aragonite can be made in the laboratory by precipitation from a hot solution. Its crystal structure consists of Ca^{2+} ions surrounded by nine oxygen atoms in a display of a rather unusual coordination number.

Calcium oxide (quicklime) is prepared on a large scale (18 million tonnes in 1988) by heating $CaCO_3$ in lime kilns (equation 31).[1] Calcium hydroxide is called slaked lime. Soda lime is a mixture of NaOH and $Ca(OH)_2$ and is made from quicklime (CaO) and aqueous sodium hydroxide. It is much easier to handle than NaOH. Some of the more important, large volume uses of *Lime* are summarized in Table 14. Bleaching powder is made by passing $Cl_2(g)$ into slaked lime, and about 90 000 tonnes a year are produced.[12] Though bleaching powder is often written as $Ca(OCl)_2$, really it is a mixture (equation 32).

$$CaCO_3 \xrightarrow{\Delta} CaO + CO_2 \quad (31)$$

$$3Ca(OH)_2 + 2Cl_2 \longrightarrow Ca(OCl)_2{\cdot}Ca(OH)_2{\cdot}CaCl_2{\cdot}2H_2O \quad (32)$$

Peroxides are formed with increasing ease and increasing stability as the metal ions become larger.[34] Barium peroxide (BaO_2) is formed by passing air over BaO at 500 °C. Strontium peroxide can be formed in a similar way; however, this requires the employment of both high pressure and temperature. Calcium peroxide is not formed in this way, but it can be made as the hydrate by treating $Ca(OH)_2$ with H_2O_2 and then dehydrating the product. Crude MgO_2 has been made using H_2O_2, but no peroxide of beryllium is known. Presumably, this may be attributed to the desire for Be to form covalent bonds. The known peroxides all are white ionic solids that contain the $[O–O]^{2-}$ ion and can be regarded as salts of the very weak acid hydrogen peroxide. Treating peroxides with acid liberates hydrogen peroxide (e.g. equation 33).

$$BaO_2 + 2HCl \longrightarrow BaCl_2 + H_2O_2 \quad (33)$$

9 COMPOUNDS OF GROUP 2 ELEMENTS WITH GROUP 17 ELEMENTS

Dihalides of the group 2 elements, MX_2, can be prepared either by heating the metals with the halogen, or by the

action of hydrohalic acid on the metal (*see* ***Halides: Solid-state Chemistry***). The beryllium halides are covalent and hygroscopic and fume in air owing to hydrolysis. They sublime, and do not conduct electricity (Table 9). Anhydrous beryllium halides cannot be obtained from materials made in aqueous solutions because the hydrated ion $[Be(H_2O)_4]^{2+}$ is formed, for example, $[Be(H_2O)_4]Cl_2$ or $[Be(H_2O)_4]F_2$. Attempts to dehydrate these hydrates result in hydrolysis (equation 34).

$$[Be(H_2O)_4]Cl_2 \xrightarrow{\Delta} Be(OH)_2 + 2HCl + 2H_2O \quad (34)$$

The anhydrous halides are prepared best by the reactions shown in equations (35–37) (Table 10). Reaction with CCl_4 is a standard method for making anhydrous chlorides, which cannot be obtained by dehydrating hydrates (equation 37). The anhydrous halides are polymeric in the solid state (Figure 4). Beryllium chloride vapor contains $BeCl_2$ and $(BeCl_2)_2$; however, the solid is a catenated chain. Although, on initial examination, the $(BeCl_2)_n$ polymer structurally is similar to that observed for $(BeH_2)_n$, the bonding is different. Both portray clustering, but the hydride demonstrates three-center, two-electron bonding, whereas the halides exhibit halogen bridges, whereby a halogen atom is σ-bonded to one beryllium atom (classical two-center, two-electron covalent interaction) and uses a lone pair of electrons to form a coordinate bond to another beryllium atom. Thus, the contrast is one of a three-center, two-electron bonding arrangement with a three-center, four-electron configuration (Figure 5).[9]

$$BeO + NH_4F \longrightarrow (NH_4)_2[BeF_4] \xrightarrow{\Delta} BeF_2 + 2NH_4F \quad (35)$$

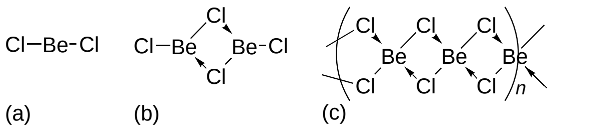

Figure 4 $BeCl_2$ structures: (a) monomer, (b) dimer, and (c) polymer. Solid lines represent covalent bonds and arrowed lines represent coordinate (Lewis base → Lewis acid) bonds. Note that the depicted structure is in resonance with other formal electron placement schemes. Thus, on average, all Be–Cl interactions appear equivalent

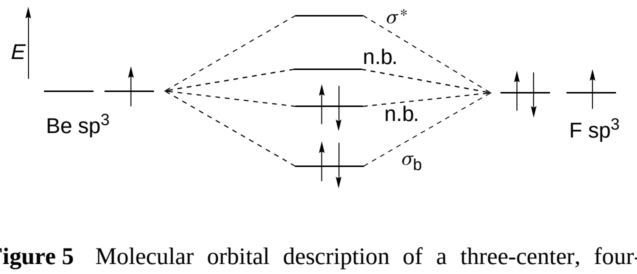

Figure 5 Molecular orbital description of a three-center, four-electron bonding arrangement

$$BeO + C + Cl_2 \xrightarrow{700\,^{\circ}C} BeCl_2 + CO \quad (36)$$

$$2BeO + CCl_4 \xrightarrow{800\,^{\circ}C} 2BeCl_2 + CO_2 \quad (37)$$

Beryllium fluoride is quite soluble in water, resulting from the high solvation energy of Be in producing $[Be(H_2O)_4]^{2+}$. Fluorides of the other metals are ionic, have high melting points, and are insoluble in water. Calcium fluoride commands industrial importance as the main source of both F_2 and HF (equations 38 and 39).[12] World production of fluorite (CaF_2) was 5.1 million tonnes in 1988. The main sources are China 22.5%, Mexico and Mongolia each 16%, the former Soviet Union 11%, and South Africa 6%. CaF_2 also is used to make prisms and cell windows for spectrophotometers. The structure of fluorite is one of the more important general solid-state forms (Figure 6) (*see* ***Solids: Characterization by Powder Diffraction*** and ***Fluorides: Solid-state Chemistry***).

$$CaF_2 + H_2SO_4 \longrightarrow 2HF + CaSO_4 \quad (38)$$

$$HF + KF \longrightarrow KHF_2 \xrightarrow{\text{electrolysis}} F_2 \quad (39)$$

The chlorides, bromides, and iodides of Mg, Ca, Sr, and Ba are ionic, have much lower melting points than the fluorides, and are readily soluble in water. The solubility decreases somewhat with increasing atomic number. The halides all form *Hydrates* and they are hygroscopic (absorb water vapor from the air). Several million tonnes of $CaCl_2$ are produced each year. Large amounts are discarded in solution as a waste product from the Solvay process as a consequence of the low market demand and concomitant uneconomical cost position. Calcium chloride is used widely for treating ice on roads, particularly in very cold climates, because a 30% eutectic mixture of $CaCl_2/H_2O$ freezes at $-55\,^{\circ}C$, compared with $NaCl/H_2O$ at $-18\,^{\circ}C$. Calcium chloride also is used to make concrete set more quickly and to improve its strength, and as 'brine' in refrigeration plants. A minor use is in laboratories as a desiccant (drying agent). Anhydrous $MgCl_2$ is important in the electrolytic method for extracting magnesium.

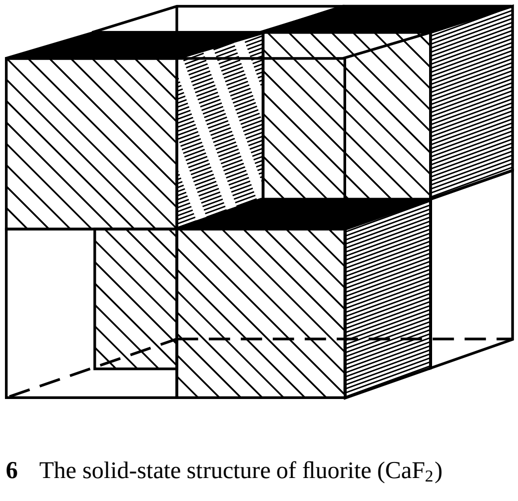

Figure 6 The solid-state structure of fluorite (CaF_2)

Beryllium fluoride (BeF_2) readily coordinates two extra F^- ions, forming the $[BeF_4]^{2-}$ complex. The tetrafluoroberyllates $M_2[BeF_4]$ are well-known complex ions, and resemble the sulfates in properties. In most cases, beryllium is four-coordinate in complexes and the tetrahedral arrangement adopted correlates with the sp^3 hybrid orbitals (*see Hybridization*) available for complex formation. The structural discussion follows from *Valence Shell Electron Pair Repulsion Model* theory. In a similar way, complexes of the type $BeCl_2{\cdot}(LB)_2$ are formed (where: Lewis base (LB) is an ether, aldehyde, or ketone with an oxygen atom that has a lone pair of electrons that can be donated). The complexes, such as $[Be(H_2O)_4]^{2+}$, are tetrahedral. Magnesium also forms halide complexes; however, they are not as prevalent as for beryllium. Complexes such as $[NEt_4]_2[MgCl_4]$ exist, but no comparable examples are reported for the heavier group 2 elements Ca, Sr, or Ba.

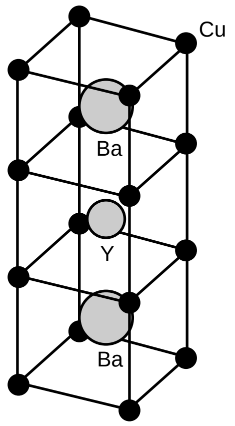

Figure 7 Unit cell depiction of the group 2 element containing superconducting metal oxide $YBa_2Cu_3O_{7-\delta}$

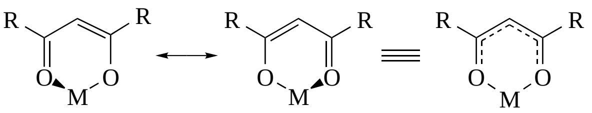
10 COMPOUNDS OF GROUP 2 ELEMENTS WITH COMPLEX LIGANDS

Superconductivity was discovered in 1911. For the first 75 years, it was confined to being observed in metallic (or intermetallic) systems. Most present superconducting materials are binary compositions that are widely utilized in the fabrication of magnets for MRI. The specific form of the material demanded for incorporation into an MRI magnet is a wire. Such wires are composed of multifilament woven compositions. Although several methods exist for the preparation of these materials, in general the traditional routes of metallurgy are applicable, owing to the nature of the compositions.

In 1986, the presence of superconductivity was observed in a metal oxide system (*see* ***Electronic Structure of Solids***). This ceramic was brittle, not ductile as for metallic samples. *Chemical Vapor Deposition* is one method for preparing metal oxide compositions. All presently known superconducting metal oxide compositions contain a group 2 element (Figure 7). Owing to the importance of this area to the future development of the inorganic chemistry of the group 2 elements, it is covered in the present context.

The proven utility of *Chemical Vapor Deposition* in other electronic materials systems (semiconductors, conductors, and insulators) has driven several research efforts to investigate its potential for SMO thin-film growth (*see Metal–Organic Chemical Vapor Deposition*). CVD potentially is well suited for the preparation of thin films of SMO on a wide range of substrates, including those of nonplanar geometries (*see* ***Thin Film Synthesis of Solids***). CVD offers the advantages of mild process conditions (i.e. low temperatures), control over microstructure and composition, high deposition rates, and possible large-scale processing. As with any CVD process, however, the critical factor in the deposition process has been the selection of precursors with suitable transport properties (*see Organometallic Chemical Vapor Deposition*).[35]

The choice of the β-diketonate compounds (*see Diketones*) was based on the earlier elegant work of Sievers,[36] who demonstrated vapor-phase separation of compounds of the general form $M(L)_n$ where n is the cation charge of the metal M, and L is either the parent pentane-2,4-dionato (i.e. acac), or a terminally alkyl-substituted derivative.[37] These metal coordination compounds, described by Coleman as 'quasiaromatic', all have the common feature of the β-diketonate ligand.[38] This bidentate, monoanionic ligand forms a six-membered MO_2C_3 ring upon resonance stabilization of the alkoxide ene–one configuration (**1**).



(**1**) R = Me: Macac; R = *t*-Bu: Mtmhd

Although the commercially available copper and yttrium precursors $Cu(tmhd)_2$ and $Y(tmhd)_3(H_2O)$ readily sublime under ambient pressures between 125 and 160 °C,[39] much higher temperatures (>250 °C) are required for the equivalent barium source, '$Ba(tmhd)_2$'. Thus, although progress has been made, currently the future development of CVD for SMO applications is hampered by the lack of suitable group 2 precursors, particularly those of Ba.[40] Precursor development for CVD of group 2 containing materials has focused primarily on substituted acac complexes.[41]

Quite recently, it has been shown that '$Ba(tmhd)_2$' does not exist as written. Supplied commercially as 'anhydrous $Ba(tmhd)_2$' this compound is, in reality, a pentabarium cluster, which was formulated as $Ba_5(tmhd)_9(OH)(H_2O)_3$; however, based upon literature precedent and by full consideration of the ligand geometries, a better formulation

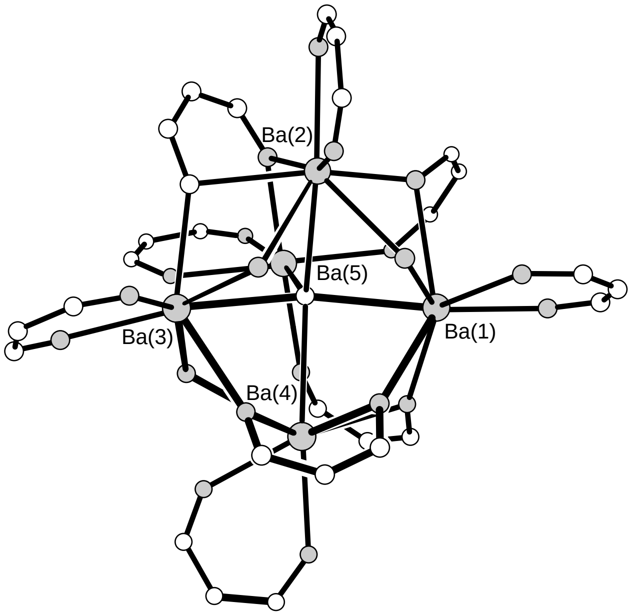


Figure 8 The molecular structure of the pentabarium cluster originally formulated as $Ba_5(tmhd)_9(OH)(H_2O)_3$, but more probably consistent with $Ba_5(tmhd)_5(Htmhd)_4(O)(OH)_3$. The *t*-butyl groups have been omitted for clarity

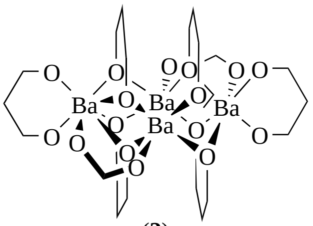
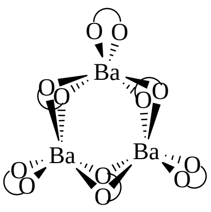


(**2**)

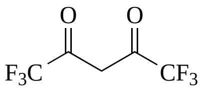


(**3**)

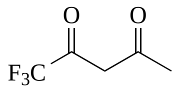
is $Ba_5(tmhd)_5(Htmhd)_4(O)(OH)_3$ (Figure 8).[42] The authentic anhydrous compound is a mixture of the trimer and tetramer, $[Ba(tmhd)_2]_n$ ($n = 3, 4$).[43] The crystal structure of $[Ba(tmhd)_2]_4$[44] (**2**) has been determined recently. The proposed structure of $[Ba(tmhd)_2]_3$, formulated by analogy with the tetramer, is depicted in (**3**).[43,45] Therefore, the tendency of these species to cluster in an effort to achieve electronically neutral, coordinatively saturated status is rather evident. Upon prolonged heating at temperatures required for sufficient mass transport, decomposition of the pentabarium cluster to nonvolatile products occurs.[46] It is likely that one of these species is $Ba_6(tmhd)_{10}(OH)_2$, since a derivative of this compound, $Ba_6(tmhd)_{10}(O_2SiMe_2){\cdot}H_2O$, has been isolated by reaction with $(Me_2SiO)_n$.[47] The most probable next step is elimination of H_2O, followed by the formation of higher molecular weight, lower vapor pressure species. The decomposition of the pentabarium cluster leads to a change in concentration of barium in the vapor over time, and therefore, devastating changes in deposition rate and film composition.[48] This decomposition has been followed in a time/temperature/pressure/humidity study by the technique of TGA–PES.[49] These results are in complete agreement with the hypothesis of hydrolysis of the metal–ligand bond (M–L) to give the protonated ligand (HL) and a metal hydroxide (M–OH). The latter species subsequently dimerizes to yield an oxide (M–O–M) and regenerate water for further reaction.[50] In addition, the high temperatures required to volatilize $[Ba(tmhd)_2]_n$ require that the entire CVD system be maintained above 250 °C to ensure that condensation of the barium source does not occur outside the deposition chamber. It is clear, therefore, that an alternative barium source with a lower evaporation temperature and higher thermal stability is desirable for research purposes and essential if thin films of SMO are to be prepared routinely by CVD.

Although the problems described above for barium precursors also are associated, albeit less severely, with the other two group 2 elements used for obtaining SMO, that is, calcium and strontium, the major research effort in several groups has been focused towards the substantially more difficult volatilization of barium.

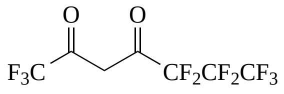
Purdy *et al.*[51] reported the synthesis of the calcium, barium, and strontium complexes of hexafluoroacetylacetone (Hhfac) (**4**) and trifluoroacetylacetone (Htfac) (**5**). CVD experiments were performed with the group 2 hfac complexes, and with $Ca(tfac)_2$ to give metal fluoride films, while $Ba(hfac)_2$ has been used to prepare films of $YBa_2Cu_3O_{7-\delta}$.[52] As with the tmhd derivative, the tfac and hfac barium complexes decompose at, or slightly above, their sublimation temperatures, resulting in significant premature thermolysis of the precursors during deposition.



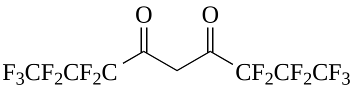
(**4**)



(**5**)



(**6**)



(**7**)

Recent work by Cole-Hamilton and coworkers[53] has demonstrated that stability and volatility are enhanced by the use of long-chain fluorinated β-diketonate ligands, that is those derived from Hdfhd (**6**) and Htdfnd (**7**). The hydrated bis(β-diketonate) complexes $M(dfhd)_2(H_2O)$ and $M(tdfnd)_2(H_2O)$ were prepared for Cu, Ca, Sr, and Ba and were all found to sublime below 200 °C with weight loss ranging from 85 to 98% (see Table 15). In addition, the anhydrous compound $Ba(tdfnd)_2$ was reported to melt at 196 °C and volatilize at 220 °C with essentially no decomposition (residual mass by TGA ca. 1%).

The only commercially available barium compound that possesses both the desired volatility and thermal stability is

(**8**)

the complex $Ba(fod)_2$ (**8**).[54] Two groups independently, and almost simultaneously, reported the use of $Ba(fod)_2$ in the preparation of $YBa_2Cu_3O_{7-\delta}$ films.[55,56] For deposition to be carried out at ambient pressure, the precursor must be heated to temperatures above 300 °C. Unlike the other precursors discussed above, no decomposition is reported. If a low pressure (5 Torr) CVD system is employed, the sublimation temperature is significantly reduced (190 °C)

Although sufficiently volatile, the fluorinated bis(β-diketonate) compounds are unsuited for preparing high quality SMO since thin films grown using either of the fluorine-containing complexes, $Ba(hfac)_2$ or $Ba(fod)_2$, contain significant quantities of BaF_2. While the formation of BaF_2 may assist in promoting epitaxy, these films require a postdeposition hydrolysis step to remove the fluorine. Although SMO lattices appear to be forgiving enough to permit observation of acceptable T_c and J_c values on BaF_2 contaminated films, goals of electronic device fabrication demand epitaxial material. Thus, obviously postdeposition washes removing contaminating material are to be avoided.

Therefore the most critical chemical issue in the CVD of barium-containing SMO thin films is the need for thermally stable nonfluorine-containing source compounds with enhanced volatility. The desire to eliminate fluorine incorporation in deposited films has prompted the investigation of methods to increase the volatility of the nonfluorinated β-diketonates by the formation of Lewis type acid–base adducts (*see Lewis Acids & Bases*), either in situ or as stable precursor compounds. Prior to the availability of definitive structural data, it had been commonly assumed (and correctly so) that the bis(β-diketonate) complexes of Ba are coordinatively unsaturated, and therefore are prone to oligomerization and/or coordination by solvent molecules, especially water (see above). It has been postulated that neutral oxygen-containing donor molecules can limit oligomerization by making a stable Lewis acid–base complex in which the metal ion is coordinatively saturated (*see Coordinative Saturation & Unsaturation*) and, as a consequence, increase the volatility of the resultant complex.

10.1 Intermolecular Stabilization

Coleman *et al.* have reported that the addition of vapors of the free ligand Htmhd to the carrier gas stabilizes the

vaporization rate of ‘$Ba(tmhd)_2$’ so that its vapor pressure remains constant for several hours.[57] This effect was previously observed by Fujinaga *et al.* while trying to separate β-diketonate compounds by gas chromatography.[58–61] Although decomposition of ‘$Ba(tmhd)_2$’ is reduced by the addition of excess neutral β-diketone, high temperatures (280–300 °C) are still required to volatilize the precursor.

The first report of enhanced volatility of a barium source compound was made by Spee, Mackor, and coworkers, who noted that thermally stable complexes can be synthesized using $Ba(hfac)_2$ and a neutral coordinating donor ligand such as a polyether, $MeO(CH_2CH_2O)_nMe$ ($n = 1–4$) (Figure 9).[62–66] These complexes show an increased volatility at reduced pressures relative to their uncomplexed parent compounds. The best results were obtained with $Ba(hfac)_2[MeO(CH_2CH_2O)_4Me]$, which becomes volatile at 150 °C at 0.03 Torr. Despite the increased volatility of the barium source, the films deposited still contain significant quantities of BaF_2, and there has been no report that the nonfluorinated ‘$Ba(tmhd)_2$’ can be volatilized by this method. This approach has been expanded by others.[67,68] Although demonstrative of the desire of barium to achieve coordination numbers of 8–12, this new chemistry has not led, at this point, to a reported volatilization of fluorine-free barium compounds.

Other workers have added THF or H_2O to the carrier gas stream in efforts to affect the requisite vapor pressure increase in $Ba(\beta\text{-diketonate})_2$ compounds.[69–71] The objective of all these experiments was to coordinatively saturate the barium atom in the vapor phase by incorporation of the lone pair electrons on the oxygen atoms of the neutral ligands into the bonding sphere of the metal. At the temperatures demanded for vapor transport, the equilibrium for dissociation of these ligands is rather unfavorable; therefore, any anticipated gain will be minimal.

A more dramatic change in volatility and stability of barium bis(β-diketonate) complexes is seen when a nitrogen-containing base, such as an amine or ammonia, is added to or used as the carrier gas, instead of an oxygen donor.[72] It has been reported that addition of a nitrogen-containing base to the carrier gas causes the barium source to melt between 70 and 100 °C and to become volatile between 130 and 230 °C (1 atm), without any visible decomposition, depending on the amine used. One difference between the nitrogen and oxygen donor ligands is that, while stable, isolable complexes were obtained between the oxygen donor ligands and barium bis(β-diketonate) complexes, no such species were initially reported for amines or ammonia. Nitrogen-free films of barium oxides have been deposited at 500 °C under ambient pressure, with NEt_3 vapor added to the nitrogen/oxygen carrier gas, while for the barium precursor, ‘$Ba(tmhd)_2$’, the temperature was maintained at 130 °C.[73]

Subsequent to the initial report of enhanced vapor transport of $[Ba(tmhd)_2]_x$ by addition of NH_3 to the carrier gas, it was discovered that an isolable compound is formed between these two species (equation 40). The X-ray diffraction crystal structure of $[Ba(tmhd)_2(NH_3)_2]_2$ indicated it to be a highly symmetric dimer (Figure 10). The localized geometry around the eight-coordinate barium atoms is nearly perfectly square-antiprismatic. The coordinated ammonia is not retained upon vapor transport. Thus, in all probability, it is the primary purpose of the added $NH_3(g)$ to break up $[Ba(tmhd)_2]_x$ from the solid and transport it as $[Ba(tmhd)_2(NH_3)_2]_2$, or some other comparably lowered nuclearity species, in the vapor phase.

$$[Ba(tmhd)_2]_n \underset{-NH_3}{\overset{+NH_3}{\rightleftharpoons}} [Ba(tmhd)_2(NH_3)_2]_2 \qquad (40)$$

Several additional examples of intermolecular stabilization have been reported. Pez[74] has prepared $Ba(hfac)_2$(18-crown-6) and Gléizes[75] has obtained the structure of $Ba(tmhd)_2(MeOH)_2$. The isolation of $Ba(tmhd)_2(TMEDA)_2$ (Figure 11) has been achieved as well, although the vapor-phase composition of this species was not determined.[76]

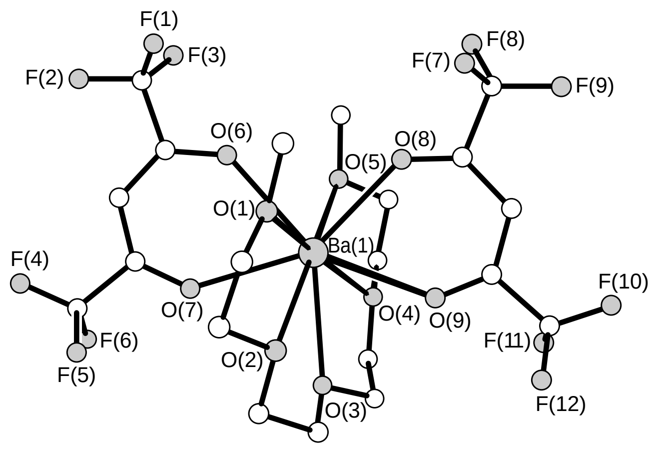

Figure 9 The molecular structure of $Ba(hfac)_2[Me_3O(CH_2CH_2O)_4Me]$

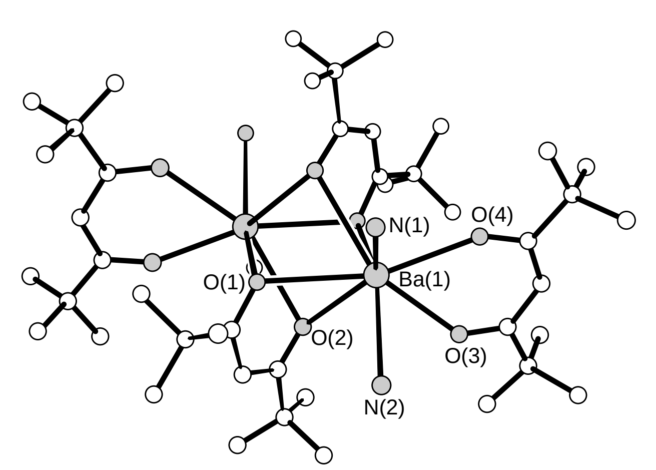

Figure 10 The molecular structure of $[Ba(tmhd)_2(NH_3)_2]_2$

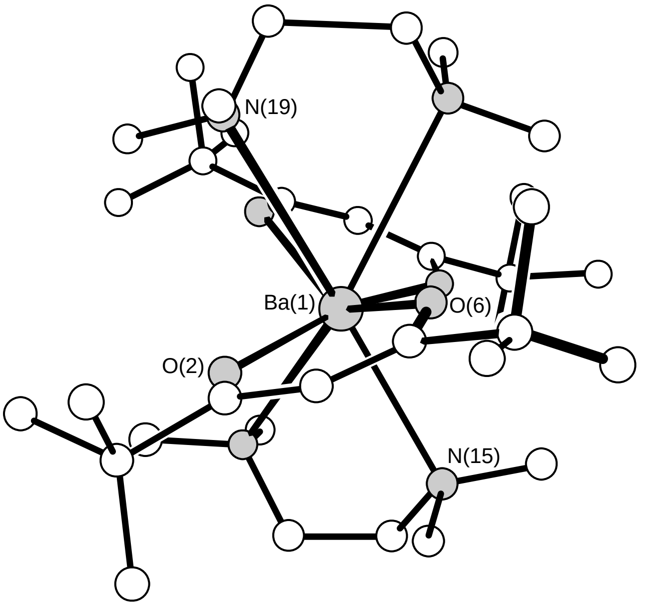

Figure 11 The molecular structure of $Ba(tmhd)_2(tmeda)_2$

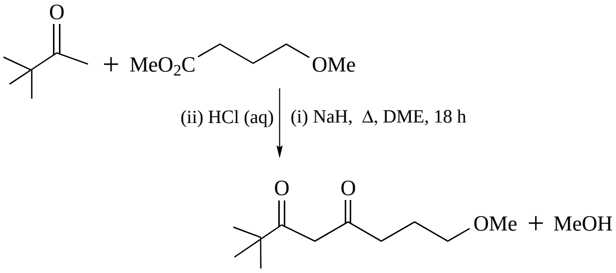
Gléizes[77] quite recently has prepared $Ba(tmhd)_2(MeOH)_2(H_2O)_2$ and reports it to be stable to repeated vapor transport without decomposition at 10^{-3} mmHg and 80 °C.

It is important to note that in none of these examples of intermolecularily stabilized barium bis(β-diketonate) complexes was found complete achievement of the criteria for CVD precursors for SMO given at the outset of this section. Therefore, other routes had to be explored in the search for the required higher volatility, higher stability vapor transport vehicles to be employed for the heavy group 2 elements desired for electronic materials applications.

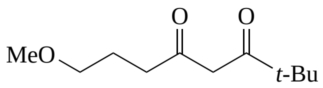
10.2 Intramolecular Stabilization

Whereas each of these above-described new compositions offered significant advantages over existing CVD sources, each also suffered some limitation that prohibited widespread exploration in the preparation of thin films (Table 15). In a radical departure from more traditional routes, the preparation of a new class of ligands, namely the β-diketo ethers, and their utilization in the formation of novel families of both main group and transition element complexes, has been investigated.[78]

Building in parallel upon the discoveries of the lowering of the molecularity of $[Ba(tmhd)_2]_{3,4}$ by intermolecular addition of Lewis bases (see above), and of the isolation of *monomeric* clam-shell oligoether alkoxides (see below),[79,80] the successful incorporation of intramolecular stability, in the form of a 'scorpion-tail', on to the well-known β-diketonate ligand backbone was achieved. The synthesis of the first example of such a ligand, Hdmmod (**9**), is a straightforward Claisen condensation (equation 41). While this procedure currently is unoptimized, it proceeds in sufficient yield (ca. 66%) to permit useful exploration of the properties of $[Hdmmod]^-$ as a potential ligand upon deprotonation at the acidic methylene position between the two carbonyl groups.



(41)



(**9**)

Following the strategy depicted in equation (42), $Cu(dmmod)_2$ was prepared from the deprotonated ligand and a Cu^{II} salt. The molecular structure of the product was determined by X-ray diffraction (Figure 12). The ligands pack over each other in the unit cell and an intermolecular fifth oxygen coordination distance of 2.98 Å is observed. The in-plane Cu–O distances are all 1.97 ± 0.03 Å and the observed geometry is almost perfectly square planar (deviation <0.02 Å). The λ_{max} in the UV (298 nm) does not indicate any significant presence of a five-coordinate square-based pyramid species in solution, when compared with $Cu(acac)_2$ (295 nm),

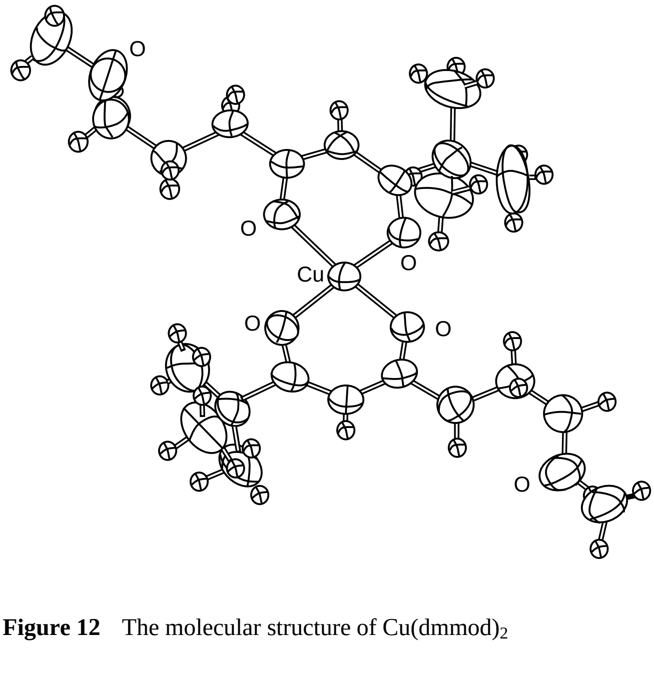


Figure 12 The molecular structure of $Cu(dmmod)_2$

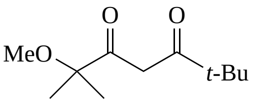
a known four-coordinate square-planar complex.[2] Thus, at this time, the observation of the presence of a rather weak fifth oxygen atom interaction with each copper center in the solid state may be explained as being the consequence of molecular packing, and not strongly dominated by tightly bound intermolecular interactions.

$$2\text{Hdmmod} + \text{Cu(NO}_3)_2 \xrightarrow[\text{EtOH/H}_2\text{O}]{\text{2KOH}} 2\text{KNO}_3 + \text{H}_2\text{O} + \text{Cu(dmmod)}_2 \qquad (42)$$

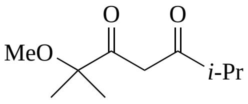
The barium bis(dmmod) complex is readily prepared by a redox reaction combining elemental barium with Hdmmod (equation 43). Purified by distillation of the excess Hdmmod, $Ba(dmmod)_2$ was identified to be authentic by elemental analysis, and found to be monomeric in benzene solution. Examination of the literature reports currently available indicates that this represents the first observation of an ambient condition liquid barium compound that is based on β-diketonate ligands.[81] Utilizing the data, it would appear that the metal center is six coordinate. Examination of space-filling molecular models lends some credence to this suggestion.

$$\text{Ba} + \text{xs Hdmmod} \longrightarrow \text{Ba(dmmod)}_2 + \text{H}_2 \qquad (43)$$

Although not reported as anhydrous compounds, $Ba(L)_2(H_2O)_n$ have been prepared for HL = Htmmhd (**10**) and Hdmmhd (**11**).



(**10**)



(**11**)

11 ADDITIONAL GROUP 2 ELEMENT COMPOUNDS

While research into SMO film growth has been conducted almost exclusively with the above-described bis(β-diketonate) complexes, an emerging emphasis is being placed on the development of alternative classes of group 2 compounds; some of these new efforts are discussed here.

11.1 Metal Halides

One report at the fall 1988 Materials Research Society Meeting,[82] during the early days of the investigation of the preparation of thin films of the SMO, described the utilization of MI_2 species as CVD sources. This preliminary disclosure does not appear to have been followed up on by subsequent workers. However, it is important to realize that the use of fluorinated β-diketonates (see above) has always been found to result in the primary deposition of BaF_2, and that this material is then subsequently converted in a second reaction step (hydrolysis) to the sought-after metal oxide. BaX_2(18-crown-6) type compounds also have been reported (X = Cl, Br, I, NO_3, OH, SCN) (*see* ***Macrocyclic Ligands***).[83]

11.2 Metal Amides

This class of compounds was, until recently, almost completely unexplored for the group 2 elements. Lappert's treatise on metal amides gives brief mention to the existence of such species.[84] Although the compounds have not yet been proven as precursors for metal oxides, several examples of compounds employing the bis[bis(trimethylsilyl)] ligand were discussed above in the section on compounds formed between group 2 elements and group 15 elements. Perhaps there will be some additional work here, which is directed towards SMO CVD, that will eventually come out from this same approach.

11.3 Metal Carboxylates

Apblett and Gueorguieva[85] have investigated the synthesis of novel low-temperature metal–organic deposition precursors for BaO, Y_2O_3, and CuO. Substantial improvement in the pyrolysis process over simple carboxylates has been realized via the rational design of the molecular precursors so that the ligands decompose readily into small, volatile fragments. One promising ligand is Hhipa (**12**), the metal complexes of which are readily prepared by reaction of the metal chlorides with the sodium salt of the carboxylate (equation 44). The calcium compound $[Ca(hipa)_2(H_2O)]_\infty$ has been characterized

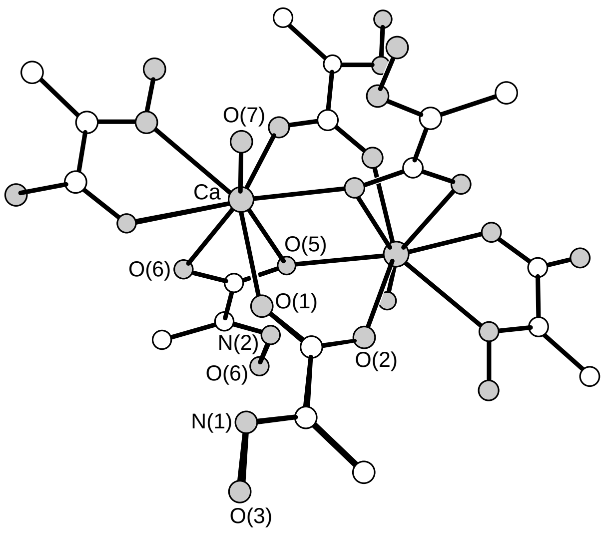


Figure 13 Section of the infinite chain structure of $[Ca(hipa)_2(H_2O)]_\infty$

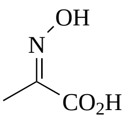
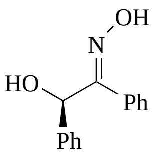
by X-ray crystallography (Figure 13).

$$MCl_x + xNa(hipa) \longrightarrow M(hipa)_x + x\ NaCl \qquad (44)$$

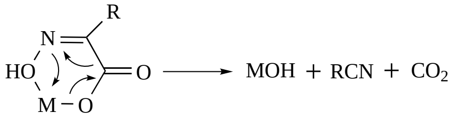


(**12**)



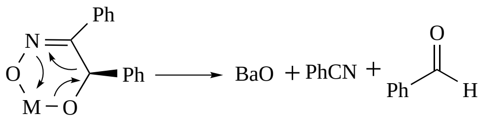
(**13**)

All of these complexes decompose cleanly at low temperature to produce acetonitrile, carbon dioxide, and initially, the metal hydroxide (equation 45). The decomposition temperatures are 144, 176, and 198 °C for Ba, Cu, and Y, respectively. In the case of copper and yttrium, the final product is the metal oxide produced by the dehydration of the hydroxide, while barium hydroxide recombines with carbon dioxide to yield the carbonate. Barium carbonate formation can be avoided, however, by use of a different ligand that avoids carbon dioxide formation. Benzoin α-oxime (Hbo) (**13**) has been found to be a quite suitable diprotic ligand for this purpose. The barium salt is easily prepared by reaction of the oxime with the metal dihydride (equation 46), and it decomposes cleanly to barium oxide by loss of benzaldehyde and benzonitrile at 250 °C (equation 47).



(45)

$$BaH_2 + Hbo \longrightarrow Ba(bo) + 2H_2(g) \qquad (46)$$



(47)

The crown ether complexes (*see Crown Ethers*) of barium carboxylates, $Ba(O_2CR)_2$(18-crown-6), have been isolated;[86] however, no studies have been reported of their suitability as BaO precursors.

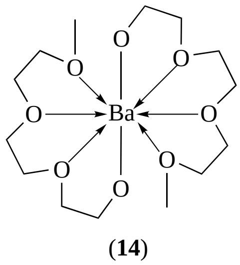
12 ELECTRONIC MATERIALS CONTAINING GROUP 2 ELEMENTS

Several members of the $MM'O_3$ class of ternary metal oxides adopt the perovskite-type ($CaTiO_3$) structure and are sought as worthy target materials possessing ferroelectric properties (*see Ferroelectricity*).[87,88] Among the more widely investigated members of this class are $BaTiO_3$ and $SrTiO_3$. Clearly, use of these materials as potential memory device components demands the presence of a viable processing route to electronically pure material. Traditional ceramic methods (*see Ceramics*) for powder compaction, followed by organic binder burnout, serve unsatisfactorily in this capacity.[89] Bulk single-crystal growth for all necessary compositions is not yet mature enough to provide the quantities of high quality material demanded for evaluation purposes. Thus, investigators have been forced to examine alternate synthetic schemes. Closed space vapor transport is, in general, not well suited to metal oxide growth. It does not appear that any work has been reported in the area of liquid phase epitaxy of these systems. Certainly, this would be a worthy pursuit and should be explored for its potential.

13 GROUP 2 ELEMENT ALKOXIDES

While the earliest work in this area was from Bradley,[90] Chisholm and Caulton, and their group, have recently prepared both cluster alkoxides and siloxides that have some increased solubility properties, for example, $HBa_5(O)(OPh)_9(THF)_8$, $H_3Ba_6(O)(O\text{-}t\text{-}Bu)(OCEt_2CH_2O)(THF)_3$,[91] $H_4Ba_6(\mu_6\text{-}O)(OCH_2CH_2OMe)_{14}$,[92] $Ba_3(OSiPh_3)_6(THF)$,[93] and $Ba(Hdbp)_2(OCH_2CH_2NMe_2)_2(HOCH_2CH_2NMe_2)_2$.[94] However, as cluster aggregates, they both are coordinatively unsaturated and involatile. The former is addressed by parasitic addition of reaction medium, whereas the latter is an intrinsic property and therefore chemically unaddressable (*see* ***Sol–Gel Synthesis of Solids***). Oligomeric species have been prepared by Hubert-Pfalzgraf[95] based on triethanolamine. Buhro[96] has isolated a mega-cluster, $Ca_9(OCH_2CH_2OMe)_{18}(HOCH_2CH_2OMe)_2$, from short-tail base-stabilized alkoxides. This work has recently been extended by Page to include mixtures of Ba, Y, and Cu for sol–gel processing.[97]

The formation of the first monomeric heavy group 2 element alkoxides has been postulated based on oligoether ligands (**14**), the molecularity of which is supported by cryoscopic molecular weight data.[80] This contrasts with the initial publications of $Ba(OR)_2$ preparations.[90] When a saturated hydrocarbon is the parent alcohol, apparently only involatile and insoluble alkoxides are formed. Quite recently, a benzene soluble bis(aryloxide), $Ba(bht)_2(THF)_2$, has been prepared; however, no volatility was reported.[98]



(**14**)

Historically, the first alkoxides of Ca, Sr, and Ba isolated were those containing sterically compact groups (OMe, OEt), which formed $[M(OR)_2]_n$ derivatives that are presumably oligomeric or polymeric.[90] The use of somewhat more sterically bulky groups has led, in recent years, to the isolation of a variety of structurally characterized cluster complexes, such as $Sr_4(OPh)_8(PhOH)_2(THF)_6$,[99] $\{Ba_4(\mu_4\text{-}O)[\mu_2\text{-}OC_6H_2\text{-}2,4,6\text{-}(CH_2NMe_2)_3]_6\}\cdot 3(\text{toluene})$,[100] and $HBa_5(O)(OPh)_9(THF)_8$.

The number of crystallographically characterized monomeric or dimeric group 2 bis(alkoxides) or bis(aryloxides) also has expanded, and includes complexes with a diverse array of ligand geometries. They include the calcium and barium aryloxides $M(bht)_2(THF)_3\cdot(THF)$,[101,102] the related strontium complex $Sr(OC_6H_2\text{-}t\text{-}Bu)_2(THF)_3$,[103] calcium bis(2,4-dinitrophenoxide),[104] barium bis(2,4,6-trinitrophenoxide),[105] hydrogen-bonded $Ba(2,6\text{-}t\text{-}Bu_2C_6H_3O)_2(HOCH_2CH_2NMe_2)_4$,[106] and the alkoxides $Ca(OR)_2(THF)_3\cdot(THF)$, $[Ca(\mu\text{-}OR)(OR)(THF)]_2$ (OR = $OC(C_6H_5)_2\text{-}4\text{-}Cl\text{-}CH_2C_6H_4$),[102] $Ba[OC_2H_4)(HOC_2H_4)_2N]_2\cdot 2EtOH$,[107] $Ba_2(OCPh_3)_4(THF)_3$,[108] and the siloxide $Ba_2(OSi\text{-}t\text{-}Bu_3)_4(THF)$.[108] It is noteworthy that the calcium, strontium, and barium $M(OAr)_2(THF)_3$ complexes are isostructural; just as with the $[M\{N(SiMe_3)_2\}_2]_2$ complexes, the interligand interactions in the bis(aryloxides) (apparently) override the structural differences that might be expected to accompany the ca. 0.35 Å change in metal radius (Table 7).

Despite the interest in group 2 bis(alkoxides) and bis(β-diketonates) as precursors to metal oxides via CVD routes, systematic studies that correlate their structure and volatility still are few. The solid-state structures of many bis(alkoxides) used for CVD work are not known, and the identity of the materials may vary greatly depending on their mode of preparation. As shown above, the widely used bis(β-diketonate) derivative '$Ba(tmhd)_2$' for example, has that formula only if prepared under rigorously anhydrous conditions; in the presence of moisture the pentanuclear cluster $Ba_5(tmhd)_9(H_2O)_3(OH)$ can form. Such uncertainties make the identification of trends in volatilities difficult.

The sublimation temperatures (onset at 10^{-5} Torr) for a series of barium bis(alkoxides) and bis(fluoroalkoxides) are plotted with the corresponding formula weights in Figure 14.[109] The greater bulk (and presumably lower oligomerization) associated with the larger alkoxides appears to counterbalance the increases in molecular weight, so that the sublimation temperatures of $Ba(O\text{-}t\text{-}Bu)_2$ and $Ba[OCH(t\text{-}Bu)_2]_2$, for example, differ by only 10 °C, despite the latter's nearly 50% greater weight. The two fluoroalkoxides are remarkably volatile for their masses; the perfluoro-t-butoxy derivative sublimes 10 °C higher than the parent compound, although the relative molecular weight has risen from 284 to 607. Increases in the volatility of complexes with fluorinated ligands have been observed in bis(β-diketonate) systems as well, and presumably stem from the disruption of intermolecular interactions.[110] Interestingly, the barium tetrahydrofurfuroxide decomposes

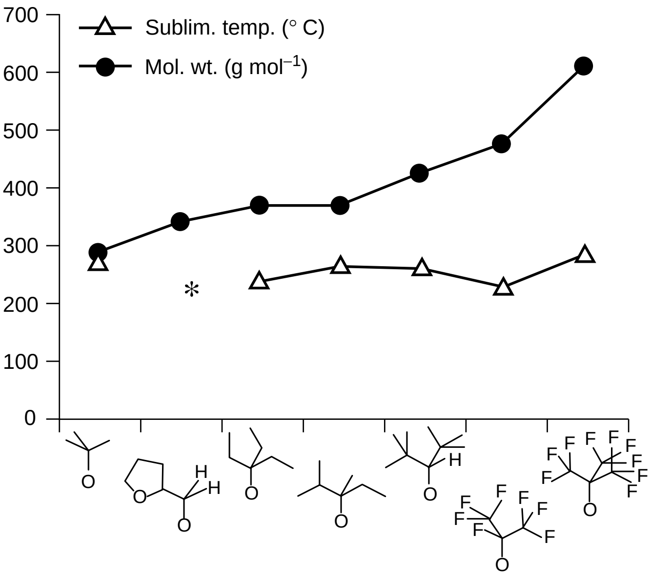


Figure 14 Plot of vapor pressure as a function of molecular weight for a series of barium bis(alkoxides) and bis(fluoroalkoxides)[26]

before subliming; the C_4H_8O ring probably binds to adjacent complexes, increasing the effective molecular weight and suppressing volatility.

Comparisons of the volatility of adducts of alkoxides with the relevant unsolvated species are difficult. For example, as discussed above, the volatility of $[Ba(tmhd)_2]_{3,4}$ is increased in the presence of excess free ligand, possibly by suppressing ligand loss in the gas phase through adduct formation.[42,57] No actual adducts of the form '$Ba(tmhd)_2\cdot(Htmhd)_n$' have been isolated from these experiments, however. The presence of ammonia has also been found to increase the volatility of $Ba(tmhd)_2$ under CVD conditions, and the NH_3 adduct $[Ba(tmhd)_2\cdot 2NH_3]_2$ has been independently prepared and structurally characterized.[43] On sublimation the coordinated NH_3 is lost, however, and the volatility of the parent compound and the adduct are nearly the same. Loss of coordinated neutral ligands on sublimation often renders the stoichiometry of gaseous species uncertain, although mass spectroscopic techniques have been used in attempts to identify oligomeric bis(alkoxides) and bis(β-diketonates) in the vapor phase.[42,109,110]

1 INTRODUCTION

1.1 Definition of the Topic

In the metallurgical sense, alloys are mixtures of metals with each other or with certain nonmetals, resulting in substances that may be single phase or multiphase. It should be noted that the term alloy, as referring to a macroscopically homogeneous mixture, is also used for nonmetals such as ceramics and semiconductors (e.g. Si–Ge alloys) and polymers (e.g. block copolymers); these alloys, however, are outside the scope of the present article.

The principal areas of science and engineering dealing with metals and alloys are chemical metallurgy and physical metallurgy. Subjects of chemical metallurgy are the extraction and refining of metals, liquid metal treatments, corrosion protection, and surface treatment of metals.[1] The study of metals and alloys with respect to their crystal structures, constitution, microstructure, and properties (especially, mechanical) is the subject of physical metallurgy.[2,3]

Although physical metallurgy had one of its roots in the theory of phase equilibria, which is a part of physical chemistry (the other root of physical metallurgy was metallurgical practice), it is a fact that, until recently, alloy chemistry and the science of alloys have not been major research subjects of inorganic chemists. This has at least two major reasons. First, the languages of bond formation are different for chemists, physicists, and metallurgists:[4] chemists tend to think in terms of Hückel theory based on the overlap of angularly dependent valence orbitals represented in real space and are not very familiar with the physicist's band structure language expressed in reciprocal space; alloy theorists come from physics and calculate cohesive and structural properties by solving local density functional (LDF) Schrödinger equations; metallurgists regard atoms as 'fuzzy balls' interacting via pair potentials. These three approaches, the number of atoms that can be treated by each of them, and the accuracy of the results obtained are shown in Figure 1.[4]

The second and perhaps most important reason is that the central concept of alloy work, namely, the microstructure and its modification by alloying and treatment, is not a chemical concept; there is no equivalent for it in chemistry. Only recently, with the rising interest in solid-state chemistry, has this begun to change; chemists adopt the band language,[5] and, largely through the use of inorganic compounds as precursors for microelectronic materials[6] and the increasing involvement of chemists in ceramics science,[7] materials chemistry[8] has become a branch of inorganic chemistry. One may now anticipate an increasing interest of chemists in the synthesis and properties of metallic alloys, motivating the comprehensive treatment presented here.

1.2 Alloy Constitution

Microstructurally, alloys are composed of alloy constituents that include alloy phases and, in some cases, unalloyed metals. Crystalline alloy phases can be subdivided into intermetallic phases, metal–nonmetal compounds such as borides or carbides (*see* ***Borides: Solid-state Chemistry***; ***Carbides: Transition Metal Solid-state Chemistry***), and terminal or complete solid solutions.

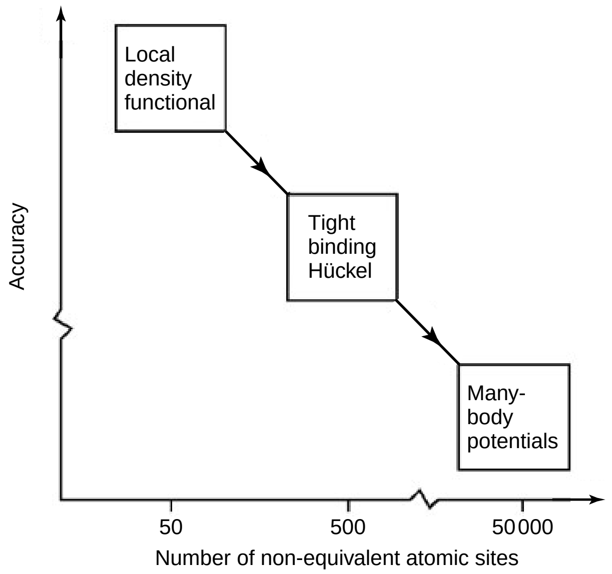

Figure 1 Schematic representation of the decrease in accuracy with increasing number of nonequivalent atomic sites that can be treated computationally by different levels of approximation. (Ref. 4. Reproduced by courtesy of D. Pettifor)

Intermetallics are stoichiometric or nonstoichiometric phases composed of two or more metallic components[9] (with possible admixtures of nonmetals as stabilizers) that crystallize with structures other than those of their metallic components. In the following, reference is often made to intermetallics, but in this article they will not be treated structurally further.

The extent and type of solid solution formation depends on several parameters.[2] If both component elements are isostructural and, in addition, similar in size, valence electron concentration, and electronegativity, a series of complete substitutional solid solutions may form across the diagram, as for V–Cr, Ni–Cu, Cu–Au, and Sb–Bi; otherwise, limited terminal solid solutions form which are substitutional for elements with a solute−solvent size difference less than ±15%, but may be interstitial for element pairs with size ratios of more than ±20%, for example, for Fe(C) or Pb(Au) (here, the bracketed element is the solute).

We also list three other alloy phase types of current interest that are not treated here in detail. Quasicrystals are alloy phases partially or completely lacking translational symmetry (*see* ***Quasicrystals***); they form both equilibrium and nonequilibrium alloy phases. Metallic glasses[10] lack crystalline symmetry entirely; they are always metastable and generally require gas-phase deposition or rapid solidification[11] to be retained, although in some cases their equilibration kinetics are so slow that they can be prepared in bulk from the melt (bulk metallic glasses).[12]

A third alloy state of great current interest is the mixed state containing both crystalline and amorphous metals or alloys, which is seen when the crystallite grain size decreases into the nm range, forming nanometer scale or, in short, 'nanocrystalline' alloys with large proportions of noncrystalline material on the grain boundaries (Figure 2) and new properties. Thus, nanocrystalline materials may exhibit superplasticity,[13] novel electronic properties,[14] or enhanced hydrogen storage capabilities (see the following text).

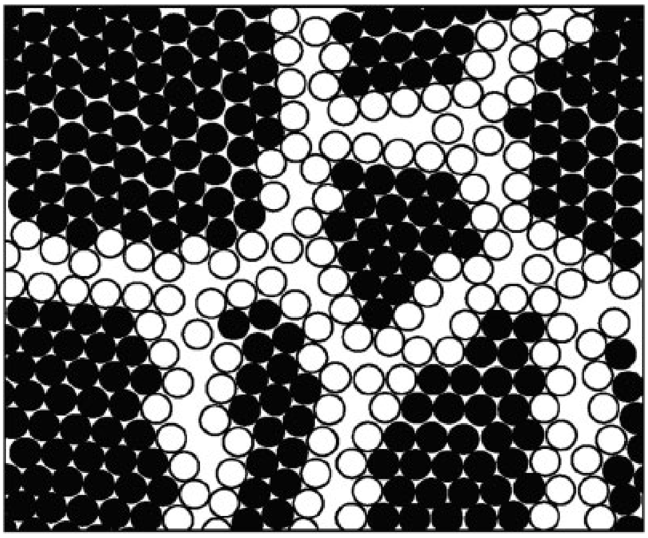

Figure 2 Atomic structure of a two-dimensional nanocrystalline material computed using pair interaction potentials. The atoms in the central portions of the nanocrystals are indicated in black; atoms in the nanograin boundary regions are represented by open circles. (Ref. 13. Reproduced by permission of Springer)

The properties of an alloy are primarily determined by those of its constituent alloy phases; however, as stated, the microstructure, that is, the phases' grain size, perfection, distribution, and so on, which is due to the thermal and mechanical history of the alloy, plays a major, modifying role. It is in this area that modern methods of alloy processing have had their most visible results, as will be seen from the review of specific types of alloys in Sections 3−5.

2 ALLOY PHASES AND PHASE DIAGRAMS

2.1 Alloy Phases

Alloy phases will be described structurally using the following multiple (and somewhat redundant) nomenclature: Name(s); Prototype (Pearson Symbol, Structure Report Symbol). As an example: CuZn (β-Cu–Zn, β-brass); CsCl (cP2, B2) type. (Note: The Pearson symbol already contains the crystal system and Bravais lattice). Alloy phase compilations with structural data are available.[15]

With reference to the classification of alloy phases given above, only a small amount of structural information on alloy phases is required for the alloys treated in this article. Disordered solid solutions are based on the terminal elements and therefore mostly belong to the three most common elemental structure types: Cu (cF4, A1) type, Mg (hP2, A3) type, and W (cI2, A2) type. Following very common usage, these three types are also occasionally referred to in the text as fcc (=face-centered cubic), hcp (=hexagonal close packed), and bcc (=body-centered cubic), respectively, although the rigour of these designations leaves something to be desired. The alloy phases of interest in the following sections on commercial and developmental alloys will be introduced as they are treated.

Next, the current status of the theoretical understanding of alloy phases is reviewed. The techniques available for first-principles calculations for alloys (and alloy phase equilibria) up to the 1990s are listed and reviewed by de Fontaine.[16] Current thinking is reviewed by Pettifor[17] who is also a major contributor to the understanding of alloy properties by fundamental computations.

For perfectly ordered crystals at absolute zero, solutions to the Schrödinger equation can be calculated on fast computers using density functional theory (DFT) based on the self-consistent local density approximation (LDA);[17] simplifying procedures using different basis functions include augmented

plane wave (APW), augmented spherical waves (ASW), the Korringa–Kohn–Rostoker (KKR), and the linear muffin-tin orbital (LMTO) methods, as well as further developments originating from these designed to include variable axial ratios. Transition metals can be handled by modern versions of the tight binding (TB) approximation, which is derived from the linear combination of atomic orbital (LCAO) method well familiar to chemists (*see LCAO Approximation*), with semiempirical matrix elements derived from the LMTO method and treated self-consistently.

For disordered systems, the task is harder because translational symmetry is lost. The direct configurational averaging (DCA) method takes all possible local cluster configurations of given stoichiometry into account and averages them; to obtain manageable computation times, this method is used in connection with the relatively simple TB method and hence applies best to transition metals. Alternatively, 'average atoms' are created to restore translational symmetry, leading to the coherent potential approximation (CPA), a mean-field technique that is used in connection with TB, KKR, or LMTO–ASA (ASA = atomic sphere approximation).[16]

Introduction of partial order at finite temperatures adds another level of complexity and difficulty. This situation is handled by the cluster variation method (CVM) free energy functional, which is expressed as a function of multisite correlation functions, whose coefficients are obtained by the generalized perturbation method (GPM) or the embedded cluster method (ECM). All of these methods are highly computationally intensive; at present, this area is probably the principal frontier of alloy phase theory.

To work around the complexities of these calculations (which greatly multiply when multicomponent systems are involved as is the case in superalloys, see Section 3.3) an empirically useful method of alloy phase prediction, PHACOMP, has been developed;[18] its predictions are based on electron concentration rules, especially d-electron shell hole concentrations (see Section 3.3).

An attractive, semiempirical application of physical insight into alloy formation is found in classifications of alloy phase data into structure maps, quantum diagrams, and so on (*see* ***Structure & Property Maps for Inorganic Solids***) where a necessarily limited number of coordinates (one to three) must reflect the physical parameters determining the property of interest. An example is given below in the Pettifor map for Ti–Al intermetallics.[4,19] Further developments in the mapping of intermetallics are due to Ceder.[20]

2.2 Phase Diagrams, Determination, and Computation

Phase diagrams provide the thermodynamic foundation for all alloy work by presenting the equilibrium constitution of alloys. Systematic phase diagram studies were first initiated about 100 years ago, when the thermodynamic foundations of phase diagrams were being established; an additional impulse came with the start of systematic crystal-structure studies following the introduction of X-ray crystallography, beginning in the 1920s.[9] Since then, vast efforts have been spent on the experimental determination of phase diagrams. As a result, for common elements such as Fe, Cu, C, and so on, almost every binary $T-x$ phase diagram is known; in the case of many other elements, constitution diagrams are known at least for their binary systems with some elements representing every group of crystal chemically similar elements, such as the early long period transition metals, noble (platinum group) metals, or the rare earth metals. Work on ternaries has also proceeded well. Binary alloy constitution diagrams have been compiled.[21,22]

From an economic viewpoint, the classical determination of alloy phase diagrams is a laborious process, involving alloy preparation and heat treatment, compositional, structural, and microstructural analysis (and, even then, not yielding reliable phase boundary information at low temperatures due to kinetic limitations). While this investment is justified for alloys of major technical importance, the need for better economics has driven an effort to use alternative methods of phase discovery such as multiple source, gradient vapor deposition or sputter deposition followed by automated analysis; alternatively, multicomponent diffusion 'couples' are used to map binary or ternary alloy systems structurally and by properties (see Section 6). These techniques have been known for decades, but they have been reintroduced more recently as high-efficiency methodologies to create 'compositional libraries' by a combinatorial approach,[23] inspired perhaps by the recent, general introduction of combinatorial methods in chemistry.

Until recently, one might have considered this immense collection of experimental information as one of the major experimentally gathered, but theoretically unexplained, bodies of data in all of the chemical sciences. As shown above, however, in recent years major progress has been made on the theory of alloys and in establishing empirical or semiempirical correlations for alloy phase formation; this, in turn, has benefited phase diagram prediction, which remains an important goal of computational alloy theory. Two principal approaches exist, which are presently in the process of slow convergence.

In the ideal case, one would have ab initio calculations (such as those described above) for all competing crystalline phases and the liquid (or liquids) involved, yielding their free energies as functions of composition and temperature and enabling standard common-tangent constructions to be made. However, since up to now first-principles calculations having the accuracy required to differentiate between competing phases are only possible for crystalline phases, complete phase diagrams (which must include the liquid) cannot yet be handled in this way.[4,16] Nonetheless, it is very valuable to be able at least to calculate the solid-state portion of relevant phase diagrams, thereby obtaining information about metastable phases, phase boundaries, phase decompositions, and ordered phases (superstructures) that are not measurable

experimentally because of slow kinetics at low temperatures. While this field of work is just opening up, it can be expected to produce important results.

At present, inclusion of the liquid into such calculations requires use of fitted free energy curves, such as those used in the more empirical approach described below, but as liquid alloy theory advances, this situation will improve. Thus, complete phase diagram calculations based on pseudopotential calculations have been presented by Hafner.[24]

The other approach, which so far has had the greater practical impact, is primarily empirical. The CALPHAD (from CALculated PHAse Diagrams) approach was pioneered by L. Kaufman,[25] a more recent presentation is by Saunders and Miodownik[26] The work of the CALPHAD group focuses on calculations based on thermochemical data such as those compiled by the Scientific Group Thermodata Europe (SGTE),[27] the ASM–NBS Alloy Phase Data Activity, PHACOMP (see above), and CALPHAD itself, but also uses the results of ab initio structural energy calculations for elements and compounds as these become available.

Phase diagrams are calculated from these data using regular solution or other appropriate solution models. Some of the great strengths of the CALPHAD approach are that it provides immediate, approximate diagrams for new systems of interest and that it can be readily extended to ternary and higher order systems that would be prohibitively complex and expensive to study experimentally. A comparison of the observed and calculated Co–V phase diagrams is shown in Figure 3.[25] To construct this diagram, the existence and structures of the intermediate phases Co_3V, σ, and CoV_3 were considered as given; the pair potential (PP) approach mentioned in Section 1.1 as preferred by metallurgists has been used in the energy computation.

Pettifor[17] showed how density functional theory (DFT, see above) may strengthen the CALPHAD conclusions for complex alloy systems by providing information on compositionally ‘nearby’ metastable alloy phases that may affect alloy properties.

3 TECHNICAL ALLOYS AND THEIR APPLICATIONS

In the following, a survey of the principal types of alloys in current use is provided, with emphasis on those alloys designed for advanced metals technology, as well as the directions of current development. An excellent introductory source on these alloys and on further developments in this area is Smith,[28] from whom much in this section is drawn.

3.1 Steels

Steels of many types constitute 90% of the world’s use of metals. Carbon steels are the backbone of the steel industry;

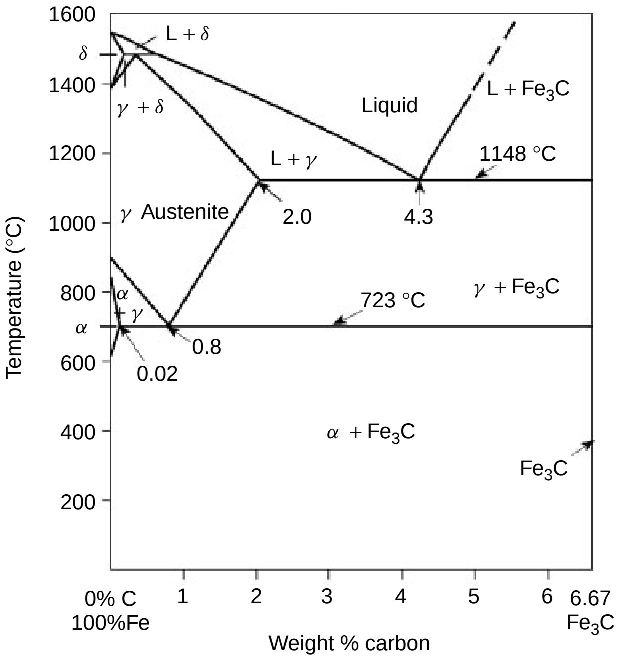

Figure 4 The Fe–Fe_3C metastable system underlying the carbon steel making technology. (Ref. 28. Reproduced by permission of McGraw-Hill)

the underlying Fe–C phase diagram (Figure 4) is therefore without doubt the most important alloy constitution diagram. Its features include the wide phase field of fcc Cu (cF4, A1) type γ-Fe (austenite), which terminates in a eutectoid decomposition of austenite into bcc W (cI2, A2) type β-Fe (ferrite) and the (metastable) compound Fe_3C (oP16, DO_{11}) type (cementite). Much of the art of steelmaking consists of controlling and modifying the formation of this eutectoid, or preventing it altogether by formation of the hard and brittle tetragonal martensite phase (see also Hornbogen[29]).

Alloy steels form the next category; they contain small levels (up to about 3%) of transition metal additives such as Ni, Cr, Mo, Mn, or Si in addition to C; the principal effect of these elements is to increase hardenability and toughness, for example, by influencing martensite formation. Even higher alloying contents, especially of Cr (up to 25%) and Ni (up to 20%) are used to obtain ferritic, martensitic, or austenitic stainless steels (with Cr favoring ferrite and Ni promoting austenite formation); the principal wrought austenitic stainless steel (AISI-304) contains 19% Cr, 9% Ni, and $<0.08\%$ C.

Despite the maturity of the steelmaking field, processing advances continue to be made. Thus, intricate thermal processing paths designated by self-explanatory terms such as 'austempering' and 'marquenching' have improved the impact resistance of plain-carbon steels. Further, two classes of high-strength, low-alloy (HSLA) steels have been developed in recent years, and such steels now play important technological roles. In one case, microalloying (of plain-carbon steels) with very small amounts of strong carbide formers such as Nb, Ti, and V has given these steels a finer grain structure associated with much greater strength (making use of a general linear correlation between yield strength and the reciprocal square root of the grain size; this is the Hall–Petch relationship).[3] Another new class consists of dual-phase steels containing hard martensite in a soft ferrite matrix, producing high values of tensile strength and total elongation. 'Maraging' (from *mar*tensite and *age* hardening) produces ultra-high strength, structural low-C steel with 18% Ni, 10% Co, 4% Mo, and 1% Ti by aging a highly martensitic steel at 500 °C for several hours, thereby forming ultrafine strengthening zones of Ni_3Mo and Ni_3Ti lying along dislocations and martensite lath boundaries. Finally, in the area of stainless steels, ferritic–austenitic duplex structures have also produced an incremental property improvement in yield strength and corrosion resistance.

Combinations of sophisticated alloying and thermal treatment thus continue to advance the science of mankind's principal structural metal.

3.2 Aluminum Alloys

Wrought heat-treatable Al alloys contain Mg, Zn, and Cu on the level of several percent as precipitation and solid solution hardening ingredients. The precipitation process forms nanometer size Guinier–Preston (GP) zones that are coherent with the matrix and produce the age-hardening effect first observed in 1906 in binary Al–Cu alloys. An alloy constitutional requirement for age hardening is a terminal solid solubility (e.g. of Cu in Al) that sharply decreases with decreasing temperature, allowing nonequilibrium precipitates (GP zones) to form from a supersaturated Al-base solid solution (age hardening). Thus, the solubility of Cu in Al decreases from 5.65% at 548 °C to $<0.2\%$ at 20 °C.

The complex Al alloys mentioned above are the mainstay of the airframe industry; however, the search for ever lighter and stronger Al alloys has recently led to the development of aluminum–lithium alloys (with $\sim$2% Li), which have a 10% higher elastic modulus and an 8% lower density than the current major high-strength aircraft alloy. Although elemental Li has a low density of $0.5\ \mathrm{g\,cm^{-3}}$ and is a soft, low-melting metal, upon introduction into an Al–Cu–Mg alloy it is quite beneficial to the strength-to-weight ratio. Unfortunately, this improvement is also expensive: due to the difficulties of manufacture and the cost of Li, Al–Li alloys have a price several times that of the alloys they replace.[30]

Amorphous Al alloys have been prepared by rapid solidification processing (RSP, see 6.); nanostructural alloys prepared from these glasses[10] have potential applications as high-strength, low-density alloys.[31]

3.3 Superalloys

This is the generic name for a class of Ni-, Co-, or Ni–Fe-based, heat-resistant alloys with high strength at high temperatures (up to 1100 °C). We focus here on Ni-based superalloys. They typically contain 15–20% Cr, 15%–20% Co, 4–10% Mo, 1–5% Al, 2–4% Ti and 0.05–0.20% C, and they derive their strength from the presence of a fine dispersion of refractory metal or Cr carbides of compositions M_6C, $M_{23}C_6$, and MC, an oriented γ' precipitate such as Ni_3(Al, Ti) that is coherent with the Ni solid solution matrix, and the absence of deleterious phases such as cellular carbides and embrittling σ phases. The latter is a complex, tetrahedrally close-packed (or Frank–Kasper) phase.[32] The elimination of the σ phase in modern superalloys was an early example of the use of an electron theoretical (and, with hindsight, somewhat oversimplifying) concept in alloy design: it had been noted that the σ phase occurred at a specific range of the average number of d-electron shell holes; subsequent alloys were designed such as to avoid this hole concentration range and thus to avoid σ phase formation. The PHACOMP method[18] mentioned above was specially designed for use in such applications; semiempirical PHACOMP/CALPHAD calculations have been used in gas turbine component alloy development work involving alloys with up to 9 functional elemental components.[33]

Superalloys are continuously being developed further for use at ever increasing temperatures (Figure 5) in response to the need for running engines at higher temperatures to increase fuel efficiency.[34] Milestones in the advancement of superalloy technology were reached with the development of directional

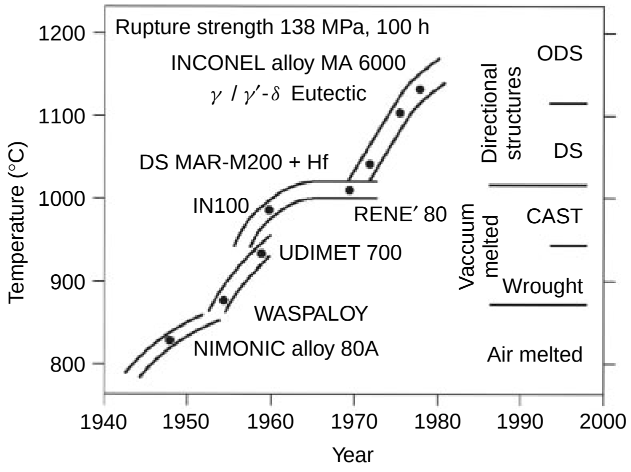

Figure 5 Progress in high-temperature engine component alloy development as a function of date, as measured by use temperature. The figure represents the service temperature at which a rupture life of 100 h would be obtained under a stress of 138 MPa. (Ref. 34. Reproduced by kind permission of Springer Science & Business Media)

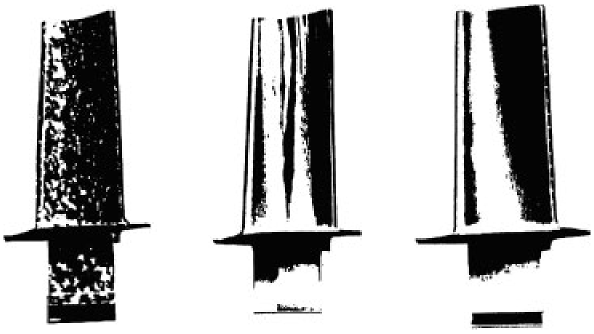

Figure 6 Advances in turbine airfoil technology from polycrystal to columnar crystal to single-crystal castings. (Ref. 28. Reproduced by permission of McGraw-Hill)[34]

casting technologies, leading from the earlier, polycrystalline turbine blades to directionally solidified, columnar grained, and then to single crystalline blades (Figure 6).[28] The latter are made by an ingenious grain selection process using a spiral solidification channel. In single crystalline material, grain boundary modifying additives are obviously no longer required, and heat treatments to reach optimum strength can be carried out without concern for coarsening grain boundary particulates that might coarsen detrimentally during treatment.

3.4 Titanium Alloys

With density and elastic modulus values between those of aluminum and iron, excellent chemical resistance, a β(bcc) → α(hcp) phase transition enabling strengthening heat treatments to be made, and ready alloyability with other transition metals and Al, Ti alloys have been developed for many uses in aerospace and the chemical industry. The principal currently used alloy is an $\alpha-\beta$ Ti alloy with 6% Al and 4% V; the next most commonly manufactured form is commercially pure, unalloyed Ti, which is also used in surgical implants. Recent developments include multicomponent alloys such as the low-creep rate $\alpha-\beta$ Ti-1100 alloy (with 6% Al, 2.75% Sn, 4.0% Zr, 0.40% Mo, and 0.45% Si) for jet engine compressors and the age-hardened Beta-C alloy (3% Al, 8% V, 6% Cr, 4% Mo, 4% Zr) with high corrosion resistance for high-temperature chloride environments.[35]

3.5 Cemental Carbides

These materials are extremely hard and wear resistant up to high temperatures (800 °C) and are used as high-speed cutting tools. They contain finely dispersed (1–3 µm size) particles of W, Ti, or Ta carbides (primarily WC) in a cobalt binder matrix (70–97.5% carbide). The direction of further development here is to produce and compound increasingly fine particulates, for example, by use of chemical precursor processes.[36]

4 STRUCTURAL INTERMETALLICS

Because of their special place in stimulating modern research on fundamental principles and the application of such principles to alloy design, we treat structural intermetallics in a special section. Due to their ordered structures and the concomitant additional bonding interactions between unlike neighbors, stoichiometric or near-stoichiometric intermetallics tend to be harder than a disordered phase of the same composition, but, at room temperature, much less ductile than such a hypothetical phase. However, some titanium and nickel aluminide intermetallics have such promising high-temperature properties that it became a challenging task for alloy designers to overcome the problem of low room-temperature ductility and absence of fracture toughness. Several causes for these deficiencies were identified, leading to different, specific alloying approaches to their remediation.[37,38]

The candidate materials are M_3Al, MAl, and MAl_3 aluminides, specifically Ti_3Al, TiAl, NiAl, Ni_3Al, and perhaps $TiAl_3$. Their structures are shown in Figure 7. It is seen that they all represent stoichiometric, ordered structures based on the three common metallic element structure types, the fcc, hcp, and bcc types (see above, Section 2.1). Compared to a material with cubic structure, hexagonal or tetragonal materials such as Ti_3Al or TiAl, respectively, have fewer available slip systems and hence, lower ductility; alloying to change their structures to a cubic one has therefore been

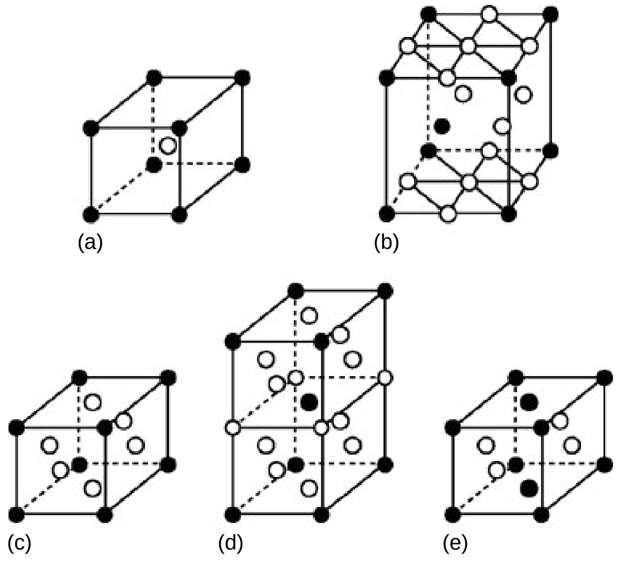

Figure 7 The unit cells of alloy phases of interest as high-temperature structural intermetallics; their structure types are: (a) NiAl: CsCl (cP2, B2) type; (b) Ti_3Al: Ni_3Sn (hP8, DO_{19}) type; (c) Ni_3Al: Cu_3Au (cP4, $L1_2$) type; (d) $TiAl_3$: $TiAl_3$ (tI8, DO_{22}) type; (e) TiAl: AuCu (tP4, $L1_{0)}$) type

considered semiempirically and theoretically and has been attempted experimentally.

One semiempirical theoretical approach has been based on structure maps (*see* ***Structure & Property Maps for Inorganic Solids***) such as the neighborhood map by Pettifor,[19,39] which is presented in a version most relevant to the issue at hand (Figure 8). These M_1–M_2–x maps, shown here for the system Ti–Al, represent selected stoichiometries for the compositions $A_{1-x}B_x$, with $x = 0$, 0.25, 0.33, 0.5, 0.67, 0.75, and 1. The plots are centered on $Ti_{1-x}Al_x$, and have as their planar coordinates the 'Mendeleev numbers' M_A and M_B of the constituents. They show the competing structure types forming in the neighborhood of the reference compound. The 'Mendeleev number' used in these maps expresses a mapping of the two-dimensional periodic table into a one-dimensional space; it characterizes the location of each element along a string run through the periodic table. If desired (i.e. cubic) phases are found in the neighborhood of the central phase, the map gives guidance in which direction along the A, B Mendeleev strings alloying should proceed. In the example chosen, it is seen that cubic phases are not found immediately near TiAl or $TiAl_3$, although for Ti_3Al the nearby (although not adjacent) phase Zr_3Al is seen to have the desired Cu_3Au type and suggests partial substitution of Ti by Zr; there are also potential substitutions with elements such as Fe or Ni that lie outside the range of this map. As mentioned above, the construction and availability of Pettifor maps has been much advanced recently by Ceder and associates.[20]

First-principles quantum mechanical calculations based on the Local Density Functional approximation have been able to obtain correctly the stable form of a given compound and to predict the energy difference between the ground state and the competing, desired Cu_3Au phase.[4] The theoretical alloy chemical approach has been complemented by many experimental studies on the effects of alloying on structure and properties.[37,38]

Another cause of poor room-temperature properties has been the grain boundary brittleness in a polycrystalline intermetallic such as Ni_3Al, which has good room-temperature strength as a single crystal. This problem was overcome when it was discovered[40,41] that minute additions of boron dramatically improve the room-temperature ductility and change the fracture mode of Ni_3Al, as seen in Figure 9.[41] Boron was found to segregate to the grain boundaries, but the mechanism of its dramatic effect is not clear. In one model it increases the cohesive strength of the grain boundaries and thus the bulk ductility (which is an unusual effect, since grain boundary segregation generally produces intergranular brittle fracture in otherwise ductile metals).[42] Another model for the boron-induced ductility effect assumes that the boron in the grain boundaries facilitates the motion of slip (the essential deformation mechanism in these intermetallic compound crystallites) across the grain boundaries, perhaps by inducing local disorder in the latter.

Briefly reviewing the technical structural intermetallic alloys, a commercial alloy based on Ni_3Al with small B, Zr, Hf, and Cr additions is now being commercialized for propulsion applications; TiAl- and Ti_3Al-based alloys are considered especially promising as matrix materials for metal-matrix composites that are given high-temperature strength by SiC or Al_2O_3 fibers.[28]

5 SELECTED APPLICATION: SPECIFIC ALLOYS

5.1 Magnetic Alloys

Magnetic alloys are classified into two categories:[44,45] soft (with low coercive field and small hysteresis loop) for alternating current devices and hard (with high coercive field and large energy product) for permanent magnet uses. Alloys for the former purpose are based on iron (which has the highest room-temperature saturation magnetization of all elements) and is alloyed for power transformer applications with about 3% Si to increase its electrical resistivity (thereby reducing eddy currents) and to reduce the loss-producing magnetic anisotropy. Amorphous Fe–Ni–Co based alloys (metallic glasses) with B and Si as glass formers produced by melt spinning constitute a new class of promising low loss alloys.[46] For higher frequencies, 'Permalloys' with 80% Fe, 20% Ni offer high magnetic permeability.

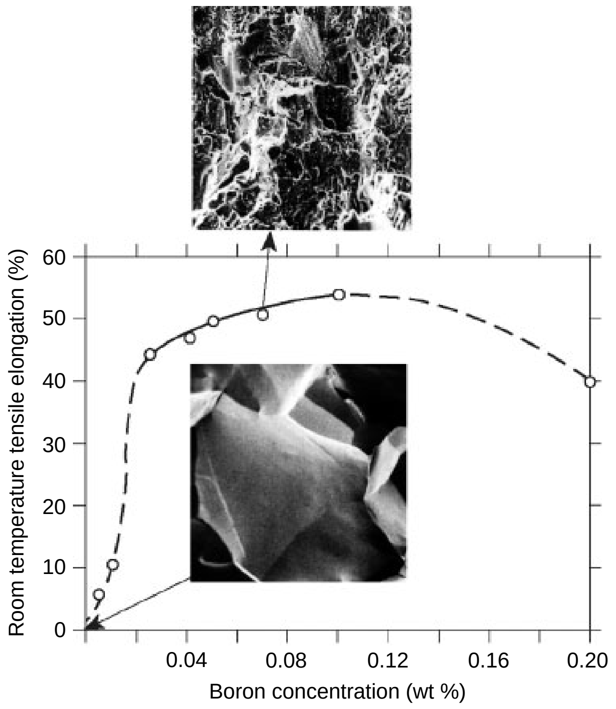

Figure 9 Enhancement of tensile elongation and change of fracture type of Ni_3Al (with 24 at. % Al) by small boron additions. (Ref. 43. Reproduced by kind permission of Springer Science & Business Media)

Hard (permanent) magnet materials have advanced from hardened steel via cast Alnico (iron–aluminum–nickel–cobalt) magnets to modern AB_5 and A_2B_{17} rare earth–cobalt alloy magnets such as $SmCo_5$ and Sm_2Co_{17}, which are made from powder particles compacted in a magnetic field and subsequently sintered to fully bring out their magnetic anisotropy. The $SmCo_5$ magnetic compound has the hexagonal $CaCu_5$ structure discussed and shown for $LaNi_5$ in the section on hydrogen absorbing alloys, below. A further advance in this area was the discovery and development[47] of the compound $Fe_{14}Nd_2B$, which can be made by rapid solidification processing, grinding the melt-quenched ribbons, and hot pressing the powder to final shape. These high-energy-product magnets are now widely available at low cost.

5.2 Superconductor Alloys

Superconductivity is the absence of resistance to dc conduction; this occurs only below a critical temperature T_c, a critical magnetic field H_c (which is a function of T and current density j), and a critical current density j_c, which is a function of T and H.[48] For alloys, T_c does not exceed 23–24 K (by contrast, some of the recently discovered ceramic high-T_c cuprate superconductors, such as $HgBa_2Ca_2Cu_3O_x$, have T_c values as high as 140 K and can have comparable j_c values),[49] Designers of superconducting solenoid magnets for use in laboratory equipment, magnetic resonance imaging devices, and particle accelerators require current densities of 10^5–10^6 A cm^{-2} in fields of 10–15 T (100–150 kG) at liquid He temperature (4.2 K). These properties can only be met by alloys displaying type II superconductivity; in these, the magnetic field (which is completely excluded by a type I superconductor when it is in its superconducting state) may penetrate the superconductor partially, producing a mixed state of normal (nonsuperconducting) regions containing the magnetic flux (flux lattice) and superconducting regions carrying the supercurrent.

Currently used magnet coil alloys are of two kinds: Nb–Ti solid solutions with $T_c < 9.5$ K and $H_c \leq 10$ T and intermetallic compound superconductors with the Cr_3Si (cI8, A15) type structure shown in Figure 10, such as Nb_3Sn with $T_c = 18.3$ K and $H_c \sim 15$ T; even larger H_c values are possible. In Nb–Ti the flux lattice is pinned by defects introduced by a high degree of cold working that occurs in the course of drawing the alloy rods clad in copper into a complex, multistrand wire. For the brittle A15 type materials, drawing in this way would introduce cracks; the compound is therefore formed in situ by a diffusion process combining Nb cores and Sn supplied either by a pool of Sn or a Cu–Sn bronze matrix. An actual wire with a diameter of 1–2 mm made by this process is composed of thousands of filaments formed into bundles.[50]

5.3 Shape Memory Alloys (SMAs) and Magnetostrictive Alloys

Certain intermetallics, among them stoichiometric NiTi and some CuZn-based phases, transform from a high-symmetry elevated temperature phase (CsCl type for NiTi) to

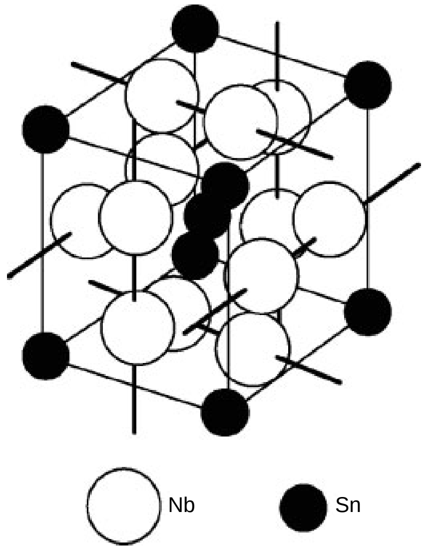

Figure 10 Unit cell of the Cr_3Si (cP8, A15) type superconducting intermetallic Nb_3Sn showing interpenetrating, orthogonal Nb atom chains. (Ref. 48. Reproduced by courtesy of W.L. Johnson)

a lower-symmetry room-temperature form by a diffusionless martensitic shear transformation.[43,51,52] The TiNi alloy is especially prominent under the designation NITINOL.[53]

These martensites have a large plastic deformability such that an SMA wire or sheet can be deformed into an arbitrary shape at ambient temperatures, for example, made into a loop. Upon heating and reversal to the cubic form, the part regains its original shape. In some properly 'trained' SMAs the reversible shape change occurs on cooling and subsequent reheating of the alloy. The martensites responsible for this remarkable effect form in lenticular shapes or laths as seen in Figure 11(a) for an Fe–Ni–Al SMA that exhibits a fractal behavior of self-similar lenses on ever-smaller scales, as shown in Figure 11(b) together with a measurement of the pertinent fractal dimension.[43] SMAs with their complex thermomechanical behavior are perhaps among the first alloy representatives of 'intelligent materials' or 'smart materials' that can sense their environment and adapt their properties to it. SMAs are industrially manufactured for applications as sensors, actuators in safety devices, spacecraft and automotive parts, and medical devices such as vascular implants (stents), blood vessel screens and probes.[54]

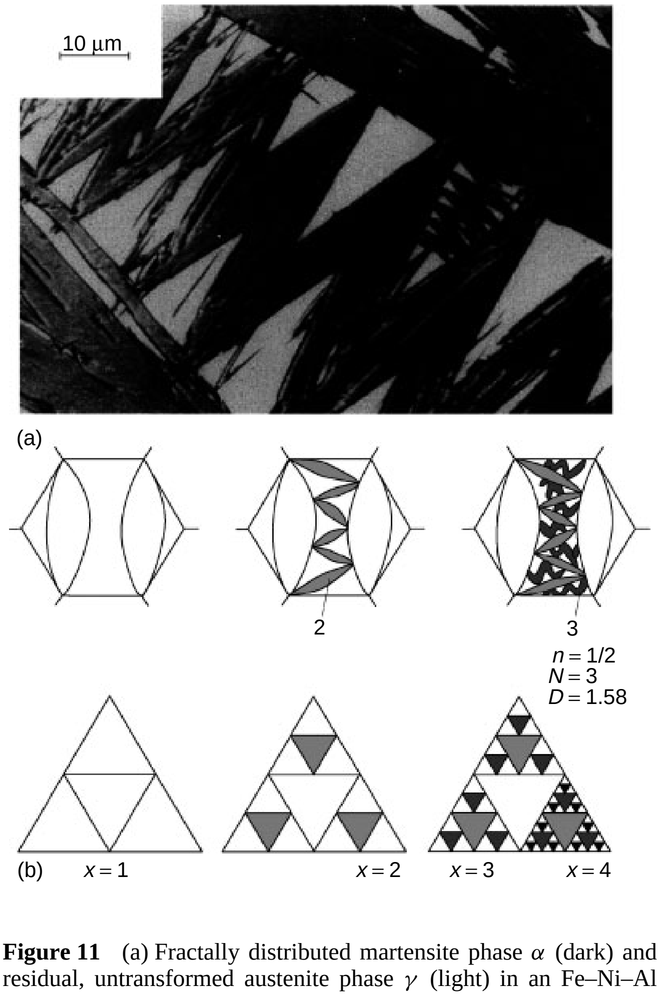

Figure 11 (a) Fractally distributed martensite phase α (dark) and residual, untransformed austenite phase γ (light) in an Fe–Ni–Al shape memory alloy (SMA); (b) (top row) schematic representation of the fractal fragmentation of austenite crystallite by martensite formation, resulting (top right) in the structure shown in (a); (bottom row) a fractal process of dimension $D = 1.58$ (Sierpinski triangle) shown for comparison. (Ref. 43. Reproduced by permission of Springer)

Magnetostrictive alloys form a subset of shape memory alloys; they undergo reversible martensitic transformations upon application and reversal of magnetic fields, resulting in large recoverable strains. Such alloys are useful as sensors and activators; a typical, widely used magnetostrictive sensor alloy is TERFENOL-D ($Tb_{1-x}Dy_xFe_2$) for which the strain is about 0.2%; large values (up to 6% in some experimental alloys such as Ni_2MnGa) are evidence of giant magnetostriction.[55]

5.4 Hydrogen Absorbing Alloys

A number of pure metals and alloys form hydrides with densities of hydrogen atoms per unit volume exceeding that of liquid hydrogen (Table 1),[56] suggesting their use as hydrogen storage media for hydrogen-based energy applications such as automotive systems.[57] Further, the reversible uptake of hydrogen can be used to form the anode (negative terminal) in secondary (storage) batteries as a hydrogen charged (metal hydride) electrode.

To be useful for storage, a candidate alloy should have a room-temperature hydride dissociation pressure in the range of 1–2 atm, with a pressure plateau ranging up to a stoichiometric ratio of hydrogen:metal ~1, with good resistance to degradation of these properties on cycling and with a reasonable materials cost. These conditions are best met by intermetallics such as FeTi, NiTi, Mg_2Ni, and $LaNi_5$, which combine an early group element having a large negative enthalpy of hydride formation with a late transition element having a small positive enthalpy, thus reducing the compound's enthalpy of hydride formation into the range appropriate for the desired dissociation pressure; possibly, the Fe or Ni component also catalyzes the reaction. (Enthalpy of formation is the dominant component-variable term in the Gibbs free energy of hydride formation, the entropy of the process being uniformly large and negative.)

Table 1 Hydrogen content of various media[56]

Medium	Density ($g\,cm^{-3}$)	Wt % of H	Atoms of H/cm^3 (10^{22})
H_2 (liquid)	0.07	100	4.2
H_2 (gas, 150 atm, 20 °C)	0.012	100	0.38
NH_3 (liquid)	0.6	17.7	6.5
MgH_2	1.4	7.6	6.7
TiH_2	3.8	4.0	9.1
VH_2	–	2.08	11.37
Mg_2NiH_4	2.6	3.6	5.6
$FeTiH_{1.74}$–$FeTiH_{0.14}$	–	1.52	5.5
$LaNi_5H_6$	8.25	1.37	6.76

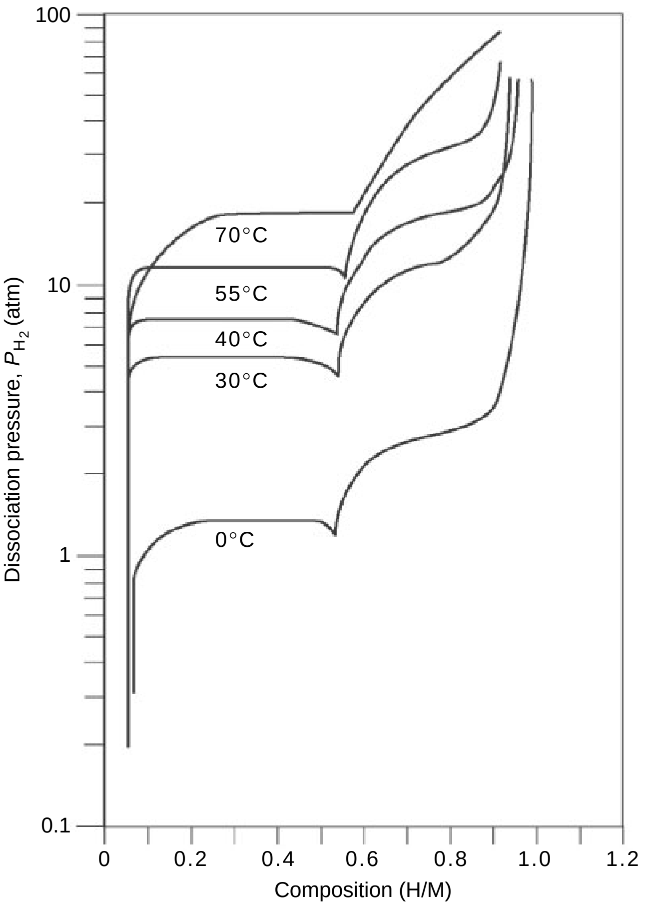

Figure 12 Hydrogen pressure–composition isotherms for the FeTi–hydrogen system.[56] (Reprinted with permission from Ref. 58. © 2003 American Chemical Society)

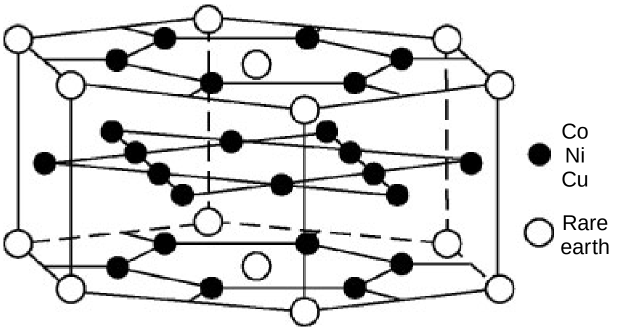

Figure 13 Pictorial representation of three unit cells of the $CaCu_5$ (hP6, $D2_d$) type structure of $LaNi_5$ and $SmCo_5$. (Ref. 32. Reproduced by permission of Kamal Girgis-deceased)

A representative isotherm plot is shown for FeTi in Figure 12.[58]

FeTi and NiTi have the ordered CsCl (cP2, A2) type structure shown in a different context for AlNi in Figure 5. $LaNi_5$ has the hexagonal $CaCu_5$ (hP6, $D2_d$) type structure shown in Figure 13.[32] (This structure type is also adopted by the magnetic compound $SmCo_5$, as mentioned above in Section 5.1.)

FeTi and $LaNi_5$ are currently the preferred ambient temperature storage and battery materials. FeTi and alloys derived from it by substitution are less expensive than $LaNi_5$ (by a factor of 5, based on recent raw materials cost) and therefore preferred for bulk storage applications, but $LaNi_5$ appears to have functional advantages such as lower sensitivity to degradation and deactivation and is currently preferred for secondary batteries. To lower the price of $LaNi_5$, La can be replaced by Mischmetal (M), a less expensive, commercial mixture of unseparated rare earth metals with about 50% Ce, 30% La, and 15% Nd, the rest consisting of the other 10 stable rare earth metals. This replacement, however, raises the plateau pressure and requires additional alloying with Ca (substituting for M) and elements chosen from the group Fe, Co, Mn, Cu, or Al (substituting for Ni) to modify the plateau pressure back to acceptable values.[59] Practical hydrogen absorbing alloy systems thus require complex alloy chemistry. In advanced FeTi type bcc alloys such as Ti-V-Mn and Ti-V-Cr, up to 2 H atoms per metal atom can be reversibly absorbed.[60]

This field receives additional attention as the interest in a hydrogen fuel economy increases; a recent review comparing storage of H in alloys with that in other media is found in Ref. 57.

5.5 Soldering and Brazing Alloys

Solders are relatively low-melting alloys used over a wide range of applications from plumbing to electronic device interconnects. They are generally eutectic alloys (a eutectic, i.e. a 'well-melting' composition in a binary alloy system lies at the intersection of two liquidus (melting) curves and thus is the composition where the melt is in equilibrium with the corresponding two solid phases; it represents the lowest melting temperature in that portion of the phase diagram).

The classical electronics solder alloy (Sn + 37 wt% Pb) contains the inhalation-toxic element lead and is being replaced in electronics for health reasons.[61] A Pb-free solder is Sn-3.5 wt% Ag;[62] indium and bismuth alloys are other eutectic-forming alloying additives to Sn.[21,22] The classical brazing alloy is at the Cu–Ag eutectic (Ag + 28.1 w% Cu) and is well suited for mechanically strong contacts with Cu and its alloys.

5.6 Coatings and Alloy Corrosion

New technologies are advancing the age-old methods for giving alloys high surface hardness for wear resistance and fatigue resistance, while retaining the toughness and strength of the core.[28] Traditional induction thermal methods have now been joined by the capability for laser treatment; the high

energy density of the laser beam and the self-quenching aspect of the process, where the workpiece itself acts as an efficient cooling medium, have combined in research arrangements to produce local cooling rates as high as 10^8 °C/s. If alloys are surface-melted under these conditions, metastable phase formation may result.[63]

Glow discharge of plasmas as a means of producing reactive ions for enhanced surface reaction are exploited in the ion nitriding[64,65] and ion carborizing[66] processes. The rather complex surface and near-surface gas-phase chemistry may involve gas reactions with sputtered surface ions and redeposition of the product.[66] Other coating technologies include ion implantation of Ti or N to improve fatigue resistance in steels, physical vapor deposition (PVD) and plasma-assisted PVD to produce hard TiN coatings,[28] and boridation.[67]

Corrosion and corrosion protection of pure metals form a vast field not covered here. For alloys, corrosion may involve de-alloying (preferential loss of one constituent) if they have different electrochemical potentials;[68] such processes have been modeled on the atomic scale by Monte Carlo methods.[69]

More generally, with greater understanding of bulk properties, interest in alloy surface processes and their dynamics has risen.[70]

6 PREPARATION AND CHARACTERIZATION

6.1 Alloy Preparation

Traditional methods comprising the vast field of alloy preparation such as smelting, purification, fabrication are not covered here; however, a few selected methods of current interest are listed with references. These include:

Rapid solidification processing (RSP), for example, by melt spinning onto a cooled copper drum, which is capable of retaining many alloys in a glassy (amorphous) state or in nanocrystalline form;[11]

Deposition by sputtering and laser ablation (vapor-phase transfer from a target bombarded by inert gas ions or laser beam) or ion beam mixing of nanoscale multilayers,[71] all of which similarly can produce nonequilibrium species;

Mechanical alloying, a process in which elemental powders are blended and alloyed by ball milling, can produce ultrafine grain sizes and nonequilibrium phases that store the mechanical energy imported in the process.[72]

6.2 Alloy Characterization

The current detailed knowledge of atomic-scale processes in alloys and the technical products made from them is due to the enormous recent advances in instrumentation, primarily in the area of analytical electron microscopy (AEM). High-resolution transmission electron microscopy (HRTEM)[73] and scanning transmission electron microscopy (STEM) permit resolution into the 0.1 and 0.2 nm range, respectively; corresponding micro-diffraction data for local structure analysis are obtained by convergent beam electron diffraction (CBED). These structural methods are further supported by submicron volume chemical analysis, by electron energy loss spectroscopy (EELS) and atom location by channeling-enhanced microanalysis (ALCHEMI),[74] supplementing the standard method of energy dispersive X-ray emission spectroscopy (EDS).[73] Three-dimensional atom distribution probes (3DAPs), a further development of field ion microscopy (FIM), permits atomic-scale materials analysis.[75]

An overview of methods for surface and interface analysis of metals and alloys is available.[76] Important atomic-scale surface structure information can be gathered by scanning tunneling microscopy (STM) or scanning atomic force microscopy (SAFM), complementing scanning electron microscopy (SEM), field ion microscopy (FIM), and small-angle neutron scattering (SANS).[69]

Glossary

Astringent: any substance or agent that causes tissues to contract or that inhibits secretion of fluids such as mucus or blood
Friedel–Crafts reaction: an alkylation or acylation of an aromatic using alkyl or acyl chlorides in the presence of a Lewis acid catalyst
Trityl: the Ph_3C^+ cation

1 INTRODUCTION

Aluminum, having an abundance of 8.3% by weight, is the commonest metallic element in the Earth's crust. It occurs widely in igneous minerals such as feldspars and micas. Weathering of these has produced the clay minerals such as vermiculite $[Mg_{1.8}Fe^{2+}_{0.9}Al_{4.3}SiO_{10}(OH)_2(H_2O)_4]$, montmorillonite $[Na_{0.2}Ca_{0.1}Al_2Si_4O_{10}(OH)_2(H_2O)_{10}]$, and kaolinite $[Al_2(OH)_4Si_2O_5]$. The most commercially important mineral source of aluminum is bauxite $[AlO_x(OH)_{3-2x}$ $(0 < x < 1)]$, which occurs in tropical and subtropical regions as a result of exhaustive leaching of silica and other metals from aluminosilicates. Aluminum also occurs in numerous well-known but rarer minerals such as spinel $[MgAl_2O_4]$, garnet $[Ca_3Al_2(SiO_4)_3]$, beryl $[Be_3Al_2Si_6O_{18}]$, cryolite $[Na_3AlF_6]$, and turquoise $[CuAl_6(PO_4)_4(OH)_8(H_2O)_4]$. Pure aluminum oxide, Al_2O_3, is known as corundum while many impure forms of Al_2O_3 occur naturally and find application as gemstones. For example, sapphires and rubies are primarily composed of aluminum oxide, but owe their distinctive colors to trace impurities. In the case of rubies, chromium yields a red color while titanium leads to the characteristic blue color of sapphires (the result of charge-transfer transitions involving the aluminum and titanium ions). Different concentrations of various impurities produce a range of colors from quite pale, owing to low concentrations, to quite deep blue. Other colors include: purple and pink, yellow, orange, green, and so on. Chrysoberyl ($BeAl_2O_4$) is both a useful gemstone and an important source for beryllium.

The high abundance of aluminum has resulted in a multitude of applications for the element and its compounds. Aluminum derives its name from alum, the double sulfate $KAl(SO_4)_2{\cdot}12H_2O$, which was used medicinally as an astringent in ancient Greece and Rome. Today, aluminum plays an important role as the pure metal and its alloys while its compounds have extensive applications as structural and medical ceramics, electronic and optical materials, catalysts, ionic conductors, coagulants for water purification, and reagents for preparation of other chemicals.[1–3]

Chemically, aluminum exhibits typical metallic behavior but it shows many similarities to boron. It combines with almost all nonmetallic elements to form compounds with aluminum in the +3 oxidation state. It also forms intermetallic compounds with metallic elements from all groups of the periodic table (*see* ***Alloys***). Aluminum exhibits exceptional affinity for oxygen and is often used as a reducing agent to obtain Cr, Mn, V (*see Thermite Reaction*). Finely powdered aluminum metal explodes upon contact with liquid oxygen but ordinarily the metal is protected from reaction with oxygen, water or dilute acids by an adherent protective oxide film. Complete reaction of aluminum may be accomplished by amalgamation with mercury or contact with solutions of salts of electropositive elements (e.g. $HgCl_2$) that destroy the oxide film. Aluminum dissolves readily in hot, concentrated hydrochloric acid (equation 1) and in aqueous NaOH or KOH at room temperature (equation 2).

$$Al(s) + 3HCl(aq) + 6H_2O \longrightarrow [Al(H_2O)_6]^{3+}(aq) + 3Cl^-(aq) + \frac{3}{2}H_2(g) \quad (1)$$

$$Al(s) + MOH(aq) + 3H_2O \longrightarrow M^+(aq) + [Al(OH)_4]^-(aq) + \frac{3}{2}H_2(g) \quad (2)$$

$Al(OH)_3$ is *amphoteric*, behaving both as a Brønsted acid and base. Thus, freshly precipitated hydroxide is readily soluble in both acid (equation 3) and alkali (equation 4).

$$Al(OH)_3(s) + 3H_3O^+(aq) \longrightarrow [Al(H_2O)_6]^{3+} \quad (3)$$

$$Al_2(SiO_3)_3 \xleftarrow{SiO_2} Al_2O_3 \xrightarrow{CaO} Ca_3(AlO_3)_2$$

Scheme 1 Solid-state amphoteric reaction of alumina

$$Al(OH)_3(s) + OH^-(aq) \longrightarrow [Al(OH)_4]^-(aq) \quad (4)$$

Amphoteric behavior is also exhibited in the solid-state reactions of aluminum (Scheme 1).

Aluminum compounds of weak acids hydrolyze readily to $Al(OH)_3$ and the protonated acid. For example, aluminum sulfide hydrolyzes with production of H_2S (equation 5). Similar reactions of the selenide and telluride provide the most facile method for synthesis of H_2Se and H_2Te, respectively.

$$Al_2S_3 + 6H_2O \longrightarrow 2Al(OH)_3 + 3H_2S \quad (5)$$

Similarly, the nitride, carbide, cyanide, carboxylate, and carbonate salts of aluminum are unstable in aqueous solution. Aluminum salts of strong acids form solutions of the hydrated cation (*see Hydrates*). These solutions are acidic owing to the partial dissociation of one of the coordinated water molecules (equation 6), the pK_a of $[Al(H_2O)_6]^{3+}$ being 4.95 (*see Acidity Constants*). Note that this pK_a is quite similar to that of acetic acid. The second step in the hydrolysis reaction yields a dihydroxide species that undergoes condensation to form polynuclear cations (see Section 8). Antiperspirants often include an ingredient called *aluminum chlorhydrate* that is really a mixture of the chloride salts of the monohydroxide and dihydroxide aluminum cations. The aluminum in these compounds causes pores on the surface of the skin to contract leading to a reduction in perspiration.

$$[Al(H_2O)_6]^{3+} \rightleftharpoons [Al(H_2O)_5(OH)]^{2+} + H^+(aq) \quad (6)$$

If the pH of the solution is gradually increased, the deprotonation is accompanied by formation of hydroxide bridges to give polynuclear species and then to precipitation of the hydrous oxide. This hydrolysis is particularly useful for water clarification since the hydroxide nucleates on fine suspended particles, precipitating them from solution.

The amphoterism and facile hydrolysis of hydrates of aluminum salts make it impossible to prepare anhydrous salts by dehydration. For example, the strength of the aluminum–oxygen bond in $[Al(H_2O)_6]Cl_3$ precludes the formation of Al–Cl bonds and Al_2O_3 is obtained upon heating (equation 7).

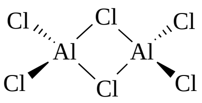
$$2[Al(H_2O)_6]Cl_3 \xrightarrow{\Delta} Al_2O_3 + 6HCl + 9H_2O \quad (7)$$

Some physical and chemical properties of aluminum are presented in Table 1. As expected for the [Ne] $3s^23p^1$ configuration, the fourth ionization potential is prohibitively high. Therefore, the most common oxidation state of aluminum is three although compounds of aluminum(I) can be prepared. However, the latter species quickly disproportionate to elemental aluminum and aluminum(III) compounds.

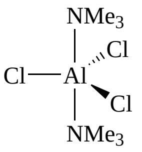
Table 1 Atomic and physical properties of aluminum

Property	Value
Atomic number	13
Number of naturally occurring isotopes	1
Atomic weight	26.98154
Electronic configuration	$[Ne]3s^23p^1$
Ionization energy ($kJ\,mol^{-1}$)	
I	577.4
II	1816.1
III	2744.1
IV	11563.0
Mp (°C)	660
Bp (°C)	2327
E^0 for $M^{3+} + 3e^- \rightarrow M(s)$ (V)	−1.66
Metal radius (pm)	143
Ionic radius (pm) (6-coord.) III	53.5

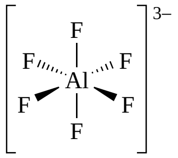
While compounds with three coordination are known, these species are strong Lewis acids and usually achieve four coordination by formation of three-center two-electron bonds, for example, Al_2Cl_6 (**1**) (*see Bridging Ligand*). Aluminum is not restricted to an octet of electrons in its valence shell and compounds with coordination numbers of five and six may be prepared, for example, $Cl_3Al{\cdot}2NMe_3$ (**2**), $[AlF_6]^{3-}$ (**3**).



(**1**)



(**2**)



(**3**)

Aluminum-27 NMR is particularly useful for the identification of the coordination number of aluminum, both in solution and the solid state. This nucleus is 100% abundant and fairly easy to observe despite its quadrupolar nature ($I = 5/2$, $Q = 1.49 \times 10^{-29}\,m^2$). Tetrahedrally coordinated aluminum is found in the range $\delta = 40-140$ ppm, octahedrally coordinated aluminum between −46 and 40 ppm, and five-coordinate aluminum between 25 and 60 ppm.

2 PREPARATION AND USES OF METALLIC ALUMINUM

While aluminum occurs most commonly in aluminosilicate minerals, its extraction from them is prohibitively difficult. It is therefore prepared from bauxite in a two-step procedure. First, bauxite is purified by the Bayer process; this involves dissolution in aqueous NaOH, separation from insoluble impurities (red mud containing Fe_2O_3), and then precipitation of $Al(OH)_3$ by treatment of the solution with carbon dioxide. Calcining at 1200 °C produces Al_2O_3, which is subsequently electrolyzed to produce aluminum metal. The electrolysis is

performed at 950 °C in molten cryolite (Na_3AlF_6); graphite-lined tanks are used as the cathodes and graphite rods as the anodes. The molten aluminum thus produced sinks to the bottom of the cell and is drawn off. The process requires vast amounts of electrical power and aluminum production is therefore usually associated with hydroelectric power generation.

Pure aluminum metal is a hard silvery-white metal with the face-centered cubic close-packed structure (*see Close Packing*). Among its many desirable properties are: it is light, nonmagnetic, nonsparking, and nontoxic, and is capable of taking a high polish. As well, it has high thermal and electrical conductivity, excellent corrosion resistance, and high malleability and ductility.

The use of aluminum as a structural metal appears to contradict the fact that it is a very reactive metal with a high negative standard reduction potential. Metallic aluminum is not found in nature for this reason. The cause of aluminum metal's stability is the formation of a protective oxide layer on the surface of the metal. Any exposed surface of aluminum metal reacts with dioxygen to form an impermeable layer of aluminum oxide, Al_2O_3 that is 1–100 nm thick. This layer protects the underlying aluminum from further chemical reaction with oxygen, water, and many other reactive chemicals. However, any reagent that can disrupt the oxide layer (especially acids, bases, chloride ions, and mercury salts) can result in corrosion or rapid reaction of aluminum. The formation of a strongly adherent, protective oxide layer can be explained by the close similarity between the ionic radius of the oxide anion (124 pm) and the metallic radius of aluminum (143 pm) as well as the extremely small radius of aluminum(III) ions (53.5 pm). As a consequence, the oxygen ions can pack readily on the aluminum surface while the aluminum ions formed by oxidation enter the interstitial octahedral sites of the oxygen lattice as shown in Figure 1.

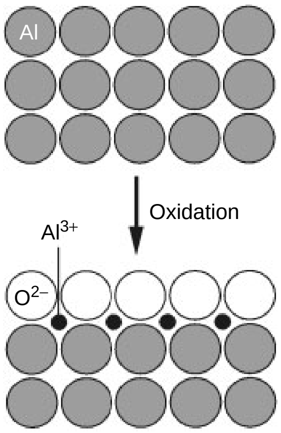


Figure 1 Schematic representation of the formation of the oxide layer on aluminum metal

The protection afforded by the native oxide layer may be enhanced by anoding the metal. This is done by immersing the metal in 15–20% sulfuric acid and connecting it to the positive terminal so that the metal at the surface is oxidized to alumina. Usually, a layer 10–20 µm thick is used and this provides protection between pH 4.5 and 8.7 and makes the metal quite suitable for outdoor use. Thicker oxide layers also provide excellent abrasion resistance. Furthermore, the oxide layer may be colored by incorporating suitable organic or inorganic compounds. Photographic plates can also be prepared by incorporation of photosensitive materials.

Aluminum is now used extensively in the construction industry, for domestic utensils, drink containers, electrical cables (having twice the weight-for-weight conductance of copper) and as alloys in ship, aircraft, and spacecraft construction. In the last respect, the mechanical properties of aluminum can be greatly improved by alloying it with copper, manganese, silicon, magnesium, or zinc. The properties and uses of a number of typical alloys are given in Table 2. One particularly interesting intermetallic compound, Al_4Li_9, is formed by the reaction of lithium with aluminum. It

Table 2 Composition, properties, and applications of aluminum and its alloys

Alloy designation	Alloying metals	Properties and applications
1000 Series	Pure Al (<1% of other elements)	Good properties except for limited mechanical strength. Used in chemical equipment, reflectors, heat exchangers, buildings, and decorative trim.
2000 Series	Copper (∼5%)	Excellent strength and machinability, limited corrosion resistance. Used for components requiring high strength/weight ratio, e.g. truck trailer panels, aircraft structure parts.
3000 Series	Manganese (∼1.2%)	Moderate strength, high workability. Used for cooking utensils, heat exchangers, storage tanks, awnings, furniture, highway signs, roofing, side panels, etc.
4000 Series	Silicon (≤12%)	Low mp and low coefficient of expansion. Used for castings and as filler material for brazing and welding; readily anodized to attractive gray colors.
5000 Series	Magnesium (0.3–5%)	Good strength and weldability coupled with excellent corrosion resistance in marine atmospheres. Used for ornamental and decorative trim, streetlight standards, ships, boats, cryogenic vessels, gun mounts, and crane parts.
6000 Series	Magnesium/silicon	Good formability and high corrosion resistance. Used in buildings, transportation equipment, bridges, railings, and welded construction.
7000 Series	Zinc (3–8%) and magnesium	When heat treated and aged have a very high strength. Used principally for aircraft structures, mobile equipment, and equipment requiring high strength/weight ratio.

has a structure that contains polymeric zig-zag aluminum chains with lithium atoms between them. Each atom attains coordination number 14 (*see* ***Alloys***).

3 ALUMINUM HYDRIDES AND RELATED COMPLEXES

Allane, AlH_3, can be detected as a monomer and dimer when aluminum is vaporized in hydrogen but AlH_3 is a colorless involatile solid that is extensively polymerized via Al–H–Al bonds. Several crystalline and amorphous phases of $(AlH_3)_n$ have been reported and the structure of α-AlH_3 has been determined by X-ray and neutron diffraction. Each aluminum is surrounded by six hydrogen atoms that bridge to six other aluminum atoms. All Al–H distances are identical (172 pm), suggesting three-center two-electron bonding. The Al–H–Al angle is 141° and the closest Al–Al distance is 324 pm. The latter is appreciably shorter than that found in aluminum metal (340 pm) but it is believed that there is no metal–metal bonding.[4]

AlH_3 is most conveniently prepared by the reaction of $LiAlH_4$ and $AlCl_3$ in diethyl ether (equation 8).

$$3LiAlH_4 + AlCl_3 \xrightarrow{Et_2O} 4AlH_3(OEt_2)_n + 3LiCl \quad (8)$$

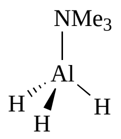
The LiCl is filtered off and, upon sitting, the filtrate deposits an intractable etherate of variable composition. This can be avoided by working up the solution with an excess of $LiAlH_4$ and some $LiBH_4$ in a large excess of benzene at reflux. This leads to the eventual formation of crystals of α-AlH_3. Variation of the conditions produces other crystalline modifications of AlH_3.

AlH_3 is thermally unstable above 150 °C and is a strong-reducing agent that reacts violently with water and other protic reagents with the liberation of hydrogen. Such reactions may be used to form $Al(NH_2)_3$, $Al(PH_2)_3$, and $Al(N_3)_3$. It readily forms adducts with strong Lewis bases but these are more conveniently prepared from the reaction of the aluminum trichloride adducts with lithium hydride (equation 9).

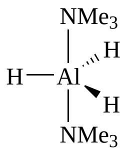
$$3LiH + L\cdot AlCl_3 \xrightarrow{Et_2O} L\cdot AlH_3 + 3LiCl \quad (9)$$

The most studied adducts are the trialkylamine alanes. Trimethylamine reacts to give both 1:1 and 2:1 adducts with AlH_3, but the latter is stable only in the presence of an excess of amine. The monoamine has a tetrahedral structure (**4**) and is a white, volatile crystalline solid (mp 75 °C) that is readily hydrolyzed by water. Like the etherate, it slowly decomposes to $(AlH_3)_n$. The bisamine has a trigonal bipyramidal structure with the amines in the axial positions (**5**). This was the first compound in which aluminum was demonstrated to adopt a five-coordinate structure. Tetrahydrofuran also gives 1:1 and 1:2 complexes but diethyl ether only gives the 1:1 complex.

Lithium aluminum hydride, $LiAlH_4$, is a white solid that is stable in dry air but is rapidly decomposed by moisture. It is



(**4**)



(**5**)

highly reactive towards all protic reagents and many organic functional groups. It is thermally unstable, decomposing rapidly at 100 °C. It may be synthesized by the reaction of LiH with $AlCl_3$ (equation 10). It is also prepared on the industrial scale by metathesis of $NaAlH_4$ with LiCl in diethyl ether, the sodium salt being prepared by direct high-pressure reaction of the elements (equation 11).

$$4LiH + AlCl_3 \xrightarrow{Et_2O} LiAlH_4 + 3LiCl \quad (10)$$

$$Na + Al + 2H_2 \xrightarrow[350\ atm]{140\,^\circ C,\ THF} NaAlH_4 \quad (11)$$

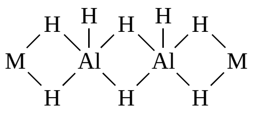
The structure of $LiAlH_4$, deviates considerably from the simple ionic formulation, $Li^+[AlH_4]^-$. It consists of tetrahedral AlH_4 groups (Al–H 155 pm) that are bridged by Li so that each Li is surrounded by four hydrogen atoms at 188–200 pm (cf. 204 pm in LiH) and a fifth at 216 pm.

$LiAlH_4$ is an outstanding versatile reducing and hydrogenating reagent for both organic and inorganic compounds.[4–6] The reaction of $LiAlH_4$ with inorganic halides produces a variety of products depending on the relative stabilities of the corresponding tetrahydroaluminate and element. The halides of groups 15 and 16 are converted cleanly to the corresponding hydrides (equation 12) while the halides of groups 9 and 10 are converted to unstable hydrido species that decompose to the metals (equation 13). Other transition metals and group 11 metals form complexes with AlH_4 (equation 14). In the latter complexes, aluminum is usually five-coordinate with structural units such as (**6**), (**7**), and (**8**).[7]

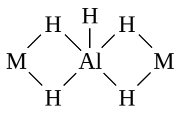
$$4MX_n + nLiAlH_4 \longrightarrow 4MH_n + nLiAlX_4 \quad (12)$$

$$4MX_n + nLiAlH_4 \longrightarrow 4M + 2nH_2 + nLiAlX_4 \quad (13)$$

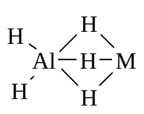
$$4MX_n + nLiAlH_4 \longrightarrow M(AlH_4)_n + nLiX_4 \quad (14)$$



(**6**)



(**7**)



(**8**)

$LiAlH_4$ also reacts readily with inorganic oxides. For example, $COCl_2$ is converted to MeOH, CO_2 to $LiAl(OMe)_4$ or $LiAl(OCH_2O)$, and NO is reduced to hyponitrous acid, HON=NOH.

The most important applications of $LiAlH_4$ are in organic synthesis. It reacts with more than 60 organic functional groups (Table 3). Reactions are usually performed in ether, in which $LiAlH_4$ is highly soluble (22 wt%). For

many reactions, however, $LiAlH_4$ has been replaced by more selective, less expensive borohydrides or organometallic hydrides.

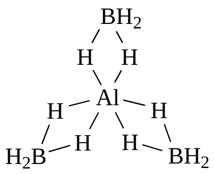
Lithium and sodium salts of AlH_6^{3-} can be prepared by direct interaction of the metals under pressure or by reaction of $NaAlH_4$ with two equivalents of NaH (equation 15).

$$2NaH + NaAlH_4 \longrightarrow Na_3(AlH_6) \quad (15)$$

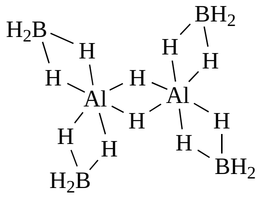
Another complex hydride, $Al(BH_4)_3$ (**9**), a colorless liquid (mp −64.5 °C, bp 44.6 °C), was the first compound demonstrated to be fluxional (*see Fluxional Molecule*). Its thermal decomposition also led to the first compound to be discovered and structurally characterized by NMR spectroscopy, $Al_2B_4H_{18}$ (**10**). Reaction of $Al(BH_4)_3$ with a variety of boranes produces compounds analogous to boron hydride clusters such as AlB_4H_{11}, $AlB_5H_{11}^-$, AlB_5H_{12}, $AlB_6H_{12}^-$, and AlB_6H_{13} (*see* ***Boron Hydrides***).[8]

4 ALUMINUM HALIDES

The monohalides of aluminum are produced as short-lived diatomic species in the gas phase by the reaction of the trihalides with aluminum at 1000 °C. The instability of these



(**9**)



(**10**)

species is not a result of an unfavorable enthalpy of formation but is due to the facile disproportionation into the more stable AlX_3 species (equation 16, Table 4).

$$3AlX \longrightarrow 2Al + AlX_3 \quad (16)$$

AlF_3 is made by reaction of Al_2O_3 with HF gas at 700 °C (equation 17), while the rest of the trihalides may be prepared by the direct combination of the elements, a highly exothermic process. Of the four aluminum trihalides, AlF_3 is unique in being nonvolatile, insoluble, and in possessing a much higher heat of formation (Table 5).

$$Al_2O_3 + 6HF \longrightarrow 2AlF_3 + 3H_2O \quad (17)$$

These differences may result, in part, from the higher coordination number of aluminum in AlF_3. In it, each aluminum atom is surrounded by a distorted octahedron of six fluorine atoms. Each fluorine is two-coordinate, being corner-shared by pairs of octahedra. Thus, the structure is similar to ReO_3 and has a relatively open lattice. As a result, numerous sites exist for water molecules, leading to the occurrence of a wide range of nonstoichiometric and stoichiometric hydrates ($AlF_3{\cdot}(H_2O)_n$; $n = 1, 3, 9$). Quite curiously, no hexahydrate corresponding to $[Al(H_2O)_6]Cl_3$ is known.

The interaction of AlF_3 with metal fluorides provides an extensive family of structures that all contain octahedral AlF_6 units. AlF_6 octahedral units also occur in Na_3AlF_6 and $Li_3Na_3Al_2F_{12}$, but these do not contain discrete $[AlF_6]^{3-}$ ions since there is significant bonding between the AlF_6 units and the other metals. The Na_3AlF_6 structure is closely related to perovskite (ABO_3) in which one-third of the sodium and all the aluminum atoms occupy the octahedral 'B' sites and

Table 4 Properties of AlX

Table 5 Properties of crystalline AlX_3

Properties	AlF_3	$AlCl_3$	$AlBr_3$	AlI_3
Mp (°C)	1290	192.4	97.8	189.4
Sublimation pt (1 atm/°C)	1272	180	256	382
ΔH_f° (kJ mol^{-1})	1498	707	527	310

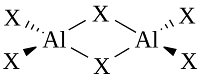
the remaining two-thirds of the sodium atoms occupy the 12-coordinate ‘A’ sites (*see* ***Oxides: Solid-state Chemistry***).

The sharing of two opposite vertices of AlF_6 units, as in Tl_2AlF_5, leads to polymeric chains with ‘AlF_5’ stoichiometry. In $TlAlF_4$ and $KAlF_4$, AlF_6 units share four equatorial vertices, yielding layers with ‘AlF_4’ stoichiometry.

More complex patterns of sharing vertices occur in compounds with intermediate stoichiometries. For example, $Na_5Al_3F_{14}$ contains layers of ‘Al_3F_{14}’ built up by one-third of the AlF_6 octahedra sharing four equatorial vertices and the remainder sharing two opposite vertices. Na_2MgAlF_7 contains both AlF_6 and MgF_6 octahedra that are linked together by sharing four vertices of the AlF_6 units and all those of the MgF_6 units (*see* ***Fluorides: Solid-state Chemistry***).

As indicated earlier, Na_3AlF_6 (cryolite) is the most important aluminum fluoride since it serves as the solvent for the electrolytic preparation of aluminum.

Solid $AlCl_3$ also contains six-coordinate aluminum. The layered lattice exhibits a rapid increase in electrical conductivity as the melting point (192.4 °C) is approached, at which temperature it rapidly falls to zero. This coincides with an 85% increase in volume, which results from a change in coordination of aluminum from six to four. The melt consists of discrete Al_2Cl_6 molecules (**11**). These molecules predominate in the gas phase up to 400 °C, beyond which they dissociate to trigonal planar $AlCl_3$ monomers.



(**11**)

On the other hand, Al_2Br_6 and Al_2I_6 are both dimeric in the solid state as well as in the liquid and gaseous states. They also dissociate to monomers in the gas phase with $\Delta H_{dissoc} = 59$ and 50 kJ mol^{-1} for the bromide and iodide, respectively.

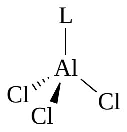
In all the dimeric Al_2X_3 species, the terminal M–X distance is 10–20 pm shorter than the bridging M–X distance (Table 6). The external X–M–X angle is in the range 110–125° while the internal one is in the range 70–102° (*see* ***Hard & Soft Acids and Bases***).[9]

The trihalides of aluminum are very strong Lewis acids, and $AlCl_3$ finds extensive use as a Friedel–Crafts catalyst as a result of this. A wide variety of adducts are known and these exhibit an enormous range of stability, modes of bonding, structures, and properties.[10] Aromatic hydrocarbons and alkenes only interact weakly but crystalline adducts may be isolated, for example, the clathrate complex $Al_2Br_6{\cdot}C_6H_6$.

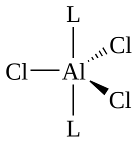
Table 6 Bond distances in Al_2X_6 molecules

X	M–X bridge (pm)	M–X terminal (pm)
Cl	2.21	2.06
Br	2.33	2.21
I	2.58	2.53

Mesitylene and xylenes interact more strongly, forming weak monomeric complexes, $Br_3Al{\cdot}L$. A typical strong complex is formed by Me_3N, which forms both the tetrahedral 1:1 complex (**12**) and the 1:2 trigonal bipyramidal complex (**13**).



(**12**)



(**13**)

Vibrational spectroscopy indicates that alkyl halides form weak R–X–AlX_3 complexes. On the other hand, halides that are readily ionized (e.g. trityl chloride) show a high degree of charge separation and may be formulated as $R^+[AlCl_4]^-$. Acyl halides, RCOX, may coordinate through the halide atom, the carbonyl oxygen, or form ionic species, $RCO^+AlX_4^-$. However, vibrational spectroscopy and X-ray crystallography have not provided conclusive evidence concerning the reactive species present in Friedel–Crafts alkylations in nonaqueous solvents.

Aluminum’s tendency to form tetrahedral $AlCl_4^-$ anions is exhibited in the formation of many interesting compounds. For example, the compound $Cl_3Al{\cdot}ClICl_2$ may be described as $[ICl_2]^+[AlCl_4]^-$. $POCl_3$ reacts with $AlCl_3$ to form three types of compounds, the ordinary 1:1 and 2:1 complexes (where $AlCl_3$ is O-bonded) and a third ionic species with the unusual formulation$[Al(OPCl_3)_6]^{3+}[AlCl_4]_3^-$. Similarly, $AlCl_3$ reacts with THF to form $[AlCl_2(THF)_4]^+[AlCl_4]^-$ while with acetonitrile, $[(MeCN)_5AlCl]^{2+}[AlCl_4]_2^-$ is obtained. Crystalline salts of $[AlCl_4]^-$ may also be obtained by reaction of alkali metal chlorides or $[R_4N]Cl$ with $AlCl_3$ in an organic solvent. $[AlBr_4]^-$ and $[AlI_4]^-$ salts may be obtained in a similar manner.

An oxonium salt may be readily prepared from the reaction of $AlCl_3$ with HCl in diethyl ether (equation 18). This is a viscous oil similar to quaternary ammonium salt ionic liquids.

$$AlCl_3 + HCl \xrightarrow{Et_2O} [(EtO)_nH]^+[AlCl_4]^- \qquad (18)$$

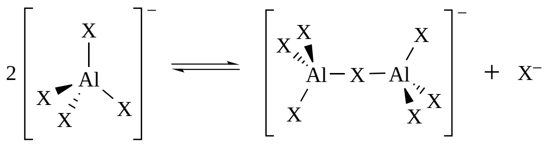
Aluminum chloride/sodium chloride mixtures have been much used as a molten salt medium (mp 173 °C) for electrolytic and other reactions.[11] The principal equilibria that occur in solution are given in Scheme 2.

Conducting liquids are produced at room temperature by the reaction of 1-methyl-3-ethylimidazolium chloride or *N*-butylpyridinium chloride with $AlCl_3$. These liquids are good

$$2AlCl_4^- \rightleftharpoons Al_2Cl_7^- + Cl^-$$
$$2Al_2Cl_7^- \rightleftharpoons Al_3Cl_{10}^- + Cl^-$$
$$2Al_3Cl_{10}^- \rightleftharpoons Al_2Cl_6 + 2Cl^-$$

Scheme 2 Equilibria in $AlCl_3$/chloride melts

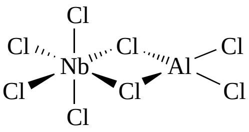
solvents for both organic and inorganic compounds. The principal equilibrium in this case is between $AlCl_4^-$ (**14**) and $Al_2Cl_7^-$ (**15**) (equation 19). The bromide and iodide analogs of (**14**) and (**15**) are obtained from KX/AlX_3 ($X = Br, I$) melts.[11]



(19)

(**14**) (**15**)

$AlCl_3$ reacts with other metal chlorides such as $CaCl_2$, $NbCl_5$, $NdCl_3$, $CrCl_3$, or UCl_5 to produce mixed halides with halogen bridges, for example, $Cl_4Nb(\mu\text{-}Cl)_2AlCl_2$ (**16**). Many of these complexes are very volatile; for example, the vapor pressure of $NdCl_3$ is increased by a factor of 10^{13} at 600 °C. A related reaction of $AlCl_3$ with $HgCl_2$ and mercury at 200 °C yields the molecular species $Hg_3Cl_2{\cdot}2AlCl_3$ (**17**).



$AlCl_3$— ClHgHgCl—$AlCl_3$

(**16**) (**17**)

A wide range of aluminum compounds may be conveniently prepared from $AlCl_3$ and alkali metal salts of various anions (equations 20–23).

$$LiY + AlCl_3 \longrightarrow AlCl_2Y + LiCl \quad (20)$$

$$2LiY + AlCl_3 \longrightarrow AlClY_2 + 2LiCl \quad (21)$$

$$3LiY + AlCl_3 \longrightarrow AlY_3 + 3LiCl \quad (22)$$

$$4LiY + AlCl_3 \longrightarrow LiAlY_4 + 3LiCl \quad (23)$$

$$(Y = R, OR, NR_2, N{=}CR_2, H)$$

Also, $AlCl_3$ is a good transhalogenation reagent for the conversion of nonmetal fluorides to the corresponding chloride; for example, BF_3 to BCl_3 (equation 24).

$$BF_3 + AlCl_3 \longrightarrow AlF_3 + BCl_3 \quad (24)$$

5 ALUMINUM OXIDES AND HYDROXIDES

The oxides, hydroxides, and mixed oxyhydroxides of aluminum form an extended family of compounds that have immense technological importance.[12]

Al_2O_3 occurs as the mineral corundum (α-Al_2O_3) and as emery, a granular form of corundum that is contaminated with silica and iron oxide. In α-Al_2O_3, the oxide ions form a hexagonal close-packed array with aluminum ions regularly distributed among the octahedral holes (Figure 2). It is a very hard material (Moh 9) (*see Moh's Hardness*), has a high melting point (2045 °C), and is nonvolatile, inert, and a good electrical insulator. As a result, it finds many applications in abrasives, refractories, and ceramics. Larger crystals when colored with metal ions are prized as gemstones, for example, ruby (Cr^{III}, red), sapphire ($Fe^{II/III}$, Ti^{IV}, blue), oriental emerald (Cr^{III}/V^{III}, green), oriental amethyst (Cr^{III}, Ti^{IV}, violet), and oriental topaz (Fe^{III}, yellow). Many aluminum-oxide based gemstones are synthesized for use as laser materials. Indeed, the first laser was created in 1961 by Theodore Maimanat using a rod of synthetic ruby as the lasing medium. Another example is alexandrite (chromium-doped chrysoberyl), which is both a particularly attractive precious gem and a uniquely versatile solid-state laser material with the distinction of being the first solid-state laser medium capable of tunable operation at room temperature.

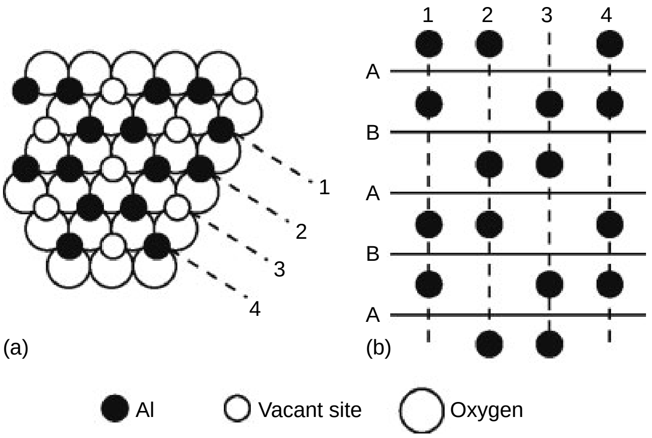


Figure 2 Schematic representation of the structure of α-Al_2O_3. (a) Pattern of occupancy by aluminum of the octahedral sites between the hexagonal close-packed planes of oxide ions and (b) stacking sequences of successive planes of aluminum atoms

Pure α-Al_2O_3 may be prepared by calcination of various Al salts, firing γ-Al_2O_3 or any of the hydrous oxides above 1200 °C, and by the oxidation of aluminum metal. Often single crystals of pure alumina that are prepared industrially are called *sapphires*. Large boules of synthetic sapphire are grown by melting aluminum oxide above 2060 °C and then directionally cooling. The resulting synthetic sapphires are anisotropic, monoaxial crystals that have a variety of technological applications and are also gaining popularity as gemstones known as white sapphires. Synthetic sapphire is one of the hardest and strongest materials, and is rated mechanically only second to diamond; It is one of the hardest materials available that when combined with a high modulus of elasticity and high tensile strength, makes it extremely wear, abrasion and impact resistant. For example, its abrasion stability is eight times higher than that of steel. It is colorless with an optical transmission window that ranges from 190 nm in the ultraviolet to 5 μm in the infrared. It had good dielectric qualities that make it a very good electrical insulator and it is thermally very stable and does not lose any of its mechanical and optical qualities from cryogenic temperatures to over 2000 °C. It has a thermal conductivity greater than most

dielectrics, and even better than many metals. It is also very corrosion resistant to a wider range of chemicals than just about any standard hard material available. Because of these unique properties sapphire is used as the material for production of ultraviolet, visible and near-infrared optics for operation under critical conditions such as high temperature, high pressure, or in chemically aggressive or abrasive environments. The high thermal conductivity also makes it an ideal substrate for GaN microelectronics.

γ-Al_2O_3, the second modification of alumina, has a less compact cubic close-packed structure. This is a defect spinel-type structure (see below) that is composed of a face-centered cubic array of 32 oxygen atoms with the aluminum atoms randomly occupying $21\frac{1}{3}$ of 16 octahedral and eight tetrahedral interstices. It is readily prepared by the low-temperature (<450 °C) dehydration of gibbsite, γ-$Al(OH)_3$, or boehmite, γ-AlOOH. Quite unlike α-Al_2O_3, γ-Al_2O_3 or ‘activated alumina’ readily absorbs water and dissolves in acids. Progressive dehydration of γ-alumina leads to porous materials that have great value as catalysts, catalyst supports, ion-exchangers, and chromatographic media.

Yet another form of Al_2O_3 forms on the surface of aluminum metal. This has a defect sodium chloride structure with aluminum ions occupying two-thirds of the octahedral holes.

In 1974, ICI announced the production of alumina fibers known as ‘*saffil alumina*’. These microcrystalline fibers are flexible, resilient, and have high tensile strength. They are easily fashioned into rope, yarn, cloth, blankets, paper, boards, and objects of any shape. Numerous small pores (10–20 pm) occur between the microcrystals, providing significant surface area (100–150 $m^2\,g^{-1}$) that enhances the fiber’s performance as insulation, filtration media, and catalyst supports. The fibers are very inert, withstanding temperatures to 1400 °C and attack by hot alkali and acids. The fibers are therefore employed as high-temperature insulation, electric-cable sheathing, and in the filtration of hot corrosive liquids. They have also found significant application in metal/ceramic composites in which they contribute high structural stiffness coupled with low density.

Diaspore, α-AlO(OH), occurs in some types of clay and bauxite and can be synthesized by hydrothermal treatment of boehmite, γ-AlO(OH), in 0.4% aqueous NaOH at 380 °C and 500 atm. Crystalline boehmite is easily obtained upon warming the amorphous, gelatinous precipitate that forms when cold solutions of aluminum salts are treated with ammonia.

Both α-AlO(OH) and γ-AlO(OH) contain double chains of edge-shared AlO_6 octahedra. In γ-AlO(OH), these chains share a further two edges to form puckered sheets, while in α-AlO(OH) the edge-sharing produces a 3-D structure (Figure 3). The latter leads to hexagonal close-packing of the oxygen atoms, accounting for the ready dehydration of diaspore to α-Al_2O_3 at 450 °C. As noted earlier, boehmite dehydrates to γ-alumina.

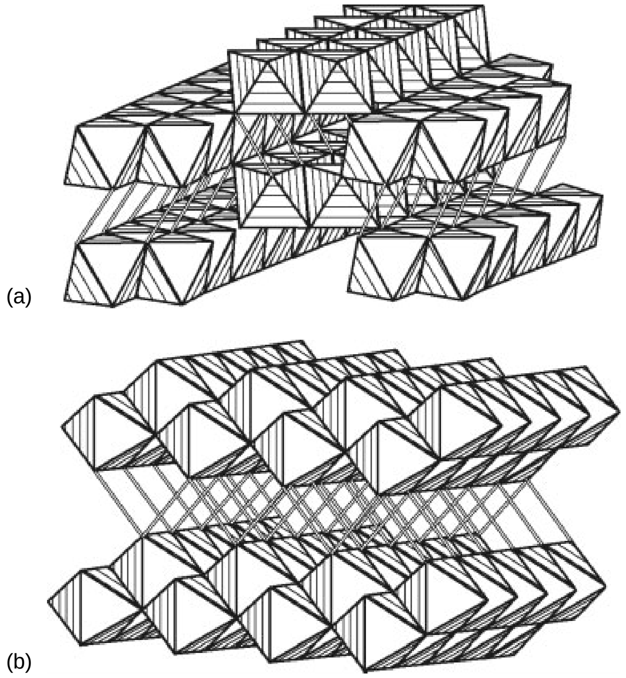

Figure 3 Structure of (a) diaspore and (b) boehmite. The aluminum atoms are octahedrally surrounded by five oxide and one hydroxide anions. The hydrogen bonds are shown as double lines

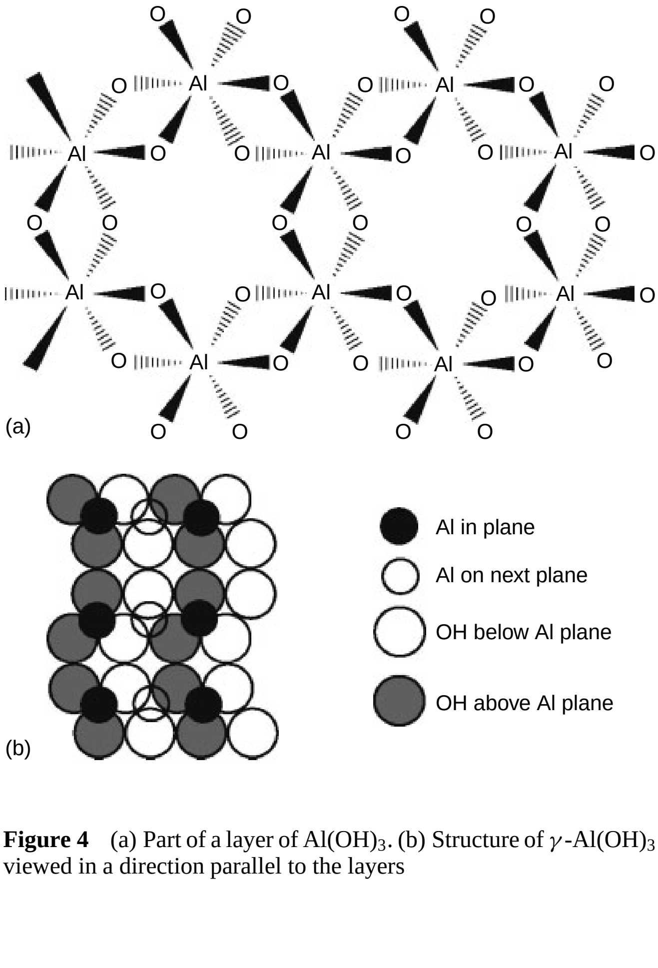

Figure 4 (a) Part of a layer of $Al(OH)_3$. (b) Structure of γ-$Al(OH)_3$ viewed in a direction parallel to the layers

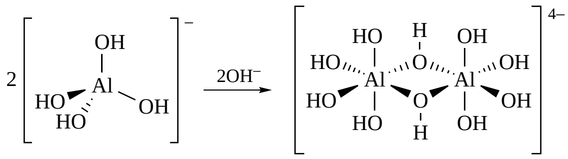
Bayerite, α-$Al(OH)_3$, is not a naturally occurring mineral but it can be made by precipitation from cold, alkaline solutions (equation 25).

$$2[Al(OH)_4]^-(aq) + CO_2(g) \longrightarrow 2Al(OH)_3(s) + CO_3^{2-}(aq) + H_2O \quad (25)$$

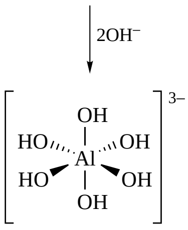
Gibbsite, γ-$Al(OH)_3$, is a more stable form that is prepared by slow precipitation from warm alkaline solutions or by heating bayerite in aqueous sodium aluminate solution at 80 °C. Both bayerite and gibbsite have layers of composition $Al(OH)_3$ formed by the sharing of $Al(OH)_6$ octahedra in such a way that a pair of close-packed OH^- layers are formed with aluminum atoms in two-thirds of the octahedral holes. The two phases differ in the way the layers are stacked; in α-$Al(OH)_3$, it is approximately hexagonal close-packing but in the γ-form two out of three layers stack together directly on top of each other (Figure 4). It should also be noted that a third form of $Al(OH)_3$, nordstrandite, has an intermediate stacking arrangement between those of the α- and γ-forms. It is prepared by aging the gelatinous hydroxide in the presence of a chelating agent such as ethylene glycol, ethylene diamine, or EDTA. As indicated earlier, gibbsite can be dehydrated to boehmite at 100 °C and to anhydrous γ-Al_2O_3 at 150 °C. It is also amphoteric, reacting both with bases and acids (equations 26–28). Reaction with acids usually results in formation of the $[Al(H_2O)_6]^{3+}$ cation while those with base afford a variety of products such as $[Al(OH)_4]^-$ (**18**), $[Al_2(OH)_{10}]^{4-}$ (**19**), and $[Al(OH)_6]^{3-}$ (**20**).

$$Al(OH)_3(s) + 3H_3O^+(aq) \longrightarrow [Al(H_2O)_6]^{3+}(aq) \quad (26)$$

$$Al(OH)_3(s) + OH^-(aq) \longrightarrow [Al(OH)_4]^-(aq) \quad (27)$$



(**18**) (**19**)



(28)

(**20**)

The Al/O/OH family form an important catalytic system and numerous recipes have been reported for preparing catalysts of differing reactivity and absorptive power. Additionally, the basic character of the surface diminishes and the acidic nature increases in the following series: amorphous Al oxide hydrate < γ-AlO(OH) < α-$Al(OH)_3$ < γ-Al_2O_3 (pH of isoelectric points: 9.45, 9.45–9.40, 9.20, 8.00, respectively).

6 TERNARY AND MORE COMPLEX OXIDE PHASES

Numerous important mixed oxide phases are formed by the combination of aluminum oxide and one or more other metal oxides. The foremost of these from an industrial viewpoint are spinels, β-aluminas, and tricalcium aluminate, an important constituent of Portland cement.

6.1 Spinels and Related Compounds

Spinels are a large family of compounds that possess the structure of the mineral spinel, $MgAl_2O_4$. The general formula is AB_2X_4 and the unit cell contains eight of these formula units with the 32 oxygen atoms in a nearly perfect cubic close-packed array. In the normal spinel structure, eight 'A' metal atoms occupy tetrahedral sites while the 16 'B' atoms occupy octahedral sites. Thus, the unit cell can be thought of as being composed of eight alternating cubic building blocks of Zn–S and Na–Cl type structures surrounded by an additional 14 'A' atoms in a face-centered cubic array (Figure 5).

Many spinel compounds adopt an alternative structure where half the B cations occupy the tetrahedral sites while the remaining B cations and A cations occupy the octahedral sites. These are known as inverse spinels. The occupancy of the latter sites may be random or ordered. The adoption of an inverse spinel versus a spinel structure depends on a variety of factors; the relative size of the A and B cations, the relative lattice energies, ligand-field stabilization, energies of octahedral versus tetrahedral coordination, and polarization or covalency effects. For example, in $MgAl_2O_4$ one might expect the small

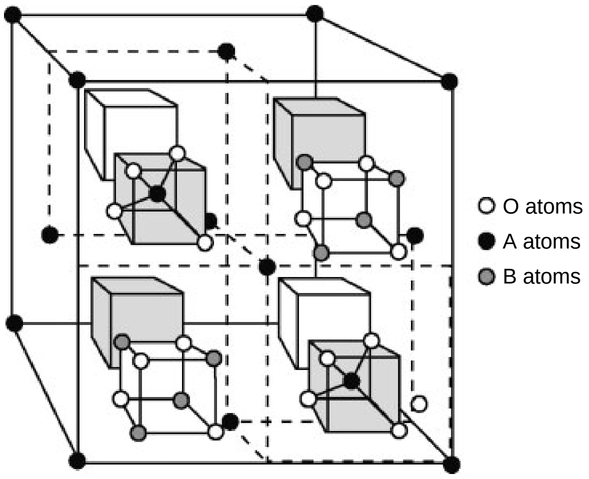


Figure 5 Spinel structure, AB_2O_4, composed of eight octants of alternating AO_4 tetrahedra and B_2O_4 cubes. The four oxygen atoms have the same orientation in all octants and therefore build up a face-centered cubic lattice of 32 ions. The four 'A' octants contain four 'A' ions while the four 'B' octants contain 16 'B' ions. The unit cell is completed by a surrounding face-centered cubic array of 14 'A' ions. These are shared with adjacent unit cells and comprise the remaining four 'A' ions required for the stoichiometry $A_8B_{16}O_{32}$

Al^{3+} ion to occupy the tetrahedral site but this is outweighed by the greater lattice energy associated with having the cation of higher charge on the octahedral site, that is, $(Mg)_{tet}[Al_2]_{oct}O_4$. On the other hand, in $NiAl_2O_4$ the crystal field stabilization energy of Ni^{II} is greater in octahedral sites leading to a disordered spinel; $[Al_{0.75}Ni_{0.25}]_{tet}[Ni_{0.75}Al_{1.25}]_{oct}O_4$.

Inverse and disordered spinels are called *defect structures* because all the identical crystallographic sites are not occupied by the same cation. A different defect structure is formed when spinels have disordered valencies. For example, the divalent cations in AB_2O_4 may be replaced by equal numbers of M^I and M^{III} ions of appropriate size. As an illustration, the magnesium atoms of spinel may be replaced by lithium and aluminum atoms to give a spinel with formula $LiAl_5O_8$. This has a defect structure in which two-fifths of the aluminum atoms occupy all the tetrahedral sites: $(Al_2)_{tet}[LiAl_3]_{oct}O_8$. Similarly, disordering on the tetrahedral sites occurs in $(MAl)_{tet}[Al_4]_{oct}S_8$ where $M = Ag^+$ or Cu^+. Valency disordering can also occur when all the A^{II} ions are replaced by M^I, necessitating the replacement of the B^{III} ions by M^{IV} to achieve charge balance, for example, $(Li)_{tet}[AlTi]_{oct}O_4$. The possibilities of cation substitution are almost limitless, and cubic spinels such as $LiZn_8Al_5Ge_9O_{36}$ have been prepared.[13,14]

As mentioned earlier, γ-Al_2O_3 has a defect-spinel structure in which not all the cation sites are occupied. This can be thought of as being derived from spinel by replacing magnesium by aluminum and maintaining charge balance by leaving one site vacant for every three magnesium atoms replaced, that is, $Al_{\frac{64}{3}}[\ ]_{\frac{8}{3}}O_{32}$.

The sensitive dependence of electrical and magnetic properties of spinels on temperature, composition, and detailed cation arrangement allows extensive tailoring of their properties for use in the solid-state electronics industry. For example, $CuAl_2O_4$ and $CoAl_2O_4$ are used extensively in negative temperature coefficient resistors. Spinels are also employed in catalysis: $NiAl_2O_4$ for methanation and dehydrogenation, $FeAl_2O_4$ for oxidation of chlorocarbons and ammonia production, $CoAl_2O_4$ for oxidation and desulfurization, and $ZnAl_2O_4$ for oxidations of organics, aromatization, dehydrogenation, and cracking and reforming of hydrocarbons (*see* ***Oxide Catalysts in Solid-state Chemistry***). As well, $ZnAl_2O_4$ and $FeAl_2O_4$ are used in glass ceramics, Co_2AlO_4 is used as a pigment in photography, Fe_2AlO_4 as an absorbent for H_2S, and $ZnAl_2O_4$ is used as an anticorrosion coating, an abrasive, a pigment, in moisture sensors, and as a screen-printable dielectric compound for printed circuits.

When the divalent cation becomes too large for the spinel structure to be adopted (e.g. Ca^{2+}, Ba^{2+}, and Pb^{2+}), a tridymite (SiO_2) structure is obtained that has the divalent cation in the interstices (*see* ***Silicon: Inorganic Chemistry***). These are synthesized by reaction of the oxides at temperatures over 800 °C. The barium and calcium derivatives are used in ceramics and refractories. In particular, $BaAl_2O_4$ is used in nuclear reactors; $BaAl_2O_4$ and $CaAl_2O_4$ are also used as supports for transition and lanthanide metal phosphors.

6.2 β-Aluminas and Related Compounds

Sodium β-alumina has achieved substantial importance as a solid-state electrolyte owing to its extremely high ionic conductivity (*see* ***Ionic Conductors***).[15,16] The compound has the idealized formula of $NaAl_{11}O_{17}$ (i.e. $Na_2O{\cdot}11Al_2O_3$) and only bears the name of β-alumina because earlier studies either did not detect or ignored the presence of sodium. Indeed, it is the latter cations that stabilize the structure. This is closely related to spinel with no fewer than 50 of 58 atoms in the unit cell being arranged exactly as in spinel. The large sodium atoms along with an equal number of oxygen atoms are arranged in loosely packed planes between the spinel blocks. There are several sites in the layer between the spinel blocks that the sodium ions can occupy, permitting rapid 2-D diffusion of sodium in this plane and resulting in a low resistivity of 30 ohm cm. The structure can easily accommodate additional sodium ions and even single crystals often contain 20–30% more sodium than indicated by the idealized formula.

Sodium β-alumina can be prepared by heating Na_2CO_3, $NaNO_3$, or NaOH with any modification of alumina or its hydrates to 1500 °C in a sealed platinum vessel (to prevent loss of Na_2O). The processing temperature may be dropped to 1000 °C by addition of fluoride in the form of NaF or AlF_3. The sodium is easily replaced by other metals (Li, K, Rb, Cu^I, Ag^I, Ga^I, In^I, or Ti^I) by heating sodium β-alumina with an appropriate molten salt. The NO^+, $NH_4{}^+$ and H_3O^+ salts have also been prepared.

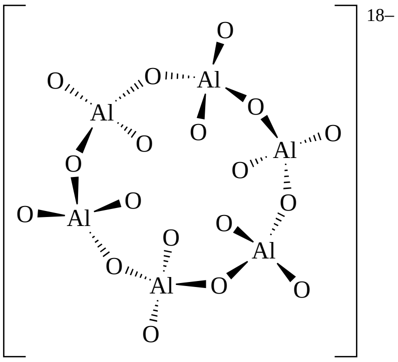
The β-aluminas have been extensively used as permeable membranes in sodium–sulfur batteries since they provide the unique properties of allowing sodium transport but neither sulfur nor electron conduction and they are not attacked by molten sodium or sulfur.

Numerous other sodium aluminates are known including a number of alkali-rich aluminates with quite different structures from the β-aluminas. Depending on stoichiometry, the solid-state reaction of α-Al_2O_3 with Na_2O at 700 °C yields colorless crystals of Na_5AlO_4, $Na_7Al_3O_8$, and $Na_{17}Al_5O_{16}$. Na_5AlO_4 and the isoelectronic Li_5AlO_4 contain discrete AlO_4 tetrahedra. $Na_7Al_3O_8$ contains rings of six AlO_4 tetrahedra that are linked together by four oxygen bridges to form an infinite chain. $Na_7Al_{15}O_{10}$ contains discrete chain anions, $[O_3Al(OAlO_2)_3OAlO_3]^{17-}$, formed by linking the corners of five AlO_4 tetrahedra.[17,18] Li_5AlO_4 is an ionic conductor with possible applications in batteries. It is also used as a blanket material in the nuclear power industry. $MAlO_2$ (where M = Li, Na, K) are prepared by reaction of Al_2O_3 with the alkali metal carbonates at elevated temperatures. The latter two compounds have the $NaFeO_2$ structure (*see* ***Iron: Inorganic & Coordination Chemistry***). $NaAlO_2$ is used in water treatment, sizing of paper, and as a raw material for manufacture of zeolites, ceramics, and catalysts in the petroleum industry (*see* ***Zeolites***).

6.3 Calcium Aluminates

The calcium aluminates are an extensive family of compounds that amply demonstrate the diverse structural chemistry of aluminum. They are easily prepared by reaction of CaO and Al_2O_3 in appropriate ratios.

Tricalcium aluminate is one of the components of Portland cement (a mixture of 26% Ca_2SiO_4, 51% Ca_3SiO_5, 11% $Ca_3Al_2O_6$, and 1% $Ca_4Al_2FeO_{10}$). The structure of $Ca_3Al_2O_6$ contains a 12-membered ring composed of six-fused AlO_4 tetrahedra (**21**). This compound is readily hydrolyzed and, depending on the temperature, forms the hexahydrate (above 21 °C) or a mixture of $2CaO{\cdot}Al_2O_3{\cdot}5{-}9H_2O$ and $4CaO{\cdot}Al_2O_3{\cdot}12{-}14H_2O$ (below 21 °C).



(**21**)

Another important calcium aluminate occurs in high-alumina cement, also known as *ciment fondu*. This is manufactured by fusing limestone, bauxite, and small amounts of SiO_2 and TiO_2 at 1500 °C. The most important components of the cement are $CaAl_2O_4$, $Ca_2Al_2SiO_7$, and $Ca_6Al_8FeSiO_{21}$. High-alumina cement develops very high strength in the very early stages of hydrolysis (within one day). It is not resistant to long exposure to warm moist conditions but it does have superior resistance to corrosion by seawater and acids. Owing to its ability to withstand temperatures to 1500 °C, it has also been used as a refractory cement. As noted earlier, $CaAl_2O_4$ has the tridymite structure.

$CaAl_4O_7$ has a structure that is composed of linked, distorted AlO_4 tetrahedra and seven-coordinate calcium atoms. It is used in laser materials as a host for Nd^{3+}.

$Ca_4Al_6O_{13}$ [better formulated as $Ca_4O(Al_6O_{12})$] has a structure that is related to sodalite (*see* ***Zeolites***). This contains AlO_4 tetrahedra that are linked to form cubooctahedra. These are, in turn, linked to form an infinite framework with OCa_4 tetrahedra in the cavities.

$Ca_5Al_6O_{14}$ has twisted sheets of distorted AlO_4 tetrahedra that are linked by their corners. The calcium atoms are six-coordinate and lie between the Al_6O_{14} sheets.

$CaAl_{12}O_{19}$ occurs as a constituent of cement and is a component of steel-making slags. It is used as a support for rare-earth phosphors and as a refractory material. It has a very complex structure containing four, five, and six-coordinate aluminum.

7 ALUMINUM OXYACID SALTS

The propensity of aluminum salts to form the hexaaqua ion, $[Al(H_2O)_6]^{3+}$, upon exposure to water requires that most aluminum oxyacid salts be prepared by nonaqueous routes. Some of these salts are of particular technological value.

7.1 Aluminum Phosphates

Aluminum reacts readily with hot phosphoric acid to give a variety of products depending on the reaction conditions. Thus $Al(PO_4H_2)_3$ is formed at 25 °C, $Al(PO_4H_2)(PO_4H)$ is formed at 100–120 °C, and $AlPO_4$ is formed at higher temperatures. $Al(PO_4H_2)_3$ is used as a binder for glazes, a metal coating, and in dental cements. $Al(PO_4H)(PO_4H_2)$ is a constituent of many commercial binders and adhesives.[19]

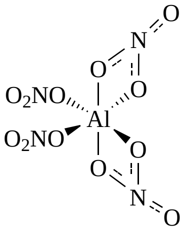
$AlPO_4$ is isoelectronic with silica and, as such, readily forms glasses and SiO_2-like crystalline materials. As well, framework structures similar to zeolites may be prepared by the use of amines as templates. Like zeolites, these are active in catalytic reactions such as methanol conversion to hydrocarbons (*see* ***Zeolites***).[20,21] As a ceramic material, $AlPO_4$ is an infusible material that is insoluble in water but is soluble in alkali hydroxides. It is often used with calcium sulfate and sodium silicate for dental cements. $AlPO_4$ is also used as a white pigment that also acts as a corrosion inhibitor.

Aluminum trimetaphosphate, $Al(PO_3)_3$, is obtained from a melt of Al_2O_3 and HPO_3. The structure is composed of chains of PO_4 tetrahedra that are connected by AlO_6 octahedra. $Al(PO_3)_3$ is a constituent of glasses, coatings, binders, and ceramics as well as a catalyst for esterifications and oxidation of alkenes (*see* ***Phosphates: Solid-state Chemistry***).

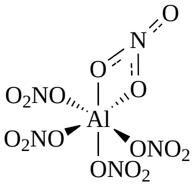
There are a number of minerals composed of aluminum phosphate that form geologically as precipitates from circulating phosphate-rich water. These include variscite, $AlPO_4{\cdot}2H_2O$, wavellite, $Al_3(PO_4)_2(OH,F)_3{\cdot}5(H_2O)$, wardite $NaAl_3(PO_4)_2(OH)_4{\cdot}2(H_2O)$, and brazilianite, $NaAl_3(PO_4)_2(OH)_4$ (one of a very few phosphate gemstones). Synthetic sodium aluminum phosphate is used as a leavening agent or acid in baking powders. Unlike other leavening agents; it reacts slowly with sodium bicarbonate in the mixing stage, leading to the majority of carbon dioxide delivery occuring during the oven stage. The result is a baked product that is crunchy and has fine texture. Turquoise, $CuAl_6(PO_4)_4(OH)_8{\cdot}5(H_2O)$, is another important aluminum phosphate that is possibly the most valuable, nontransparent mineral in the jewelry trade. It has been mined for centuries since at least 6000 BC by early Egyptians.

7.2 Aluminum Nitrates

Reaction of $AlBr_3$ with N_2O_5 produces white hygroscopic crystals of the salt $[NO_2]^+[Al(NO_3)_4]^-$. The $[Al(NO_3)_4]^-$ anion (**22**) may also be obtained as the alkali metal or tetraethylammonium salts by the reaction of the appropriate nitrate salt, nitric acid, or N_2O_5 with $AlBr_3$. Use of an excess of metal nitrate affords the $[Al(NO_3)_5]^{2-}$ anion (**23**).



(**22**)



(**23**)

Thermal decomposition of $Al(NO_3)_2N_2O_5$ produces anhydrous $Al(NO_3)_3$. All the nitrates of aluminum are powerful oxidants and may react explosively with organic solvents. They also decompose to oxides rather readily, as low as 65 °C in the case of $Al(NO_3)_3$.

7.3 Aluminum Sulfates and Selenates

$Al_2(SO_4)_3$ occurs in the hydrated form as the mineral alunogen, $Al_2(SO_4)_3 \cdot 18H_2O$, and may also be obtained by treatment of $Al(OH)_3$ with sulfuric acid. $Al_2(SeO_4)_3$ is obtained in a similar manner. Unlike most hydrated aluminum salts, the anhydrous forms are obtained simply upon heating the hydrates to 325 °C. $Al_2(SO_4)_3$ is used in water purification as a flocculent and as sizing for paper. It is also used as a mordant in the dying of cloth, a process by which it fixes the dye to the cloth by rendering the dye insoluble. In one important water-treatment process, aluminum sulfate is used to precipitate phosphate from water as aluminum phosphate. This is important in preventing algal blooms that are detrimental to aquatic life.

The alums, $MAl(SO_4)_2$, are obtained from reaction of $Al(OH)_3$ with M_2SO_4/H_2SO_4 mixtures (equation 29). The structure is composed of alternating layers of six-coordinate aluminum and potassium ions with the sulfate anions between them. The potassium derivative is used as a mordant, paper sizing, deodorant, and coagulation agent for rubber, and for curing furs and water purification. The sodium salt is used as a flame retardant, in tanning and the dying and printing of fibers, in the preparation of inks, lacquers, paper, vegetal gum, cement, porcelain, explosives, ammonia synthesis catalysts, and is a component of baking powder.

$$2Al(OH)_3 + M_2SO_4 + 3H_2SO_4 \longrightarrow 2MAl(SO_4)_2 + 6H_2O \quad (29)$$

(M = any monovalent cation except Li)

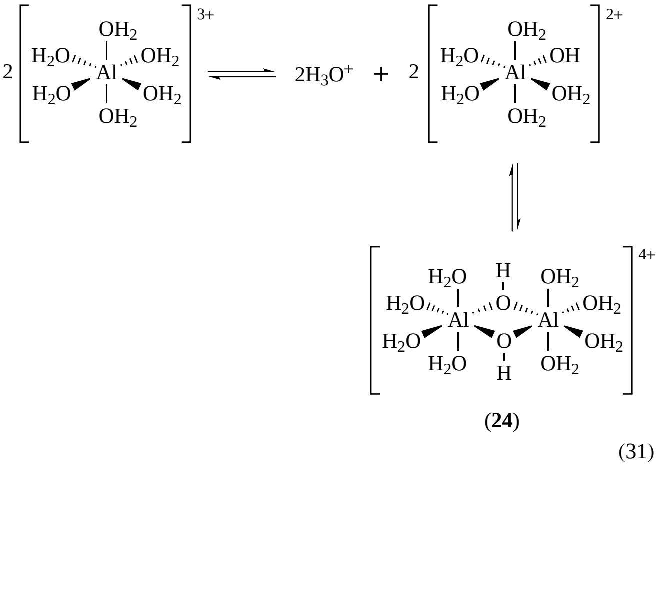
7.4 Aluminum Salts of Halogen Oxyacids

Aluminum perchlorate, $Al(ClO_4)_3$, is synthesized by treatment of $AlCl_3$ with $AgClO_4$ in C_6H_6 (equation 30). It is a very strong oxidant that reacts slowly with paraffin hydrocarbons. It decomposes at 150 °C and should be considered a potential explosive. Aluminum periodate may be obtained in the same manner. Aluminum iodate, $Al(IO_3)_3$, is obtained by thermal decomposition of $[Al(OH_2)_6][IO_3][HI_2O_6] \cdot HIO_3$ at 340 °C.

$$3AgClO_4 + AlCl_3 \longrightarrow Al(ClO_4)_3 + 3AgCl \quad (30)$$

8 THE AQUA IONS AND AQUEOUS CHEMISTRY

Aluminum forms a wide variety of salts including chlorides, nitrates, perchlorates, and so on that contain the hexaaquaaluminum(III) cation, $[Al(H_2O)_6]^{3+}$. These ions exist both in aqueous solution and crystalline solids. The ions are acidic and as salts of weak acids are extensively hydrolyzed (equation 31) by water. The $[Al(H_2O)_5OH]^{2+}$ ion has been observed in dilute solution but there is a very high equilibrium constant for formation of a hydroxide-bridged dimer (**24**). This dimer has been characterized in several crystalline salts. The hydrolysis of $[Al(OH_2)_6]^{3+}$ over a wide range of pH provides a great variety of species including the $[(H_2O)_5Al(OH)]^{2+}$ monomer and dimer listed above, $Al(OH)_3$, $[Al(OH)_4]^-$, $[Al_3(OH)_{11}]^{2-}$, $[Al_6(OH)_{15}]^{3+}$, and $[Al_8(OH)_{22}]^{2+}$. The formation of these hydrolyzed species depends markedly on the exact conditions used.[22] One remarkable species, $[AlO_4 \cdot Al_{12}(OH)_{24}(H_2O)_{12}]^{7+}$, is obtained by hydrolysis of (**24**) with sodium carbonate. This has a Keggin-type structure with a central AlO_4 tetrahedral core surrounded by 12 AlO_6 octahedra.



(**24**)

(31)

9 ALUMINOSILICATES

Aluminosilicates form an extensive family of compounds that include layered compounds (such as clays, talc, and micas), 3-D compounds, (e.g. feldspars, such as granite), and microporous solids known as molecular sieves.[23] The structural diversity of these materials is contributed to by aluminum's ability to occupy both tetrahedral and octahedral holes as it also does in γ-Al_2O_3. Thus, aluminum substitution for silicon in silicate minerals may lead to replacement of silicon in tetrahedral sites or the aluminum can occupy an octahedral environment external to the silicate lattice. Replacement of Si^{IV} with Al^{III} requires the presence of an additional cation such as H^+, Na^+, or 0.5 Ca^{2+} to balance the charge. These additional cations have a profound effect on the properties of the aluminosilicates. This accounts for the many types of layered and 3-D structures (*see* ***Silicon: Inorganic Chemistry***).

The molecular sieves are aluminosilicates of particular importance. They are crystalline materials that have open structures that contain pores and channels that have molecular dimensions. This family of materials includes the zeolites, which have numerous applications in heterogeneous catalysis, ion-exchange materials, absorption of molecular species, and gas separation. While some zeolites occur naturally, they are usually manufactured from silicon and aluminum oxides mixed with tetraalkylammonium 'templates' in a high-pressure autoclave (*see* ***Zeolites***).

10 ALUMINUM CHALCOGENIDES

Under ordinary conditions, the stable binary chalcogenides (*Chalcogens*) of aluminum are Al_2S_3 (white), Al_2Se_3 (gray), and Al_2Te_3 (dark gray). Their band gaps are 4.1, 3.1, and 2.2 eV, respectively, showing the expected trend to smaller band gap (*see Band Gap*). They are prepared by the direct combination of the elements at 1000 °C and must be protected from moisture owing to rapid hydrolysis to $Al(OH)_3$ and H_2X ($X = S$, Se, Te) (equation 32). The relatively large size of the anions with respect to aluminum leads to tetrahedral coordination of the latter. Therefore, the various polymorphs adopt a wurtzite structure with two-thirds of the available metal sites being occupied by aluminum. If this occupation is ordered, the modification is called α-Al_2X_3; if not, then the phase is called β-Al_2X_3. Al_2S_3 also forms a γ-form similar to γ-alumina (*see* ***Chalcogenides: Solid-state Chemistry***).

$$Al_2Y_3 + 6H_2O \longrightarrow 2Al(OH)_3 + 3H_2Y \quad (Y = S, Se, Te) \tag{32}$$

Al_7Te_{10} may be prepared by fusion of the elements. It is one of the few compounds with an Al–Al bond. The structure consists of Te_4Al_4–Al_4Te_4 units that contain Al_2Te_2 four-membered rings (*see* ***Tellurium: Inorganic Chemistry***).

11 ALUMINUM PNICTIDES

The compounds of group 13 and group 15 have achieved considerable technological importance owing to their application as III–V semiconductors (these compounds are isoelectronic with Si and Ge) (*see Compound Semiconductor*). AlN, AlP, AlAs, and AlSb may all be prepared by direct combination of the elements at elevated pressures (*see Pnictide*). All have the sphlaerite structure with the exception of aluminum nitride, which has the wurtzite structure. The properties of the compounds are given in Table 7 and they show the clear trends towards lower-melting point and smaller band gap with increasing atomic number of the pnictide (*see also* ***Phosphides: Solid-state Chemistry***).

Aluminum nitride was first synthesized in 1877, but it was a relatively unimportant material until mid-1980s when its potential for application in microelectronics was realized. It has very high thermal conductivity for a ceramic material (320 W/m·K) that is second only to beryllium oxide Unlike BeO, AlN is nontoxic so it became the material of choice for substrates for microelectronic circuits that require rapid removal of heat. A high dielectric strength (>20 kV/mm) and high resistivity (10^{10} ohm·cm) also contribute to the performance of AlN in these applications. AlN is generally synthesized by carbothermal reduction of alumina or by direct nitridation of aluminium. AlN can also be prepared by reaction of $AlCl_3$ and NH_3 at 1200 °C (equation 33).[24] Fashioning AlN into ceramic bodies and substrates is difficult because it does not have a melting point but dissociates above 2500 °C at atmospheric pressure. The material's strong covalent bonding makes it resistant to sintering without the assistance of liquid forming additives. Such additives include oxides like Y_2O_3 or CaO that allow sintering to be achieved at temperatures between 1600 and 1900 °C. As a powder, aluminum nitride is susceptible to hydrolysis by water or humidity to produce aluminum hydroxide and ammonia. This is not a problem for ceramic monoliths since the reaction is limited to the surface. Items manufactured from AlN are resistant to attack from most molten salts including chlorides and cryolite and most molten metals including aluminium, lithium, and copper. Unfortunately, aluminum nitride is readily attacked

Table 7 Some properties of Al III–V compounds

Property	AlN	AlP	AlAs	AlSb
Color	Pale/yellow	Yellow	Orange	Black
Mp (°C)	>2200 decomp	2000	1740	1060
E_g (eV)	4.26	2.45	2.16	1.50

by acids and alkalis as are most aluminum compounds. Films of AlN can provide useful wear resistance and may be obtained by various chemical vapor deposition methods (*see Metal–Organic Chemical Vapor Deposition*).

$$AlCl_3 + 4NH_3 \longrightarrow AlN + 3NH_4Cl \quad (33)$$

Aluminum phosphide, like aluminum nitride, reacts with moisture but in this case the gaseous product is phosphine, PH_3, a very toxic gas. For this reason, AlP is used as a fumigant to control insects in stored products such as raw agricultural products, animal feeds, processed foods (for example, flour and sugar), tobacco, wood, paper, leather, hair, and feathers. It is also used for control of rodents such as rats, mice, squirrels, and gophers in and around mills, food processing plants, warehouses and silos, and in rail cars, ships, and shipping containers.

12 MIXED ALUMINUM CHALCOGENIDE HALIDES

The reaction of aluminum halides with a variety of oxides at elevated temperatures yields the aluminum oxyhalides, AlOX (equation 34). These compounds are insoluble, moisture-sensitive compounds that have an interesting layered structure. The aluminum atoms have tetrahedral coordination by three oxygen atoms and one halide atom. The oxygen atoms of the tetrahedra are shared between three aluminum atoms, providing a puckered 'AlO' layer. The halide atoms cap the tetrahedra, half of them above and half of them below the AlO layer in an alternating fashion.[25] The hydrate of AlOCl is used as an antiperspirant.

$$3AlX_3 + M_2O_3 \longrightarrow 3AlOX + 2MX_3 \quad (34)$$
$$(M = As, Bi, Sb; X = Cl, Br, I)$$

Analogous sulfur, selenium, and tellurium compounds are easily prepared by reaction of the aluminum halides with the appropriate aluminum chalcogenide (equation 35).

$$Al_2Y_3 + AlX_3 \longrightarrow 3AlYX \quad (35)$$
$$(Y = S, Se, Te; X = Cl, Br, I)$$

Several oxyhalide anions have also been characterized, for example, $[Al_3OCl_8]^-$ and $[Al_4O_2Cl_{10}]^{2-}$.

13 ALUMINUM CARBIDE AND BORIDES

Al_4C_3 is prepared by direct union of the elements at elevated temperatures. It forms pale-yellow crystals (mp 2200 °C) with a very complex structure. This consists of AlC_4 tetrahedra that are linked to form a layered lattice. There are two types of carbon atoms: one that is surrounded by a distorted octahedron of aluminum atoms at 217 pm and one that is surrounded by four aluminum atoms at 190–194 pm and a fifth one at 221 pm. Aluminum carbide hydrolyzes very readily to $Al(OH)_3$ and methane (equation 36) (*see* ***Carbides: Transition Metal Solid-state Chemistry***).

$$Al_4C_3 + 12H_2O \longrightarrow 4Al(OH)_3 + 3CH_4 \quad (36)$$

There are several aluminum boride phases known.[26] One of the more common, AlB_{12}, is employed in the manufacture of lightweight armor, as a catalyst for organic reactions, and as a economical replacement for diamond abrasive. It has a complex structure composed of B_{12} icosahedra, B_{19} units (twinned icosahedra), and single boron atoms in a 2:1:1 ratio. The aluminum atoms are distributed statistically over all the boron sites. AlB_{12} is synthesized by direct combination of the elements at 1100 °C or by reaction of aluminum with $Na_4B_4O_7$ at 1100 °C.

AlB_2 may be conveniently prepared by reaction of aluminum with H_3BO_3, KBF_4, or B_2O_3/KCl mixtures at temperatures between 800 and 1300 °C. AlB_2 is a metallic conductor (conductivity of 333 $\Omega^{-1}\,m^{-1}$) that slowly reacts with water and aqueous hydrochloric acid. The structure consists of hexagonal nets of boron atoms with each boron atom surrounded by six aluminum atoms at the corners of trigonal prisms.

An aluminum boride that is intermediate between the two extremes above, AlB_4, has a structure consisting of B_6 octahedra that are linked by B_2 units forming tunnel-like cavities in which the aluminum atoms lie (*see* ***Boron: Inorganic Chemistry***).

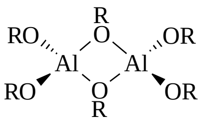
14 ALKOXIDES

The alkoxides of aluminum have become particularly important owing to their utility in sol–gel processes[18] (*see* ***Sol–Gel Synthesis of Solids***). They are also useful as reducing agents for aldehydes and ketones and other catalytic reactions.[27]

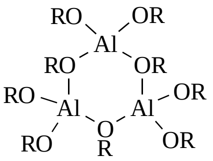
Aluminum alkoxides can be prepared by reaction of alcohols with the metal in the presence of catalytic amounts of $HgCl_2$ or I_2 (equation 37). As mentioned previously, they can also be obtained by treatment of $AlCl_3$ with sodium alkoxides. Furthermore, the alkoxides may be interconverted by a transesterification reaction (equation 38).

$$2Al + 6ROH \longrightarrow 2Al(OR)_3 + 3H_2 \quad (37)$$
$$Al(OR)_3 + 3MeCO_2R' \longrightarrow Al(OR')_3 + 3MeCO_2R \quad (38)$$

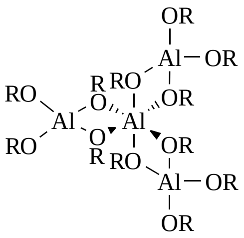
The alkoxides of aluminum are polymeric with aluminum achieving four or six coordination. The adopted structure depends greatly on the bulkiness of the alkyl groups. For sterically large groups, for example, tertiary butyl, the preferred structure is a dimer (**25**). The isopropoxide, on the other hand, is trimeric (**26**) at elevated temperatures but tetrameric (**27**) at room temperature.[27]



(**25**)



(**26**)



(**27**)

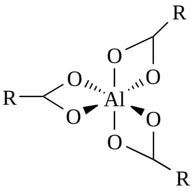
The siloxides of aluminum can be prepared in the same manner as the alkoxides and exhibit similar structural features. Interest in these compounds arose from a desire for sol–gel or polymeric precursors for aluminosilicates. Unfortunately, these compounds extensively hydrolyze, losing most of the silicon as the silanol. However, the investigation of the hydrolysis of $(Et_3SiO)_3Al$ has generated considerable insight into the structure and composition of alkoxy- and siloxy-substituted alumoxane polymers, '$(ROAlO)_n$'.[28] These macromolecules are now believed to have a structure related to that of boehmite.

15 ALUMINUM CARBOXYLATES

Aluminum carboxylates have been extensively investigated because of their applications as textile finishing, gelling, and therapeutic agents. Despite this, the structural aspects of their chemistry are not well established.[29]

Aluminum tricarboxylates may be synthesized by methods analogous to those employed for the alkoxides. However, they are best obtained by the reaction of the alkoxides with carboxylic acids (equation 39). The tricarboxylates have been demonstrated to be monomeric in benzene and octahedral coordination (**28**) of aluminum was proposed.

$$Al(OR)_3 + 3RCO_2H \longrightarrow 3ROH +$$



(**28**)

(39)

The tricarboxylates are highly susceptible to hydrolysis, are nonvolatile, and thermally unstable. They lose one equivalent of acid anhydride upon heating to 200 °C to form carboxy-substituted alumoxanes, $(RCO_2AlO)_n$. The latter compounds have been used as precursors for alumina fibers and films and are more conveniently prepared from the mixed aluminum alkoxide monocarboxylate (equation 40).

$$Al(OR)_2(O_2CR') + H_2O \longrightarrow ROH + Al(OR)(OH)(O_2CR') \xrightarrow{\Delta} ROH + [OAl(O_2CR')]_n \quad (40)$$

Glossary

Aluminum alkyl: compounds of aluminum in which a bond exists between aluminum and a carbon of an alkyl group

1 INTRODUCTION

Aluminum is the most abundant metal and the third most abundant element in the Earth's crust, behind only oxygen and silicon. Its low weight and useful properties make aluminum and its alloys valuable materials for manufacturing and electrical applications. Inorganic compounds of aluminum are plentiful and used as absorbents, catalysts, ionic conductors, ceramics, and electrical materials. Organometallic compounds of aluminum are also of great industrial importance and fundamental discoveries continue to be made regarding the variety of coordination numbers, structures, oxidation states, and reactivity exhibited by aluminum.[1–4]

The preparation of the first organoaluminum compound, $Et_3Al_2I_3$, was reported by Hallwachs and Schafarik in 1859, but the utility of organoaluminum reagents was not realized for nearly a hundred years. This was likely due to the misconception that organoaluminum compounds were less reactive than the better-studied organozinc and organomagnesium reagents. This perception and the status of organoaluminum compounds changed suddenly with the pioneering work of Karl Ziegler in 1949.[5] Ziegler discovered that base-free alkylaluminum compounds could be synthesized on large scale by direct synthesis from aluminum, hydrogen, and alkenes. He also showed that these organoaluminum compounds react with ethylene to give long-chain terminal alkenes and alcohols, products that are still used today for the production of surfactants and detergents. In 1953, Ziegler applied for his first patent on the polymerization of ethylene under mild conditions using a catalyst comprised of a trialkylaluminum compound and an early transition metal such as titanium and zirconium. Karl Ziegler shared the 1963 Nobel Prize in Chemistry with Giulio Natta for his contribution to Ziegler–Natta alkene polymerization catalysis.

During the same period, Edwin Vandenberg and his colleagues at Hercules were independently working on Ziegler-type catalysts for the polymerization of propylene and polar monomers. As part of this effort, the use of an old bottle of wet epichlorohydrin led Vandenberg to serendipitously discover that partially hydrolyzed aluminum alkyls are active catalysts for the ring-opening polymerization of epoxides and oxetanes.[6] Vandenberg catalysts composed of a partially-hydrolzed aluminum alkyl, acetylacetonate, and various proprietary additives led to the commercial production of polyether elastomers that are still of significant industrial importance today. For his contributions to polymerization catalysis using organoaluminum reagents, Ed Vandenberg was awarded the Priestley Medal, the highest honor bestowed by the American Chemical Society, in 2003.

The discoveries of Ziegler, Vandenberg, and many others in the 1950s and 1960s ushered in the modern age of organometallic chemistry of aluminum and a host of applications followed. By 1967, U.S. production capacity for organoaluminum compounds was estimated at 50–60 million lb/year. The importance of aluminum alkyls continues to rise to this day as organoaluminum compounds are used in organic synthesis, catalysis, and the preparation of new materials.

This contribution provides a summary of basic principles of the organometallic chemistry of aluminum and emphasizes new developments since publication of the first edition of the Encyclopedia of Inorganic Chemistry. References are intended to guide readers to detailed reviews covering all aspects of the organometallic chemistry of aluminum. In particular, readers should consult the classic work of Mole and Jeffery[7] and reviews by Eisch[8,9] and Robinson.[10,11]

2 ALUMINUM(III) ALKYLS, ARYLS, HYDRIDES, AND HALIDES

2.1 Preparative Routes

Four methods are used for the industrial production of simple aluminum alkyls: direct synthesis, the displacement

reaction, the growth reaction, and reduction of alkylaluminum sesquihalides.[7] In the direct synthesis developed by Ziegler, aluminum alkyls are prepared by reaction of aluminum metal, hydrogen, and a terminal alkene (equation 1). The reaction

$$Al + \frac{3}{2}H_2 + 3RR'C{=}CH_2 \longrightarrow (RR'CHCH_2)_3Al \quad (1)$$

proceeds by formation of a dialkylaluminum hydride followed by insertion of an alkene into the Al–H bond. The insertion of a substituted alkene proceeds in a Markovnikov fashion with the hydride transferred to the most substituted carbon atom of the double bond. For this reason, the use of propene or isobutene yields tri-*n*-propylaluminum or tri-*iso*-butylaluminum, respectively. Tri-*iso*-propylaluminum and tri-*tert*-butylaluminum cannot be prepared by direct synthesis.

In the case of ethylene, additional insertions occur to give mixtures of long-chain trialkylaluminum compounds via the Aufbau, or growth, reaction (equation 2). The resulting

$$R_3Al + 3nH_2C{=}CH_2 \longrightarrow \{R(CH_2CH_2)_n\}_3Al \quad (2)$$

aluminum alkyls are useful for the commercial production of long-chain terminal alkenes and alcohols, but pure aluminum alkyls are not typically prepared in this manner. This is a convenient route for the preparation of research quantities of trineohexylaluminum and trineopentylaluminum according to equations (3) and (4).

$$^tBu_3Al + 3H_2C{=}CH_2 \longrightarrow (^tBuCH_2CH_2)_3Al \quad (3)$$

$$Me_3Al + 3Me_2C{=}CH_2 \longrightarrow (Me_3CCH_2)_3Al \quad (4)$$

In the displacement reaction, reversible β-hydride elimination of an alkene from an aluminum alkyl (equation 5) is followed by insertion of a different alkene into the Al–H bond of the resulting dialkylaluminum hydride (equation 6). Three repetitions of this process yield the new trialkylaluminum compound as in equation (7). Tri-*iso*-butylaluminum obtained from the direct synthesis is a convenient starting aluminum alkyl for this process.

$$^iBu_3Al \overset{\Delta}{\rightleftharpoons} {}^iBu_2AlH + Me_2C{=}CH_2 \quad (5)$$

$$^iBu_2AlH + RR'C{=}CH_2 \longrightarrow {}^iBu_2AlCH_2CHRR' \quad (6)$$

$$^iBu_3Al + 3RR'C{=}CH_2 \rightleftharpoons (RR'CHCH_2)_3Al + 3Me_2C{=}CH_2 \quad (7)$$

Trimethylaluminum cannot be prepared by any of the above processes, which rely on alkene insertion. The industrial preparation of trimethylaluminum is achieved by reaction of ground aluminum with chloromethane to yield the sesquichloride, $Me_3Al_2Cl_3$, and subsequent reduction with sodium metal (equation 8). This procedure also works for the

$$4Al \xrightarrow{6MeCl} 2Me_3Al_2Cl_3 \xrightarrow{6Na} 2Me_3Al + 2Al + 6NaCl \quad (8)$$

preparation of Et_3Al, but direct synthesis is preferred because of the expense of the reducing agent. This method has limited utility for higher alkyls owing to competitive Lewis acid-catalyzed elimination of HX from the alkyl halide. It is worth noting that Hallwachs and Schafarik prepared the first organoaluminum compound, $Et_3Al_2I_3$, by reaction of aluminum with iodoethane.

Additional synthetic protocols are available for the preparation of research quantities of aluminum alkyls that are not commercially available by the above routes. Of these, reaction of an organomercury reagent with aluminum metal

$$2Al + 3R_2Hg \longrightarrow 2R_3Al + 3Hg \quad (9)$$

(equation 9) is the oldest and of general utility. However, owing to the toxicity of organomercury compounds (*see* ***Mercury: Organometallic Chemistry***) and environmental concerns, the use of organomercury reagents has been widely supplanted by reactions of aluminum halides with organolithium or Grignard reagents according to equations (10) and (11), respectively.

$$AlX_3 + 3RLi \longrightarrow R_3Al + 3LiX \quad (10)$$

$$AlX_3 + 3RMgX \longrightarrow R_3Al + 3MgX_2 \quad (11)$$

Reaction of anhydrous aluminum trichloride with an organolithium compound is convenient for preparation of base-free aluminum alkyls such as $^iPr_3Al$,[12] $^tBu_3Al$,[12] $(^tBuCH_2)_3Al$,[13] and $\{(Me_3Si)_2CH\}_3Al$.[14] In contrast, the use of Grignard reagents often results in the isolation of Lewis acid-base complexes $R_3Al{\cdot}L$ (L = THF, ether) rather than the more Lewis acidic R_3Al. An exception is the synthesis of tri-*tert*-amylaluminum from $AlCl_3$ and $(Me_2EtC)MgCl$ in diethyl ether and hexane.[15] The ether adduct $(Me_2EtC)_3Al{\cdot}OEt_2$ is not isolated, presumably owing to the steric congestion at aluminum based on comparison of the estimated Tolman cone angle[16] for the *tert*-amyl substituent (135–140°) with that for *tert*-butyl (126°) and isopropyl (114°) substituents.

Organoaluminum halides are most conveniently prepared by redistribution reactions. Mixing a trialkylaluminum and an aluminum halide in a 1:1, 2:1, or 1:2 ratio yields bis halide-bridged compounds $R_3Al_2X_3$, R_2AlX, or $RAlX_2$, respectively. Alternative routes include reactions of aluminum halides with organolithium or Grignard reagents in the desired stoichiometry and reaction of trialkylaluminum compounds with halogen to give the organoaluminum halide and alkyl halide. Reactions of alkyl halides with aluminum metal can also be used to prepare organoaluminum halides as previously mentioned.

The preparation of organoaluminum fluorides differs somewhat from that of other organoaluminum halides.[17] Redistribution reactions using AlF_3 do not work well, nor do reactions of AlF_3 with Grignards or organolithium reagents. Organoaluminum fluorides are best prepared by salt metathesis

upon mixing R_2AlX or $RAlX_2$ with sodium fluoride. Exchange reactions with BF_3 and reactions of a trialkylaluminum with HF also work well as shown in equations (12) and (13).

$$3R_3Al + BF_3 \longrightarrow 3R_2AlF + R_3B \qquad (12)$$

$$R_3Al + 2HF \longrightarrow RAlF_2 + 2RH \qquad (13)$$

Organoaluminum halides can be used to prepare pseudohalide derivatives, such as azides[18] and cyanides, by salt metathesis. Azides are prepared by trimethylsilylhalide elimination (equation 14) and by reaction of a trialkylaluminum with chloroazide, ClN_3. Organoaluminum cyanides have also been prepared by reactions of a trialkylaluminum with HCN (equation 15).[7]

$$R_2AlX + Me_3SiN_3 \longrightarrow R_2AlN_3 + Me_3SiX \qquad (14)$$

$$R_3Al + HCN \longrightarrow R_2AlCN + RH \qquad (15)$$

Several methods exist for the preparation of organoaluminum hydrides R_2AlH and $RAlH_2$.[7,19] Organoaluminum hydrides are obtained by alkene elimination upon heating trialkylaluminum compounds that possess a β-hydrogen (equation 5). Hydrogenolysis of Al–C bonds can be used to form hydrides (equation 16), but high temperatures and pressures are required in the absence of a transition metal catalyst. Ligand redistribution reactions and reduction of organoaluminum halides with metal hydrides are also employed.

$$Et_3Al + H_2 \xrightarrow[300\ \text{atm}]{120\,^\circ\text{C}} Et_2AlH + CH_3CH_3 \qquad (16)$$

Several of the trialkylaluminum and alkylaluminum halides and hydrides mentioned above are commercially available. Alkynyl, alkenyl, cyclopentadienyl, and aryl derivatives are, in general, not commercially available and must be synthesized for laboratory use. Alkynyl derivatives can be prepared by salt metathesis, as in the reaction of Et_2AlCl with $NaC{\equiv}CEt$ to give $Et_2AlC{\equiv}CEt$.[20] The acidity of terminal alkynes is sufficient for preparation of alkynyl aluminum compounds by alkane or hydrogen elimination upon reaction with a trialkylaluminum or an aluminum hydride (equation 17), respectively.[21] Trialkynyl aluminum compounds are typically isolated as Lewis base adducts to stabilize them against otherwise facile polymerization. Alkenyl compounds of aluminum have similarly been prepared.

$$H_3Al(NMe_3) + 3HCCPh \xrightarrow{-3H_2} (PhCC)_3Al(NMe_3) \qquad (17)$$

Cyclopentadienyl compounds of aluminum have been increasing studied over the past decade.[22–25] They are prepared using the same methods used for simple aluminum alkyls. Tris(cyclopentadienyl)aluminum, for example, can be prepared by reaction of Cp_2Hg with aluminum and by reaction of $AlCl_3$ with magnesocene (equation 18). Magnesocene

$$3Cp_2Mg + 2AlCl_3 \longrightarrow 3MgCl_2 + 2Cp_3Al \qquad (18)$$

derivatives are very effective for preparing cyclopentadienylaluminum compounds such as $(C_5MeH_4)_3Al$, (1,2,4-$C_5Me_3H_2)_3Al$, and $(C_5Me_4H)_3Al$. Incomplete exchange occurs upon reaction of $(C_5Me_5)_2Mg$ with $AlCl_3$ and Cp^*AlCl_2 is obtained. Cyclopentadienyl aluminum compounds are often prepared by salt metathesis reactions of $AlCl_3$ or an organoaluminum halide with a CpM derivative (M = Li, Na, K, Tl), but again, exchange is not always complete and cyclopentadienylaluminum halides are sometimes obtained. Cyclopentadienylaluminum compounds have also been prepared by trimethylsilylchloride elimination and alkane elimination reactions, but these preparative routes are less common. Redistribution reactions can occur as in the conversion of Cp_2AlMe to Cp_3Al and $CpAlMe_2$.

Jordan and coworkers have recently prepared several *ansa*-bis(indenyl) compounds $\{(AlMe_2L)\text{indenyl}\}_2SiMe_2$ and 1,2-$\{(AlMe_2L)\text{indenyl}\}_2C_2H_4$ (L = THF, Et_2O, 1,4-dioxane) by a salt metathesis route.[26] These were reacted with $M(NMe_2)_4$ (M = Zr, Hf) to eliminate $[Me_2AlNMe_2]_2$ and form *ansa*-metallocene complexes of bis(dimethylamido)zirconium and bis(dimethylamido)hafnium. A simple tris(indenyl)aluminum compound has been prepared by reaction of bis(indenyl)mercury with aluminum metal.[7]

Similar to aluminum alkyls, aluminum aryls are prepared from organomercury, organomagnesium, organolithium, organoborane, or organotin reagents. Triphenylaluminum and substituted derivatives can be prepared by several of these methods. Halide derivatives such as Ph_2AlCl and $PhAlCl_2$ are prepared by ligand redistribution upon reaction of Ph_3Al with $AlCl_3$.

Monomeric trimesitylaluminum is prepared from Mes_2Hg and aluminum,[27] or by removing THF or ether from $Mes_3Al{\cdot}L$ (L = THF, OEt_2) with heating in vacuo.[28] Mesityl derivatives $Mes_2MeAl{\cdot}THF$, $Mes_2EtAl{\cdot}THF$, and $Mes_2ClAl{\cdot}THF$ were prepared by reactions of MesMgBr with $MeAlCl_2$, $EtAlCl_2$, and $AlCl_3$, respectively,[29] and the chloro-bridged dimer $[Mes_2AlCl]_2$ has been prepared by ligand redistribution. Tris(pentamethylphenyl)aluminum is obtained base-free by reaction of $AlCl_3$ with C_6Me_5MgBr in diethyl ether.[30] The isolation of the base-free alane is in contrast to the formation of $Mes_3Al{\cdot}L$ by the Grignard route.

There are fewer preparative methods for *m*-terphenyl derivatives of aluminum.[31] Aluminum bromide reacts with $[2,4,6\text{-}Ph_3C_6H_2Li]_2$ to give $2,4,6\text{-}Ph_3C_6H_2AlBr_2{\cdot}OEt_2$, but analogous procedures do not give the corresponding dichlorides. Alternatively, reaction of $[2,6\text{-}Mes_2C_6H_3Li]_2$ with $AlH_3{\cdot}NMe_3$ in ether, followed by reaction with chlorotrimethylsilane yields $(2,6\text{-}Mes_2C_6H_3)AlH_2{\cdot}OEt_2$. Ether can be removed in vacuo and additional treatment with chlorotrimethylsilane yields the organoaluminum dichloride

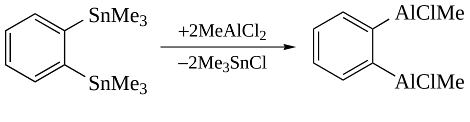
as the etherate complex. The base-free dichloride can be obtained by refluxing in hexane. Wehmschulte and coworkers reacted $(2,6\text{-}Mes_2C_6H_3)AlH_2{\cdot}OEt_2$ with $[2,6\text{-}Mes_2C_6H_3Li]_2$ to give $(2,6\text{-}Mes_2C_6H_3)_2AlH$, a rare example of a monomeric aluminum hydride.[32]

The synthesis of highly Lewis acidic fluorinated arylaluminum compounds such as $Al(C_6F_5)_3$ has been of interest in recent years,[33] but efforts have been hindered by the proclivity of aluminum to abstract fluoride, often resulting in violent decomposition. The preferred synthesis of $Al(C_6F_5)_3$ is by stirring commercially available $B(C_6F_5)_3$ with Me_3Al at room temperature in toluene and hexanes (equation 19).[34] The reaction does not go to completion but can be driven to do so by precipitation of the desired product as the toluene solvate

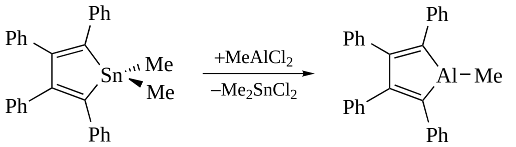
$$Me_3Al + B(C_6F_5)_3 \xrightarrow{\text{toluene}} Al(C_6F_5)_3 + Me_3B \qquad (19)$$

$(C_6F_5)_3Al{\cdot}0.5$ toluene upon addition of hexanes. Isolation of the toluene solvate is preferred since it has greater thermal and shock stability than the solvate-free material. Aluminum halides react with C_6F_5Li to yield $(C_6F_5)_3Al{\cdot}OEt_2$, but attempts to remove the ether resulted in an explosion.[7] Roesky and coworkers prepared $(C_6F_5)_3Al{\cdot}THF$ by ligand redistribution upon heating $(C_6F_5)AlMe_2$ and distilling off the trimethylaluminum as it formed.[35] The intermediate $(C_6F_5)AlMe_2$ was not, however, purified or characterized. An alkyl derivative of a pentafluorophenyl alane, $(C_6F_5)_xAlR_{3-x}$ (R = alkyl; $x = 1, 2$), has been isolated and structurally characterized, that being the bis methyl-bridged $(C_6F_5)_3Al_2Me_3$ prepared by reaction of $B(C_6F_5)_3$ and Me_3Al.[36] The compounds $(C_6F_5)_2AlMe$ and $(C_6F_5)AlMe_2$ and their ether adducts $(C_6F_5)_2MeAl{\cdot}OEt_2$ and $(C_6F_5)Me_2Al{\cdot}OEt_2$ have been generated in situ and characterized by NMR spectroscopy.[36,37] Spectroscopic data suggest that $(C_6F_5)_2AlMe$ and $(C_6F_5)AlMe_2$ exist as methyl-bridged dimers. The formation of $(C_6F_5)_2AlEt$ was implicated in ethene and propene polymerizations catalyzed with a mixture of $Al(C_6F_5)_3$ and Et_3Al.[38] Pentafluorophenylaluminum halides $(C_6F_5)AlBr_2$ and $(C_6F_5)_2AlBr$ have been prepared from the reaction of $(C_6F_5)HgMe$ and $AlBr_3$.[7] Chen recently prepared $(C_6F_5)_2AlCl$ by reaction of $Al(C_6F_5)_3$ with CH_2Cl_2.[39] Attempts to prepare tris(perfluorobiphenyl)aluminum instead led to the formation of the fluoroaluminate $Li[(C_{12}F_9)_3AlF]$, presumably by a fluoride abstraction reaction.[40]

Tin–aluminum exchange has been used to prepare bidentate aryl aluminum compounds and aluminoles as illustrated in equations (20) and (21).[41]



(20)



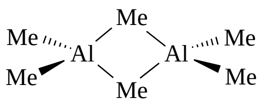
(21)

2.2 Associative Properties and Structures

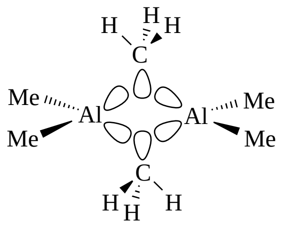
Aluminum alkyls, alkylaluminum halides, and alkylaluminum hydrides strongly associate in solution and in the solid state.[42] The association of trialkylaluminum compounds is in stark contrast to the monomeric nature of trialkylboron (*see* ***Boron: Organoboranes***) and trialkylgallium (*see* ***Gallium: Organometallic Chemistry***) compounds.

Trialkylaluminum and alkylaluminum hydrides associate with alkyl or hydride bridges. Since there are no available lone-pair electrons with which to form bridges by standard two-center two-electron interactions, multicenter bonding is invoked in the same manner as for electron-deficient boranes (*see* ***Boron Hydrides***), alkyllithium (*see* ***Alkali Metals: Organometallic Chemistry***), dialkylberyllium and dialkylmagnesium compounds (*see* ***Beryllium & Magnesium: Organometallic Chemistry***).

Trialkylaluminum compounds exist predominately as dimers with two bridging alkyl groups as for trimethylaluminum (**1**). The bonding in Me_6Al_2 is analogous to that in diborane. The aluminum atoms are sp^3 hybridized and four of the sp^3 hybrid orbitals are utilized for formation of two-center two-electron bonds to the four terminal methyl groups. The bonding interaction for each bridging methyl can be described as overlap of two Al sp^3 hybrid orbitals and an sp^3 hybrid orbital from the methyl carbon as in (**2**). The resulting molecular orbital for each bridge interaction is populated with two electrons to give a three-center two-electron bond.



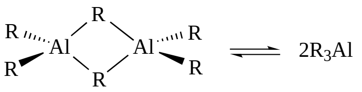
(**1**)



(**2**)

Trialkylaluminum compounds undergo monomer-dimer equilibria (equation 22) in noncoordinating solvents. Cryoscopic molecular weight measurements indicate that trimethylaluminum is predominately a dimer in toluene solutions, and

this is confirmed by NMR spectroscopy. The ^{1}H NMR spectrum of Me_3Al in toluene at −70 °C exhibits two resonances in a 2:1 ratio for the terminal and bridging methyl groups, respectively, of the dimer. Similar ^{1}H NMR data was obtained in support of dimeric triethylaluminum at −70 °C. Exchange is rapid as evidenced by a single sharp methyl resonance in the room temperature ^{1}H NMR spectrum of Me_3Al.

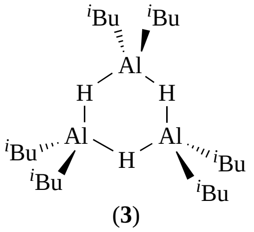


(22)

The position of monomer-dimer equilibria for trialkylaluminum compounds shift to favor monomer formation with increasing length and bulk of the alkyl. The percent dissociation of Me_6Al_2, Et_6Al_2, $^nPr_6Al_2$, $^nBu_6Al_2$, and $^iBu_6Al_2$ at 20 °C in 0.05 mole fraction cyclohexane solutions are 2.9×10^{-4}, 5.01×10^{-3}, 2.53×10^{-2}, 3.76×10^{-2}, and 1.64×10^{-1}, respectively. Monomer concentration also increases with increasing temperature and decreasing concentration of the aluminum alkyl.[43]

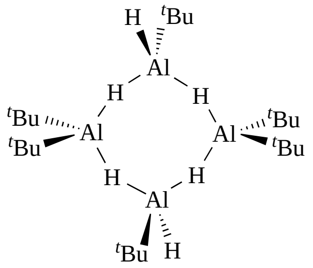
Redistribution reactions of aluminum alkyls require dissociation into monomers. Enthalpy of dissociation for trimethylaluminum is 19.40 kcal mol^{-1} whereas for $^iBu_6Al_2$ it is 8.1 kcal mol^{-1}. For comparison, enthalpies of dissociation of simple Lewis acid-base adducts $Me_3Al \cdot L$ (L = amine, ether, phosphine, phosphine oxide) are generally in the range of 17–32 kcal mol^{-1}, with most being greater than 20 kcal mol^{-1}.[7]

In contrast to the dimeric trialkylaluminum compounds, many dialkylaluminum hydrides prefer trimeric structures with bridging hydrides as shown for $^iBu_2AlH$ (**3**). Uhl and coworkers have prepared and structurally characterized the novel tetrameric sesquihydride $[^tBu_3Al_2H_3]_2$ (**4**), which also exhibits bridging hydrides with large Al–H–Al angles of 149(2) and 155(2)°.[44]



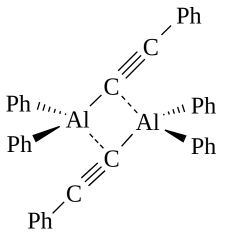
(**3**)

The alkyl groups do not bridge in the organoaluminum hydrides, and this is in keeping with decreasing bridging ability in the order H > Me > Et > ^{n}Bu > ^{i}Bu. Alkyls with branching at the α or β positions are particularly poor bridging groups for aluminum compounds and cryoscopic molecular weight measurements indicate that several aluminum trialkyls are monomeric in solution. These include $^tBu_3Al$,[12] $(^tBuCH_2)_3Al$,[13] $(Me_2EtC)_3Al$,[15] and $\{(Me_3Si)_2CH\}_3Al$.[14]



(**4**)

Aluminum alkynyl groups can be either terminal or bridging. In Lewis acid-base complexes where the aluminum centers are four-coordinate, such as in $(PhC{\equiv}C)_3Al \cdot NMe_3$, alkynyl substituents are terminal with Al–C–C angles ranging from 160 to 180°. In the absence of a strong σ-donor, however, additional interactions between the alkynyl π system and aluminum may exist. The alkynyl compound $[PhC{\equiv}CAlPh_2]_2$ (**5**) exists as a dimer with bridging alkynyl groups. The bonding is described as σ bonding of the alkynyl C_α to one aluminum and π donation to the second aluminum center.

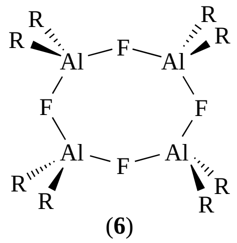


(**5**)

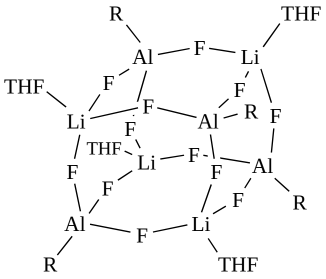
The structures of organoaluminum halides R_nAlX_{3-n} are dominated by dimeric structures with Al_2X_2 four-membered rings for X = Cl, Br, and I. Unlike the aluminum alkyls, these halide bridges are electron-precise and result from intermolecular Lewis acid-base complexation. These dimers do dissociate and readily react with Lewis bases, but the enthalpies of dissociation are higher than those for the aluminum alkyls. In many cases, the strength of the association is sufficient that dimers are observed in the gas phase.

Organoaluminum fluorides differ from the chloride, bromide, and iodide analogs in that bridging structures with large Al–F–Al angles are preferred (*see* ***Fluorides: Solid-state Chemistry***).[17,45] Dialkylaluminum fluorides, R_2AlF, exist as tetramers (**6**) with Al_4F_4 eight-membered rings in solution and in the solid state for R = Me, Et, ^{i}Pr, ^{t}Bu, and as trimers with six-membered Al_3F_3 rings for R = ^{n}Pr and ^{i}Bu. This linear bridging ability is also observed upon reaction of organoaluminum fluorides with alkali fluoride to form alanates such as the cubanoidal cage compound $[(Me_3Si)_3CAlF_3M(THF)]_4$ (M = Li, Na) (**7**). Linear fluoride bridges are observed in $K[R_3AlFAlR_3]$ (R = Me, Et).

The structures of cyclopentadienylaluminum(III) compounds are highly fluxional.[22–25] In solution, aluminum centers



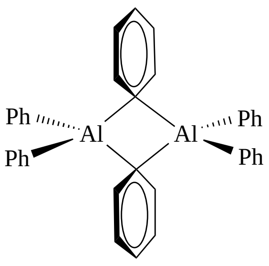
(**6**)



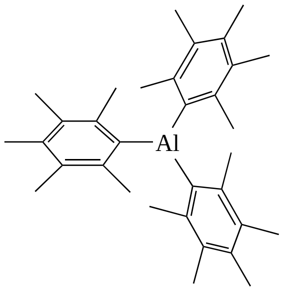
(**7**)

migrate freely around the Cp rings and this migration cannot be frozen out on the NMR timescale even at −90 °C. Simple signal-averaged spectra with sharp Cp resonances are observed. In the solid state, cyclopentadienyl rings adopt a variety of coordination modes including η^1, η^2, η^3, and η^5. Only the η^4 coordination mode has yet to be observed by X-ray crystallography. The η^2 coordination mode is most prevalent and calculations suggest a slight energetic preference for η^2 coordination, but this is obviously dependent on steric and electronic factors. Drew and Haaland originally proposed η^2 coordination for gas-phase $CpAlMe_2$ based on electron diffraction data. Dihapto coordination has since been observed in the solid-state structures of Cp_2AlMe and Cp^*_2AlMe. $CpAlMe_2$ exhibits a polymeric structure with each Cp coordinated η^1 at C_1 to one aluminum atom and η^1 at C_3 to a different aluminum atom. The η^3 coordination mode is observed in the chloride-bridged dimers $[Cp^*AlClR]_2$ (R = Me, Et, ^{i}Bu). Observation of η^5 coordination has been more common in recent years. Examples of η^5-cyclopentadienyl groups include $[Cp^*AlCl_2]_2$, $CpAl(BHT)_2$, $[(BHT)CpAl]_2O$, and $[Cp^*_2Al]^+$. In the molecular structure of $(1,2,4\text{-}Me_3C_5H_2)_3Al$, one of the trimethylcyclopentadienyl groups is coordinated η^5 whereas the other two are coordinated η^1. Pentahapto coordination is also observed in many Cp* derivatives of aluminum(I).

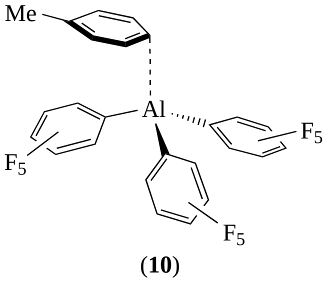
Cryoscopic molecular weight determinations and X-ray crystallography confirm that triphenylaluminum (**8**) is a dimer in solution and in the solid state. The bridging phenyl group in the molecular structure of Al_2Ph_6 bridges through one carbon. The plane of the bridging phenyls is perpendicular to that of the core Al_2C_2 four-membered ring. Mesityl groups are sufficiently bulky that Mes_3Al is a monomer in solution and in the solid state,[27] as is the related triarylaluminum compound $(C_6Me_5)_3Al$ (**9**).[30] In each compound, the aluminum center is trigonal planar with the aryl groups propellered to reduce steric interactions. In contrast, $(C_6F_5)_3Al$ crystallizes as solvates $(C_6F_5)_3Al{\cdot}$toluene (**10**) and $(C_6F_5)_3Al{\cdot}$benzene, the molecular structures of which reveal an η^1-toluene or η^1-benzene bound to the slightly pyramidalized four-coordinate aluminum.[46] The Al–C–C angles for the bound arenes are 99.1 and 96.1°, suggesting that this is a π-arene complex rather than a Wheland intermediate. Arene coordination is attributed to the high Lewis acidity of $(C_6F_5)_3Al$ and is analogous to coordination of toluene to silylium cations as in the structurally characterized $[Et_3Si{\cdot}\text{toluene}]^+$. The arene-aluminum interactions in $(C_6F_5)_3Al{\cdot}$toluene and $(C_6F_5)_3Al{\cdot}$benzene are retained in C_6D_6 solutions.



(**8**)



(**9**)



(**10**)

Those new to the subject and wanting more information on the characterization of organoaluminum compounds can consult several good references. Joan Mason has published a text in which she discusses the structural information that can be gleaned from ^{27}Al NMR spectroscopy and the problems associated with the technique.[47] The text tabulates ^{27}Al NMR chemical shift and $W_{1/2}$ data. Shapiro has also tabulated ^{27}Al NMR chemical shifts for cyclopentadienylaluminum compounds.[22] Holloway and Melnik published a review of

structural data for organoaluminum compounds.[48] There is also a compilation of 727 organoaluminum compounds with references to the synthesis and spectroscopic and structural characterization of each compound.[49]

2.3 Reactivity

Neat aluminum trialkyls are highly reactive, colorless liquids that spontaneously ignite in the presence of oxygen, react violently with water, and must be manipulated and stored under an inert atmosphere. Trialkylaluminum compounds react vigorously with halogenated solvents and even react with silicone stopcock grease[50] with cleavage of Si–O and formation of Al–O bonds. Reactivity is greatest for trimethylaluminum (37.4 wt% Al) and decreases with decreasing weight percent of aluminum. Handling aluminum alkyls as dilute solutions in inert hydrocarbons reduces the risk of ignition. Tri-*iso*-butylaluminum is typically available as a 25-wt% solution in toluene. Bulky alkyl and aryl groups moderate the reactivity. Aluminum triaryls are white solids that fume in air, but oxidize more slowly than do aluminum trialkyls.

The reactivity of organoaluminum compounds is attributed to their low thermodynamic stability and high kinetic lability. The mean bond enthalpy for the Al–C bond in Me_3Al is 274 kJ mol^{-1} (Table 1).[51] This is less than the E–C bond enthalpies for E = boron, carbon, nitrogen, and silicon and only 55 and 65% of the Al–O and Al–Cl bond enthalpies, respectively. There is clearly a strong thermodynamic driving force for oxidation and hydrolysis. Enthalpies of combustion and hydrolysis for Et_3Al, for example, are 5104 and 527 kJ mol^{-1}, respectively.[7] Although Al–C bonds may be considered weak based on mean bond enthalpies, they are comparable in strength to P–C bonds, which are considerably less reactive than Al–C bonds in aluminum trialkyls. Thus, the reactivity of organoaluminum compounds is equally related to their kinetic lability. This lability is due to the availability of a low-lying acceptor orbital in three-coordinate monomeric trialkylaluminum compounds and potential participation of empty *d* orbitals. Furthermore, the Al–C bond is highly polarized in the direction $Al^{\delta+}$–$C^{\delta-}$ since the difference in the Pauling electronegativity of aluminum (1.6) and carbon (2.5) is greater than for any other M–C bond of a *p*-block metal besides thallium. Selected Pauling electronegativities are as follows: C (2.5), B (2.0), Si (1.9), Ga (1.8), In (1.8), Al (1.6).

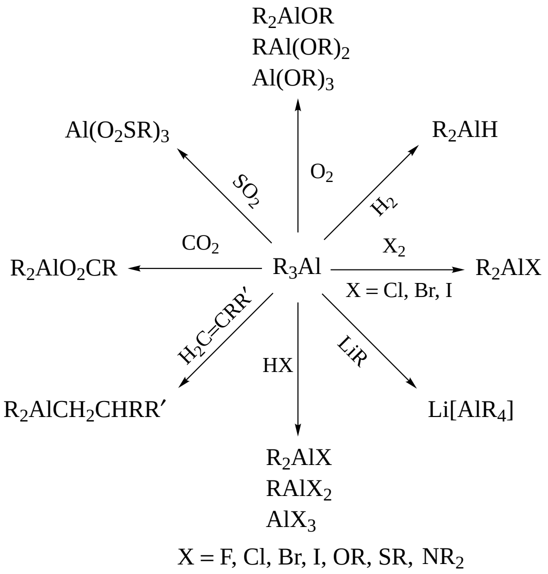
Table 1 Selected mean bond dissociation enthalpies (kJ mol^{-1}) for *p*-block elements

B–C	365	C–C	358
Al–C	274	Si–C	311
Ga–C	247	Ge–C	249
Al–O	500	N–C	314
Al–Cl	420	P–C	276

Much of the reaction chemistry of aluminum trialkyls can be classified by the following reaction types, some of which are illustrated in Scheme 1: oxidation, alkane elimination in the presence of protic reagents, Al–C bond cleavage via halogenation and hydrogenation, insertion reactions, β-hydrogen elimination (equation 5), and coordination of Lewis bases.

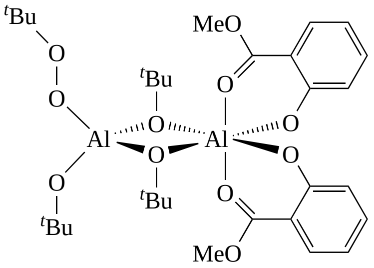
Protic reagents such as water, alcohols, acids, and primary and secondary amines react rapidly with aluminum alkyls resulting in alkane elimination and coordination of the conjugate base of the protic reagent. Reagents must be added slowly to avoid dangerous exothermic reaction and gas evolution, particularly for Me_3Al and Et_3Al. Subsequent reactivity of the Al–C bonds decreases as more alkyl groups are removed, and vigorous conditions are often required to remove the last aluminum alkyl. Reaction of Me_3Al with alcohol rapidly forms Me_2AlOR' followed by formation of $MeAl(OR')_2$, but the last methyl group in $MeAl(OR')_2$ reacts with alcohols reluctantly.

Insertion reactions are commonplace for organoaluminum compounds. Insertion of oxygen into the Al–C bonds of alumium trialkyls proceeds cleanly at low temperatures in hydrocarbon solvents to give aluminum alkoxides. The first insertion is rapid, as usually is the second. The third insertion is considerably slower depending on the steric bulk of the resulting alkoxide complexes. Oxygen insertion is believed to proceed via an alkylperoxy intermediate R_2AlOOR by analogy to the structurally characterized gallium and indium alkylperoxides $[{}^tBu_2MOO{}^tBu]_2$ (M = Ga, In).[52] Lewinski and coworkers have structurally characterized an alkylperoxide complex of aluminum (**11**) isolated after O_2 insertion into the Al–C bonds of ${}^tBu_2Al$(methylsalicylate).[53,54] Complex



Scheme 1 Representative reactions of trialkylaluminum compounds

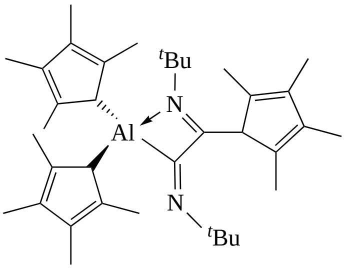
(**11**) slowly decomposes in solution at room temperature with conversion of the *tert*-butylperoxy group to a *tert*-butylalkoxide ligand. Analogous to reactions of oxygen with aluminum trialkyls, sulfur, selenium, and tellurium insert into Al–C bonds of R_3Al to give $[R_2Al(\mu\text{-}ER)]_2$ and in some cases $[RAlE]_4$ (E = S, Se, Te).[15,55]



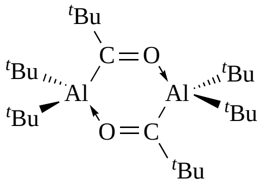
(**11**)

Insertions of carbon dioxide, sulfur dioxide, and sulfur trioxide yield aluminum carboxylates, sulfinates, and sulfonates, respectively. Treatment of the resulting complexes with aqueous acid yields the corresponding alkylcarboxylic, alkylsulphinic, and alkylsulphonic acids. High pressure and temperatures of 220–240 °C are required for multiple insertions of CO_2 to yield more than one equivalent of carboxylic acid per aluminum. Excess aluminum trialkyl must be avoided or the initially formed carboxylate is completely alkylated to a trialkylcarbinol. Reaction of Et_3Al with CO_2, for example, gives a 90% yield of triethylcarbinol.

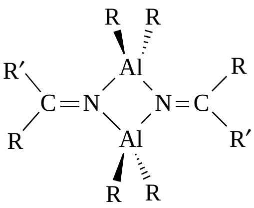
There are examples of insertion for many other unsaturated molecules including N_2O_4, CS_2, N≡CR, R_2C=O, CO, and C≡NR. Reaction of N_2O_4 with Et_3Al gives diethylhydroxylamine upon protic workup. For carbon disulfide, C–S bond cleavage is often observed, leading to formal insertion of thiocarbonyl and sulfur. Shapiro recently reported the first example of isocyanide insertion into an Al–C bond.[56] Compound (**12**) was obtained by insertion of two molecules of *tert*-butylisocyanide into an Al–C bond of $(C_5Me_5H)_3Al$. Isocyanide insertion did not occur for less bulky cyclopentadienyl derivatives, prompting the authors to speculate that the reaction was promoted by labilization of the Al–C bond by steric congestion at the aluminum center. The first example of CO insertion into an Al–C bond has also been reported recently. Mason and coworkers found that $^t Bu_3Al$ reacts rapidly with CO at room temperature and atmospheric pressure to give the bridging acyl dimer (**13**).[57] As in the isocyanide case, relief of steric congestion may be a factor in promoting this reaction. Insertion of CO was not observed for more common aluminum trialkyls such as Me_3Al, Et_3Al, and $^i Bu_3Al$ under a variety of conditions. Nitriles insert more readily into Al–C bonds than do isocyanides and CO to give dialkylaluminum ketimides (**14**). A table of many known examples is provided in the text by Mole.[7]



(**12**)



(**13**)



(**14**)

The most prominent insertion reactions are those of alkenes and alkynes into Al–H and Al–C bonds. These hydroalumination and carbalumination reactions are of tremendous importance in the synthesis of aluminum alkyls as already described for the Aufbau reaction and direct synthesis, as well as for the use of aluminum alkyls in organic synthesis. Carbalumination gives *cis*-addition products with the R_2Al fragment bound to the least substituted carbon atom of the alkene and alkynes react faster than alkenes. In hydroalumination, the R_2Al fragment is also bound to the least substituted carbon of the starting alkene. Hydroalumination becomes more difficult with increasing substitution of the alkene in the order

$$H_2C{=}CH_2 > H_2C{=}CHR > H_2C{=}CR_2 > HRC{=}CHR$$

Synthetic applications of double hydroalumination and double carbalumination are discussed in a recent review.[58]

Aluminum alkyls are stronger Lewis acids than the trialkyls of boron and gallium, and complex formation in the presence of Lewis bases is an important aspect of the reaction chemistry of organoaluminum compounds. The Lewis acidity of organoaluminum compounds accounts for the strong association of aluminum alkyls and hydrides by three-center two-electron bonds, as well as association of organoaluminum

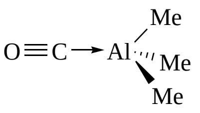
Table 2 Bond dissociation enthalpies of selected trimethylaluminum complexes

Lewis base	$\Delta H°$ (kcal mol^{-1})	Solvent
$Me_3P{=}O$	32.0 ± 0.2	benzene
Me_3N	30.0 ± 0.2	hexane
$Me_2S{=}O$	28.6 ± 0.2	hexane/5% benzene
pyridine	27.6 ± 0.2	hexane
Et_3N	26.5 ± 0.2	hexane
2-picoline	26.1 ± 0.2	hexane
THF	22.9 ± 0.2	hexane
Et_3P	22.1 ± 0.3	hexane
Me_3P	21.0 ± 0.2	hexane
Me_2O	20.3 ± 0.2	hexane
2,6-lutidine	19.9 ± 0.2	hexane
Me_2S	16.6 ± 0.2	hexane

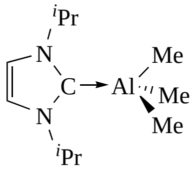
halides and pseudohalides by coordinate covalent bonds. The strength of the association of trimethylaluminum with Lewis bases is evident in enthalpies of dissociation, representative examples of which are shown in Table 2.[7] The data also show that trimethylaluminum is a hard acid in the Pearson Hard-Soft Acid-Base (*see* ***Hard & Soft Acids and Bases***) sense as indicated by the high enthalpies of dissociation for the hard donors $Me_3P{=}O$ and $Me_2S{=}O$. For pairs of structurally similar donors, enthalpies of dissociation are greatest for the harder donor, such as $Me_3N > Me_3P$, $Et_3N > Et_3P$, and $Me_2O > Me_2S$. Competition experiments also support the enthalpy data. Trimethylphosphine oxide, for example, will displace diethyl ether from $Me_3Al{\cdot}OEt_2$ to form $Me_3Al{\cdot}O{=}PMe_3$. Enthalpies are also affected by steric interactions, with greater steric bulk of the base leading to lower enthalpies of dissociation. This is seen in decreasing enthalpies of dissociation for complexes of heterocyclic bases in the order pyridine > 2-picoline > 2,6-lutidine.

Organoaluminum compounds are sufficiently Lewis acidic to interact with weak Lewis bases such as alkyl halides, although stable and thoroughly characterized examples are few. Instead, many trialkylaluminum compounds react violently with halogenated solvents. The adduct $Me_3SiF{\cdot}AlEt_3$, with weak F→Al donation, has been characterized by NMR spectroscopy and this adduct is thermally stable to 30 °C. Structurally characterized examples of aryl halides forming dative bonds to aluminum have been reported for cationic organoaluminum complexes as will be discussed later.

In other recent developments, Sanchez, Arrington, and Arrington reported that Me_3Al binds CO to form $OC{\rightarrow}AlMe_3$ (**15**) in an argon matrix at 15–35 K.[59] Robinson reported the first neutral carbene complex (**16**) of an aluminum trialkyl in 1996.[60] Complexes in which there is intramolecular base coordination have been reviewed.[61]



(**15**)



(**16**)

3 LOW-VALENT ORGANOALUMINUM COMPOUNDS

The organometallic chemistry of aluminum is dominated by the chemistry of aluminum(III), but lower oxidation state compounds are now accessible.[10,62] The first examples of this class of compounds are carbonyl complexes such as Al(CO), $Al(CO)_2$, and $Al_3(CO)$, which were generated upon exposure of aluminum atoms to CO in matrix-isolation experiments near 20 K.[63] The number, relative intensities, and frequency of the carbonyl stretches in the IR spectra, along with isotopic labeling and EPR studies were used to verify these compositions. These complexes exhibit ν_{CO} values of 1868, 1985 and 1904, and 1715 cm^{-1}, respectively, indicative of Al→CO π^* backbonding. The carbonyl species are unstable at higher temperatures and no stable carbonyl complex of aluminum, in any oxidation state, has been reported. The monomeric aluminum-alkene adducts $Al(\eta^2\text{-}C_2H_4)$ and $Al(\eta^2\text{-}C_6H_6)$ were similarly identified in inert matrices at low temperature.[10] No room-stable alkene complexes of aluminum have been reported.

Isolable low-valent organoaluminum compounds have recently become accessible based mainly on the works of Uhl[64] and Schnöckel.[65,66] In 1988, Uhl synthesized the first organoaluminum compound to contain an Al–Al bond, $\{(Me_3Si)_2CH\}_2Al{-}Al\{CH(SiMe_3)_2\}_2$, by reduction of $\{(Me_3Si)_2CH\}_2AlCl$ with potassium metal (equation 23). Surprisingly, the Al_2C_4 core of $\{(Me_3Si)_2CH\}_2Al{-}Al\{CH(SiMe_3)_2\}_2$ is nearly planar. The steric bulk

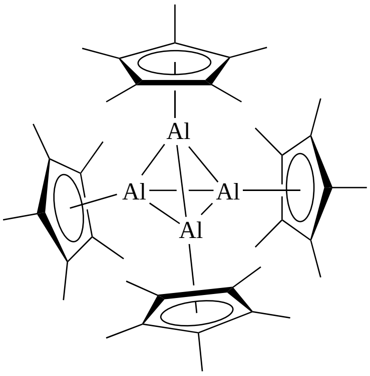
$$2R_2AlCl + 2K \xrightarrow{R\,=\,CH(SiMe_3)_2} 2KCl + R_2Al{-}AlR_2 \qquad (23)$$

of the bis(trimethylsilyl)methyl substituents are important in stabilizing the dialane from disproportionation to an aluminum trialkyl and aluminum metal. Bulky silyl and aryl derivatives have since been prepared and these dialanes have been shown to add Lewis bases, insert small molecules, and accept an electron to form Al–Al π-bonding. The dialane reacts, for example, with insertion of sulfur to form $[R_2Al{-}S{-}AlR_2]$. The dialane also reacts with simple Lewis bases such as LiBr and MeLi to give adducts $[R_2Al{-}AlR_2Br]^-$ and $[R_2Al{-}AlR_2Me]^-$. A two-electron reduction of the Al–Al bond in $R_2Al{-}AlR_2$ compounds would formally yield the

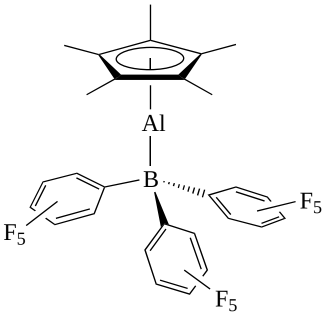
aluminum analog of an alkene (*see* ***Main Group: Multiple Bonding***). The dianion, however, remains elusive. A one-electron reduction of $R_2Al–AlR_2$ to form $[R_2Al–AlR_2]^{\bullet-}$ has been successful for both 2,4,6-triisopropylphenyl and bis(trimethylsilyl)methyl substituents.[67] Reduction leads to a planar Al_2C_4 core structure and a decrease in the Al–Al bond distance by 6–7%, from 2.660(1) Å in $\{(Me_3Si)_2CH\}_2Al–Al\{CH(SiMe_3)_2\}_2$ to 2.53(1) Å in $[\{(Me_3Si)_2CH\}_2Al–Al\{CH(SiMe_3)_2\}_2]^{\bullet-}$ and from 2.647(3) Å in $R_2Al–AlR_2$ to 2.470(2) Å in $[R_2Al–AlR_2]^{\bullet-}$ (R = 2,4,6-$^{i}Pr_3C_6H_2$). The decrease in Al–Al distance upon reduction is consistent with increased bond order. Power has similarly attempted to reduce I(R)Al–Al(R)I with two equivalents of potassium to give the dialuminene species RAl=AlR (R = 2,6-$^{i}Pr_2C_6H_3$).[68] The desired compound was not isolated, but its formation was indicated by isolation of a cycloaddition product with toluene.

In 1991, Uhl reported that reduction of $^{i}Bu_2AlCl$ with potassium in hexanes yielded $K_2[Al_{12}{}^{i}Bu_{12}]$ (Figure 1). The Al–Al distances in $[Al_{12}{}^{i}Bu_{12}]^{2-}$ average 2.660 Å, comparable to that in $\{(Me_3Si)_2CH\}_2Al–Al\{CH(SiMe_3)_2\}_2$. Despite the extensive chemistry of icosahedral boranes (*see* ***Boron: Polyhedral Carboranes***), this is the first analog of an icosahedral borane for the heavier group 13 elements. Aluminum has been incorporated into polyhedral boranes and carboranes. Polyhedral carbaalanes have also been prepared and recent developments in this area have been reviewed.[69]

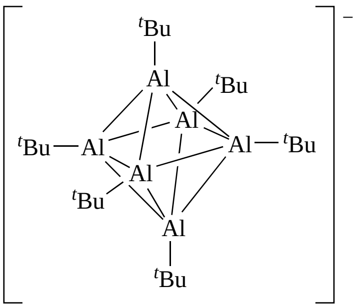
Also in 1991, Schnöckel[65,66] reported that reaction of AlCl with Cp^*_2Mg yielded $[Cp^*Al]_4$ (**17**). This can also be synthesized by reaction of $[Cp^*AlX_2]_2$ with Na/K alloy. Substituted-cyclopentadienyl and silyl derivatives of aluminum(I) have similarly been prepared.[23,24] The Al–Al bonds in $[Cp^*Al]_4$ (average 2.769 Å) are longer than those in the dialanes and may be cleaved thermally to give monomeric Cp*Al in the gas phase. The Al–Al bonds in $[Cp^*Al]_4$ insert selenium and tellurium to give the chalcogenide cubanes $[Cp^*AlE]_4$ (E = Se, Te), react with P_4 to give the cage compound $(Cp^*Al)_6P_4$, and react with $[^{t}BuAs]_4$ to give $As_2(AlCp^*)_3$ in which arsenic atoms cap the two trigonal faces of the $[AlCp^*]_3$ core. Monomeric Cp*Al retains a lone pair of electrons and may be considered a CO analog with both σ-donor and π-acceptor potential. The Cp*Al moiety functions as a ligand towards main group and transition metals to form complexes such as $Cp^*Al{\rightarrow}B(C_6F_5)_3$ (**18**), $Cp^*Al{\rightarrow}Al(C_6F_5)_3$, $Cp^*Al{\rightarrow}Cr(CO)_5$, and $Cp^*Al{\rightarrow}Fe(CO)_4$. The only hexameric organoaluminum(I) cluster containing Al–Al bonds is $[Al_6{}^{t}Bu_6]^{\bullet-}$ (**19**).



(**17**)



(**18**)



(**19**)

Although aluminum(I) halides are useful for the low-temperature preparation of organoaluminum(I) compounds, aluminum(I) halides disproportionate to AlX_3 and $2Al_{metal}$ as temperature increases from −78 °C to −30 °C. Schnöckel[65,66] has taken advantage of this disproportionation for the preparation of metalloid clusters such as $SiAl_{14}Cp^*_6$, $Al_{50}Cp^*_{12}$, and the amazing inorganic cluster $[Al_{77}\{N(SiMe_3)_2\}_{20}]^{2-}$, all of which have been characterized by X-ray crystallography.[70]

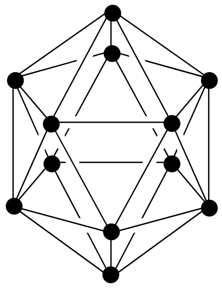


Figure 1 Icosahedral $Al_{12}{}^{2-}$ core of $K_2[Al_{12}{}^{i}Bu_{12}]$. Potassium atoms and organic substituents are omitted for clarity

These are referred to as metalloid clusters since they contain metal atoms bound only to other metal atoms and since the cores resemble bulk metal. The structure of $SiAl_{14}Cp^*_{12}$ can be described as a body-centered Al_8 cube encapsulating a single silicon atom. Each of the six faces of the Al_8 cube are capped with an AlCp* group. The structure of $Al_{50}Cp^*_{12}$ can similarly be described as an Al_8 core surrounded by an icosahedral Al_{30} shell. Each pentagonal face of the Al_{30} shell is capped by an AlCp* moiety. The Al–Al distances in $Al_{50}Cp^*_{12}$ average 2.770 Å, but range from 2.578 to 2.877 Å. The average Al–Al distances increase from the Al_8 core (2.664 Å) to the Al_{30} shell (2.765 Å) to those between the Al_{30} shell and the Cp*Al moieties (2.867 Å).

4 ORGANOALUMINUM HETEROCYCLES AND CAGE COMPOUNDS

Organoaluminum compounds form a variety of heterocycles and cage compounds with heteroatoms or polyanions that possess one or more lone pairs of electrons for use in bridge formation. Heterocycles of the type $[R_2Al(\mu_2\text{-}ER'_x)]_n$ ($n = 2, 3$) are extremely common with a diversity of bridging groups (ER'_x = F, Cl, Br, I, O, S, OR, SR, SeR, NR_2, PR_2, AsR_2, SbR_2,[71] BiR_2,[71] OH, SH, SeH, O_2SR, O_2PR, O_2AsR_2). Some of these heterocycles exhibit dimer-trimer equilibria in solution as evidenced by NMR spectroscopy and cryoscopic molecular weight measurements.

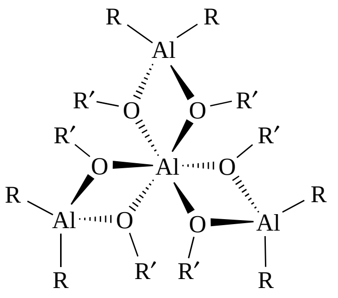
An interesting structural motif containing bridging groups is that found in alkylaluminum sesquialkoxides, which are prepared by reaction of a trialkylaluminum with an alcohol in a 2:3 ratio (equation 24) or by ligand redistribution upon reaction of a trialkylaluminum with a homoleptic aluminum alkoxide (equation 25).[72,73] Although the sesquialkoxide compounds can be formulated as $R_3Al_2(OR')_3$, this is

$$4R_3Al + 6R'OH \xrightarrow{-6RH} [Al\{(R'O)_2AlR_2\}_3] \quad (24)$$

$$2R_3Al + 2Al(OEt)_3 \longrightarrow [Al\{(EtO)_2AlR_2\}_3] \quad (25)$$

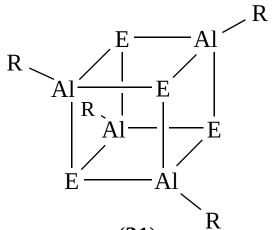
$$R = Me, Et, {}^tBu$$

an inaccurate reflection on their structure. The formula $[Al\{(R'O)_2AlR_2\}_3]$ is more descriptive. Structural studies confirm that alkylaluminum sesquialkoxides are tetramers comprised of an octahedral Al^{3+} ion connected to three tetrahedral $[R_2Al(OR)_2]^-$ moieties via bridging alkoxides as shown in (**20**). This core structure of approximate D_3 symmetry is the same as that observed for the Meerwein-Ponndorf-Verley reduction reagent, $[({}^iPrO)_3Al]_4$. There are relatively few examples of alkylaluminum sesquialkoxides, but their aluminum to oxygen ratio of 2:3 makes these compounds of interest as potential precursors to Al_2O_3 materials.



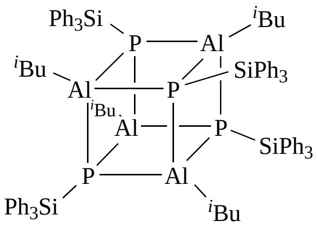
(**20**)

Bridging groups with additional donor atoms or available lone pairs of electrons can bridge three aluminum centers resulting in cage formation of the type $[RAl(\mu_3\text{-}ER)]_n$ (ER = O, S, Se, Te, NR, O_3PR, O_3AsR, O_3POR). Structures of these cage compounds are consistent with those observed for other electron-precise cage compounds of the main group elements as summarized by Veith.[74] Examples include the chalcogenide[15,55] and phosphide[75] tetramers (**21**) and (**22**). Three of the more common classes of organoaluminum heterocycles and cage complexes that have received investigation over the past 15 years are discussed in greater detail in the following three subsections.



(**21**)

E = S, Se, Te; R = ^{t}Bu, CMe_2Et



(**22**)

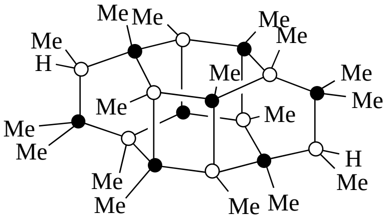
4.1 Organoaminoalanes and Organoiminoalanes

Amines react with organoaluminum compounds to give Lewis acid-base adducts. However, ammonia and primary and secondary amines may coordinate to organoaluminum compounds with subsequent alkane or hydrogen evolution to form heterocyclic aminoalanes, oligomeric iminoalanes, or in the case of ammonia, aluminum nitride.[10,11] A classic example is the

reaction of trimethylaluminum with methylamine as shown in equation (26). The reaction initially yields the

$$7Me_3Al + 7MeNH_2 \xrightarrow[-14CH_4]{215\,^\circ C} [MeAlNMe]_7 \qquad (26)$$

complex $Me_3Al{\cdot}NH_2Me$, and heating this complex to 70 °C yields cis and trans isomers of the cyclic aminoalane $[Me_2AlNHMe]_3$. Continued heating to 215 °C results in further methane elimination and formation of the heptameric iminoalane, $[MeAlNMe]_7$, via intermediate $[(Me_2AlNHMe)_2(MeAlNMe)_6]$ (**23**).



(**23**)

This reaction sequence is quite general. Primary amines react with trialkylaluminum compounds to form Lewis acid-base adducts $R_3Al{\cdot}NH_2R'$, followed by alkane elimination to form cyclic dimers and trimers of the formula $[R_2AlNHR']_n$ ($n = 2$, 3). Further alkane eliminates from the dimers and trimers at higher temperature to afford oligomeric iminoalanes $[RAlNR']_n$. The degree of association for iminoalanes ranges from 3 to 16 and structurally characterized examples exist for a trimer ($n = 3$), tetramers ($n = 4$), hexamers ($n = 6$), heptamers ($n = 7$), and octamers ($n = 8$). Structures of some of the larger oligomers, such as $[HAlN^iPr]_{10}$, $[HAlNEt]_{15}$, and $[HAlNEt]_{16}$ are not known. Each of the known structures (Figure 2) is composed of four- and six-membered rings of alternating aluminum and nitrogen atoms. The tetrahedral aluminum atoms are coordinated by three μ_3-NR′ groups.

Tetramers adopt the familiar cubane structure and hexamers adopt a drum-like structure as found in some main group metal alkoxides. The heptamer may be described as the fusion of two partial cubanes, one of which is missing an aluminum atom and the other which is missing a nitrogen atom. The octamer appears to result from the fusion of two Al_4N_4 cubanes, each opened along an edge prior to their linkage. Structurally characterized examples of cage iminoalanes include the following: $[HAlN^iPr]_4$, $[MeAlN^iPr]_4$, $[MeAlNMes]_4$, $[^tBuAlNSiPh_3]_4$, $[PhAlNPh]_4$, $[HAlN^iPr]_6$, $[HAlN^nPr]_6$, $[MeAlNPh]_6$, $[MeAlNMe]_7$, $[EtAlNMe]_7$ and $[HAlNEt]_8$. In all of these examples, Al–N distances average approximately 1.92 Å, albeit with some minor variations. For example, the Al–N distances in the six-membered rings of $[MeAlNPh]_6$ (1.912(6) Å) are slightly

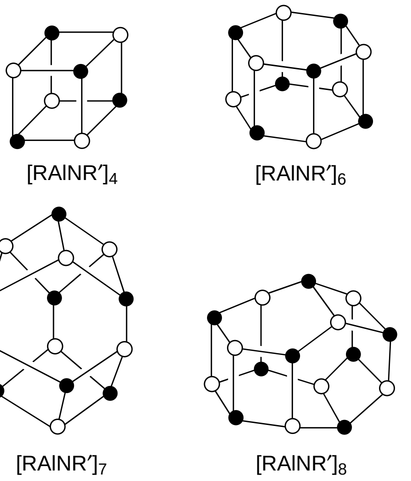


Figure 2 Core structures for organoiminoalanes with nitrogen and aluminum atoms alternating at cage vertices. Organic substituents R and R′ are omitted for clarity

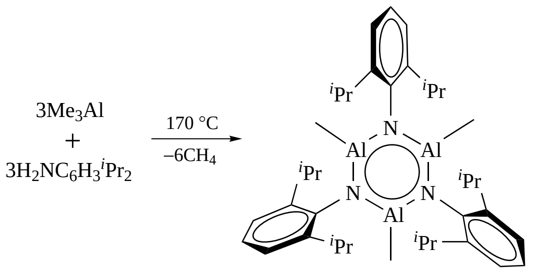
shorter than those between the six-membered rings (1.951(6) Å).

In the absence of crystallographic data, mass spectrometry has been used to verify the extent of oligomerization for several iminoalanes. Cryoscopic molecular weight measurements were less reliable. NMR (^{1}H, ^{13}C) spectroscopy is also quite useful because the symmetries of these cage compounds differ. Substituents on aluminum will give rise to a single set of resonance in tetramers, hexamers, and octamers of a drum-like structure. In contrast, aluminum substituents in an octamer of the type shown in Figure 2 give rise to two sets of resonances in a 1:1 ratio, and aluminum substituents in a heptamer give rise to three sets of resonances in a 3:3:1 ratio. Of course, the same distinctions hold true for the substituents on nitrogen.

The degree of association of iminoalanes is dependent on reaction conditions as well as on the steric requirements of the substituents on aluminum and nitrogen. Smaller substituents allow the formation of larger cages as in $[MeAlNMe]_8$, whereas sterically demanding substituents favor tetramer formation as observed for $[MeAlNMes]_4$. The steric bulk of the 2,6-diisopropylphenyl substituent on nitrogen results in formation of the trimeric iminoalane $[MeAlN(2,6\text{-}^iPr_2C_6H_3)]_3$ as shown in equation (27).[76] This trimer is unusual in that it contains both three-coordinate aluminum atoms and adjacent three-coordinate nitrogen atoms in a planar Al_3N_3 ring. The Al–N distance of 1.782(4) Å is very short by comparison with other oligomeric iminoalanes (average Al–N of 1.92 Å) and the normal range of Al–N distances (1.85–2.00 Å). This suggests the presence of N→Al π-donation and has prompted reference to this trimer as alumazine by analogy to borazine. Although there are six nitrogen lone-pair electrons available for delocalized π-bonding, no ring current suggesting aromaticity was observed

by NMR spectroscopy.



(27)

4.2 Alkylaluminoxanes

Alkylaluminoxanes, or alkylalumoxanes as they are often called, contain at least one oxide bridge between two or more aluminum centers that contain an organic substituent. Alkylaluminoxanes are most commonly obtained by partial hydrolysis of aluminum trialkyls under controlled conditions, but many other preparative routes have been described in the literature and in patents. The structures and compositions of most alkylaluminoxanes are the subject of much debate. Often referred to as black box materials, proposed structures previously focused on cyclic or polymeric structures as described in an excellent review by Pasynkiewicz.[77] New structural models for alkylaluminoxane have emerged over the past 15 years.

The hydrolysis of aluminum alkyls is believed to follow the reaction path depicted in Scheme 2.[78] Although not isolated for aluminum trialkyls, aqua complexes (**24**) have been observed by NMR spectroscopy below – 30 °C and their formation is precedented by the crystallographically characterized aqua complexes [$Al(OSiPh_3)_3(OH_2)$]·2THF and [$(C_6F_5)_3Al{\cdot}OH_2$].[79] Alkane elimination from the water complexes produces oligomers of dialkylaluminum hydroxides (**25**). Dimeric (**28**) and trimeric (**29**) oligomers of (R = Et, $(Me_3Si)_2CH$) have been characterized by NMR and IR spectroscopy. In addition, hydroxyl compounds [^{t}Bu$_2$Al(μ-OH)]$_2$, [^{t}Bu$_2$Al(μ-OH)]$_3$, [^{t}Bu$_2$Al(μ-OH)]$_3$·2THF, [^{t}Bu$_2$Al(μ-OH)]$_3$·2NCCH$_3$,

$$R_3Al + H_2O \longrightarrow R_3Al(OH_2) \quad (\mathbf{24})$$

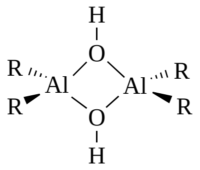
$$n\,R_3Al(OH_2) \xrightarrow{-n\,RH} [R_2AlOH]_n \quad (\mathbf{25})$$

$$[R_2AlOH]_n + n\,R_3Al \xrightarrow{-n\,RH} [R_2AlOAlR_2]_m \quad (\mathbf{26})$$

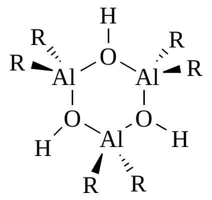
$$[R_2AlOH]_n \xrightarrow[\Delta]{-n\,RH} [RAlO]_n \quad (\mathbf{27})$$

Scheme 2 Proposed reaction scheme for hydrolysis of aluminum trialkyls

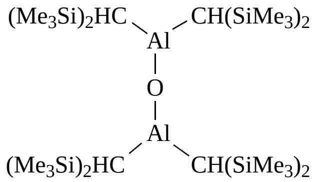
[$Mes_2Al(\mu$-OH)]$_2$·2THF, and [{$(Me_3Si)_3C$}MeAl(μ-OH)]$_2$·2THF have been isolated and characterized by X-ray crystallography. The hydroxyl protons are acidic and capable of hydrogen bonding to Lewis bases such as acetonitrile and THF. The acidity of the hydroxyl protons also allows further reaction of (**25**) with an additional equivalent of aluminum alkyl to form a tetraalkyldialuminoxane (**26**). Tetraalkyldialuminoxanes were previously proposed to be dimeric or trimeric based on molecular weight measurements. Monomeric tetraalkylaluminoxanes are not anticipated since the presence of two-coordinate oxygen and three-coordinate aluminum centers should lead to rapid oligomerization. However, Uhl isolated and structurally characterized the sterically protected monomeric tetraalkylaluminoxane [{$(Me_3Si)_2CH$}$_2$AlOAl{$CH(SiMe_3)_2$}$_2$] (**30**).[64] Compound (**30**) exhibits a planar C_4Al_2O core with a linear Al–O–Al linkage and a very short Al–O distance of 1.687(4) Å. A dimeric structure with two three-coordinate aluminum centers has been substantiated by X-ray crystallography for [^{t}Bu$_2$Al(μ-OAl^{t}Bu$_2$)]$_2$ (**31**).[80]



(**28**)

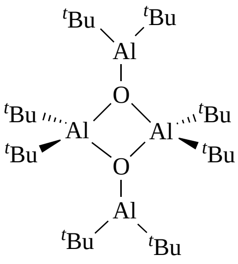


(**29**)

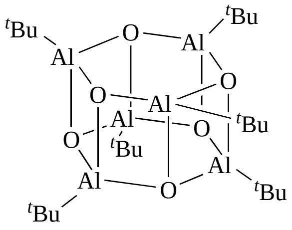


(**30**)

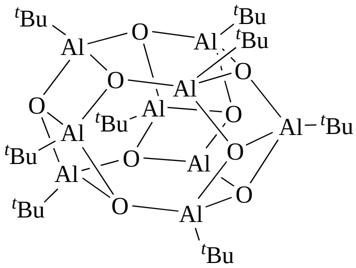
In the absence of excess trialkylaluminum, the hydroxide oligomers (**25**) undergo further alkane elimination to give oligomers of the formula [RAlO]$_n$ (**27**). Initially believed to be linear or cyclic oligomers comprised of four- and six-membered rings of alternating aluminum and oxygen atoms, isolation of a series of *tert*-butylaluminoxanes [^{t}BuAlO]$_n$ (n = 6 (**32**), 7, 8, 9 (**33**)) and crystallographic characterization demonstrated three-dimensional cage structures.[80–82] The cage



(**31**)



(**32**)

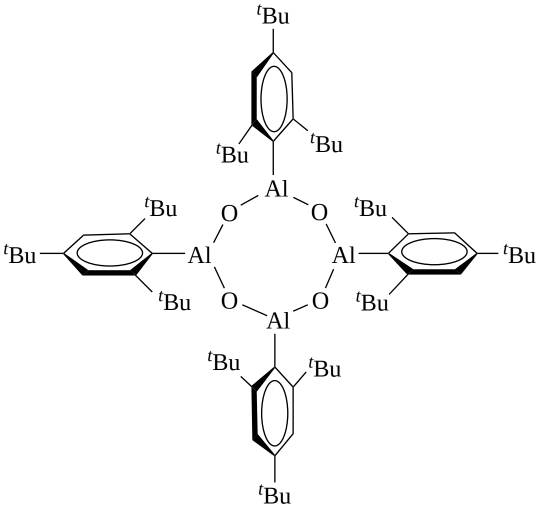


(**33**)

structures are analogous to those adopted by some alkali metal alkoxides, organogallium sulfides, and organoiminoalanes. Barron proposed that aluminoxanes with cage structures are strong Lewis acids despite the aluminum atoms being four-coordinate.[83] The cages possess a latent Lewis acidity, which is defined as proclivity of the cage to dissociate one or more Al–O bonds to form highly Lewis acidic three-coordinate aluminum centers. The driving force is proposed to be the relief of ring-strain in the cage structure. Hessen and coworkers have provided reactivity data for a boraluminoxane in support of the proposed latent Lewis acidity in cage alkylaluminoxanes.[84]

Tetrameric cage compounds with cubane structures have not been isolated. Tetramer formation is observed for $[Mes^*AlO]_4$ (**34**) in which the aluminum atoms remain three-coordinate and cage formation is precluded by the steric bulk of the Mes* substituents.[85] Compound (**34**) was prepared by reaction of $[Mes^*AlH_2]_2$ with $[Me_2SiO]_3$ and was not obtained by hydrolysis.

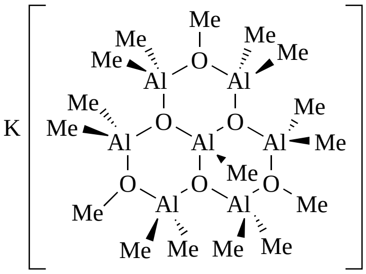
Methylaluminoxane (MAO), sometimes referred to as polymethylaluminoxane (PMAO), currently garners the most industrial interest of all the alkylaluminoxanes owing to its activity as a cocatalyst for metallocene-catalyzed alkene polymerization (*see* ***Oligomerization & Polymerization by***



(**34**)

Homogeneous Catalysis).[33,86–88] MAO is synthesized by careful hydrolysis of trimethylaluminum by one of a variety of patented procedures that vary in the mode of water delivery, including the use of water-saturated nitrogen vapor, water emulsions in organic solvents, ice, molecular sieves, and various hydrates such as $Al_2(SO_4)_3{\cdot}18H_2O$, $MgCl_2{\cdot}6H_2O$, $CuSO_4{\cdot}5H_2O$, and $FeSO_4{\cdot}7H_2O$. Nonhydrolytic routes have also been described. The method of synthesis has a dramatic influence on the catalytic activity of the resulting MAO. Changes in compositions and structures of aluminoxane products as a function of reaction conditions were detailed in studies of the hydrolysis of $^tBu_3Al$.

The structure of MAO remains enigmatic. NMR and IR spectroscopy, cryoscopic molecular weight measurements, mass spectrometry, gel-permeation chromatography (GPC), and computational methods have been used to probe the structure of MAO, but compositions and structures of components remains elusive. No neutral methylaluminoxanes have been characterized by X-ray crystallography. Atwood has characterized the anionic aluminoxanes $K[Al_7O_6Me_{16}]$ (**35**) and $[Me_4As]_2[Me_2AlOAlMe_3]_2$.[10,11]



(**35**)

In contrast to investigations of aluminoxanes bearing bulky ^tBu, Mes, Mes*, and $CH(SiMe_3)_2$ substituents, the study of

MAO is complicated by the proclivity of methyl groups to bridge aluminum centers, as well as by the high rate of methyl exchange. This leads to the presence of multiple equilibria, the positions of which are shifted upon the addition or removal of trimethylaluminum or change in conditions. Thus, MAO is likely a mixture of species rather than a single, well-defined compound. The situation is even more complicated in that the compositions, structures, and catalytic activities of MAO samples vary depending on reaction conditions and the source of water as already mentioned. Although it is appealing to denote MAO as oligomers of the formula $[MeAlO]_n$ by analogy to the well-defined *tert*-butylaluminoxanes, data suggests that trimethylaluminum accounts for up to 28% of the aluminum present in some commercial samples of MAO. GPC and ^1H NMR data also indicate that the methyl to aluminum ratio is closer to 1.5 rather than 1. Recent proposals for structures of MAO center on cage or partially opened cage structures. Sinn has proposed a cage compound of formula $Me_{24}Al_{16}O_{12}$ to be a major component of MAO.[33] Other authors have proposed a $Me_{18}Al_{12}O_9$ cage based on DFT calculations.[89] The latter structure is envisioned as resulting from addition of three Me_3Al molecules to a $[MeAlO]_9$ cage.

Modified MAOs (MMAO) that incorporate ^{i}Bu and other alkyl groups to improve stability and optimize catalytic activity are commercially available. The use of additional modifiers such as boranes, boroxines, and pentafluorophenyl derivatives has been investigated in recent years. MAO has also been supported on silica and other materials for the preparation of heterogeneous alkene polymerization catalysts. These developments are detailed in several reviews.[33,86–88,90]

4.3 Alkylaluminophosphates, -phosphinates, -phosphonates, and -arsonates

Molecular phosphates, phosphinates, phosphonates, and arsonates of aluminum adopt heterocyclic and cage structures[91,92] that are larger than those observed for iminoalanes and aluminoxanes, but topologically similar based on the isolobal relationship of a μ_3-phosphonate to a μ_3-amide and μ_3-oxide.[93] There is also an isoelectronic and structural relationship of the aluminophosphonate compounds and their analogs to the extensively studied organosilsesquioxanes of the formula $[RSiO_{1.5}]_n$. Furthermore, the molecular phosphates, phosphinates, phosphonates, and arsonates of aluminum have been investigated as soluble models of secondary building units (SBUs; Figure 3) in microporous aluminophosphate (*see* ***Phosphates: Solid-state Chemistry***) molecular sieves and as precursors[94] to new aluminophosphate and aluminoarsenate materials. The majority of these studies have been conducted since 1996.

Cyclic alkylaluminophosphinates $[R_2AlO_2PR'_2]_n$ ($n = 2$, 3) were first synthesized in 1964 by Coates and Mukherjee by reaction of a phosphinic acid, $R'_2P(O)OH$, with an aluminum alkyl. Cryoscopic molecular weight measurements, IR and Raman spectroscopic data, and selected NMR data confirm the structures to be cyclic dimers ($n = 2$) of C_{2h} symmetry. X-ray crystallography confirmed that the core structure of $[^tBu_2AlO_2PPh_2]_2$ consists of an eight-membered $Al_2P_2O_4$ ring. These $Al_2P_2O_4$ cores have a structural relationship to four-ring (4R) SBUs common to aluminophosphate and metal-substituted aluminophosphate (MAPO) molecular sieves such as $AlPO_4$-5, $AlPO_4$-12, $AlPO_4$-25, $AlPO_4$-31, MAPO-36, and MAPO-39. Cyclic trimers were reported for $[Me_2AlO_2PX_2]_3$ (X = Cl, F, H), but their structures have not been confirmed by X-ray crystallography.

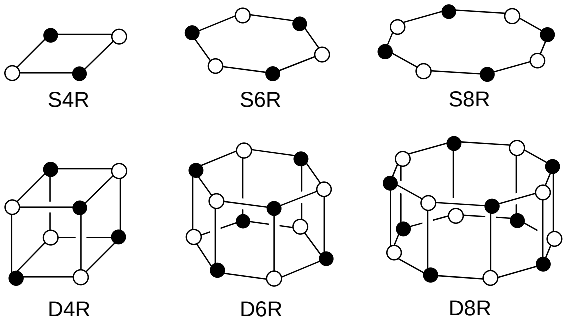


Figure 3 Secondary building units common to aluminophosphate molecular sieves. Phosphorus and aluminum atoms alternate at vertices. Not shown are the μ_2-oxo bridges on each edge

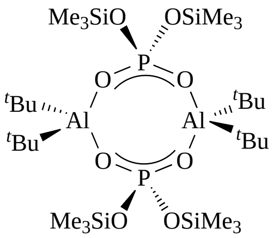
Reactions of phosphonic acids, $R'P(O)(OH)_2$, with aluminum alkyls are similarly expected to form cyclic dimers $[R_2MO_2P(OH)R'_2]_2$, but facile alkane elimination to yield oligomers $[RAlO_3PR']_n$ hinders the isolation of the intermediate dimers. The cyclic dimer $[^tBu_2AlO_2P(OH)Ph]_2$ was isolated as a crystalline solid at low temperature with the aid of bulky substituents. The poorly stable dimer was derivatized upon reaction with Me_3SiNMe_2 and the cyclic structure of the trimethylsilyl derivative $[^tBu_2AlO_2P(OSiMe_3)Ph]_2$ was confirmed by X-ray crystallography.



(**36**)

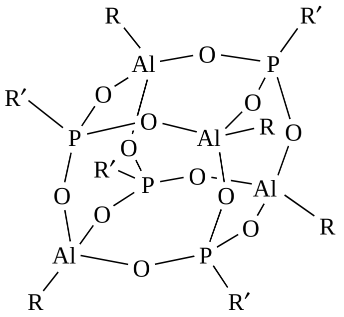
A cyclic alkylaluminophosphate $[^tBu_2AlO_2P(OSiMe_3)_2]_2$ (**36**) was obtained by Me_3SiCl elimination from reaction of $(Me_3SiO)_3P{=}O$ with $^tBu_2AlCl$. Analogous heterocycles have also been prepared by dealkylsilylation upon reaction of R_3Al with $(Me_3SiO)_3P{=}O$ at 200 °C.[95] In both cases, product formation was thermodynamically favored by the strength of the new Al–O bonds. Attempted reactions of

H_3PO_4 with ${}^tBu_3Al$ to give $[R_2AlO_2P(OH)_2R']_2$, followed by derivatization with Me_3SiNMe_2, gave complicated mixtures that contained $[{}^tBu_2AlO_2P(OSiMe_3)_2]_2$, but isolated yields are very low.

Equimolar reactions of an aluminum alkyl with a phosphonic acid under room temperature or reflux conditions yields oligomers of the formula $[RAlO_3PR']_n$ ($n = 4$, 6, 10) (equation 28).[91,92] Tetrameric ($n = 4$) derivatives (**37**) are the

$$nR_3Al + nR'P(O)(OH)_2 \xrightarrow[-2nRH]{\Delta} [RAlO_3PR']_n \quad (n = 4, 6, 10) \qquad (28)$$

most common and are obtained in high yield. Three hexamers have been isolated and structurally characterized as has the decamer $[{}^tBuAlO_3PMe]_{10}$,[96] but these were minor components of mixtures that consist mainly of tetramers. The tetramers (**37**) possess a cubanoidal $Al_4P_4O_{12}$ core structurally analogous to double-four-ring (D4R) SBUs found in aluminophosphate molecular sieves. The drum-like $Al_6P_6O_{18}$ core of hexameric derivatives resembles double-six-ring (D6R) SBUs common to $AlPO_4$-18, $AlPO_4$-52, and MAPOs isotypic to the aluminosilicates chabazite and faujasite. The structure of the decamer can be described as two edge-opened tetramers linked via Al–O–P bridges to an eight-membered $Al_2P_2O_4$ heterocycle.



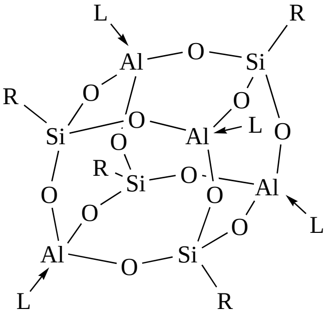
(**37**)

The tetrameric alkylaluminophosphonates (**37**) are thermally quite stable and those with smaller substituents sublime without decomposition. The most volatile of these, $[MeAlO_3PMe]_4$, sublimes to give crystals at 150 °C/0.1 mm Hg. The tetrameric alkylaluminophosphonates are also moderately stable to air and moisture. In contrast, the alkylaluminophosphate $[{}^tBuAlO_3P(OSiMe_3)]_4$, which is obtained from Me_3SiCl elimination upon reaction of ${}^tBuAlCl_2$ with $(Me_3SiO)_3P{=}O$, is readily hydrolyzed.

Cage fragmentation and rearrangements have been observed for some tetrameric alkylaluminophosphonates.[97] Reaction of $[{}^tBuAlO_3PMe]_4$ with acetylacetone in toluene at 70 °C results in precipitation of the decamer $[{}^tBuAlO_3PMe]_{10}$. This decamer rearranges to a mixture of tetramer and hexamer in $CDCl_3$ over several days. In another example, CuCl and $[{}^tBuAlO_3PC_6H_4CN]_4$ react to give crystals of $[Al({}^tBuAl)_6(O_3PC_6H_4CN)_8Cu(NCCH_3)_2]_x$. This is a one-dimensional polymer in which $[Al({}^tBuAl)_6(O_3PC_6H_4CN)_8]^-$ units are linked to $Cu(NCCH_3)_2{}^+$ moieties via two of the cyanophenyl substituents. The core structure of $[Al({}^tBuAl)_6(O_3PC_6H_4CN)_8]^-$ can be described as two $Al_4P_4O_{12}$ cubanoids sharing a common vertex occupied by an octahedral aluminum. The formation of this compound is not understood. Structural rearrangements have been better-studied for analogous alkylgallophosphonates.

Fluoride is often used as a mineralizer and structure-directing agent in the formation of aluminophosphate molecular sieves, some of which retain fluoride by encapsulation in $Al_4P_4O_{12}$ D4R cages.[98] Attempts to encapsulate fluoride in molecular compounds such as (**37**) have not been highly successful. However, Roesky and coworkers were able to prepare the unique fluoride-containing aluminophosphonate $[Cs_3(THF)_3F({}^iBuAl)_3({}^tBuPO_3)_4]_2[({}^iBuAl)_2(\mu\text{-}F)_2({}^tBuPO_3)_4]$.[99] The encapsulated fluoride resides in an $Al_4P_4O_{12}(\mu\text{-}F)_2F_2$ cage in which two aluminum centers each have an ^{i}Bu substituent and the remaining two aluminum centers have lost their alkyl substituent and have fluoride bridges to two partial tetramers. Roesky and coworkers have also characterized several aluminophosphonate cage compounds that incorporate alkali metal cations and these are described in a recent review.[92]

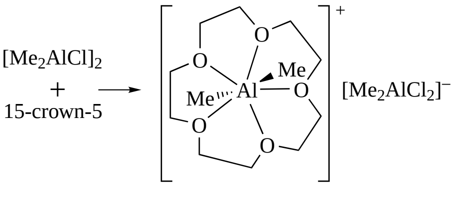
Aluminum alkyls react with bulky silane triols to give cage aluminosiloxanes that are structurally related to the molecular alkylaluminophosphonates.[100] If these reactions are conducted in a 1:1 molar ratio cyclic dimers or cubanoidal aluminosiloxanes are obtained depending on temperature. The cyclic dimer $[{}^iBu(THF)AlO_2Si(OH)R]_2$ (R = $(2,6\text{-}{}^iPr_2C_6H_3)N(SiMe_3)$) is obtained at low temperature. It contains an eight-membered $Al_2Si_2O_4$ ring similar to that found in the mineral gismondine. If the reaction of $RSi(OH)_3$ with Me_3Al or ${}^iBu_2AlH$ is conducted in a 1:1 ratio at 65 °C, compounds $[RSiO_3Al{\cdot}L]_4$ (R = $N(Ar)SiMe_3$, $Co_3(CO)_9C$; L = THF, 1,4-dioxane) (**38**) are obtained. These contain an inorganic $Al_4Si_4O_{12}$ core that is isoelectronic to the $Al_4P_4O_{12}$ core of the aluminophosphonates (**37**) and analogous to the D4R SBUs common to some aluminosilicates (*see* ***Zeolites***). Three oxygen bridges in the $Al_4Si_4O_{12}$ cage and a neutral donor define the coordination sphere of the approximately tetrahedral aluminum atoms. Organometallic derivatives are obtained upon reaction of the silane triol with $NaAlEt_2H_2$ or $LiAlH_4$ to yield $[Li(THF)]_4[RSiO_3AlH]_4$ or $[Na(THF)]_4[RSiO_3AlEt]_4$, respectively. An aluminosiloxane with a drum-like $Al_4Si_2O_6$ core is obtained if the reaction of $RSi(OH)_3$ to ${}^iBu_2AlH$ is conducted with a 1:2 ratio.



(**38**)

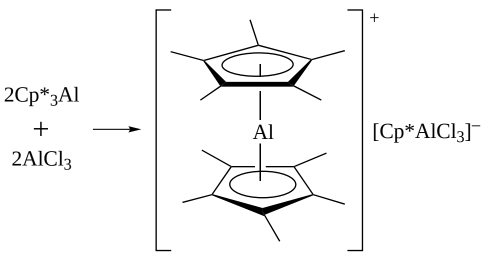
5 CATIONIC ORGANOALUMINUM COMPOUNDS

A strong interest in cationic organoaluminum compounds has developed over the past decade with the anticipation that the increased Lewis acidity of cationic reagents will allow cationic complexes to outperform their neutral analogs in various Lewis acid-catalyzed reactions. Atwood has reviewed the synthesis of group 13 cations and has classified preparative routes to organoaluminum cations into four general types: asymmetric cleavage, halide displacement, ligand redistribution, and abstraction.[101] In asymmetric cleavage, a Lewis base cleaves a halide-bridged dimer $[R_2AlX]_2$ into a base-stabilized cation and a dihaloaluminate anion. Reaction of $[Me_2AlCl]_2$ with 15-crown-5, for example, forms the cationic complex $[Me_2Al(15\text{-crown-}5)]^+$ $[Me_2AlCl_2]^-$ in which the aluminum atom resides in a pentagonal bipyramidal coordination environment of the five crown ether oxygens and two *trans*-oriented methyl groups (equation 29).



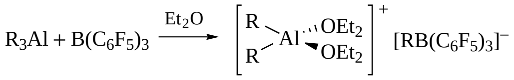
(29)

The Me_2Al^+ fragment is nearly linear with a C–Al–C angle of 178° and an Al–C distance of 2.00(2) Å. Similarly, the reaction of $[^tBu_2AlCl]_2$ with N,N,N',N'-tetramethylethylenediamine (tmeda) gives $[^tBu_2Al(\text{tmeda})]^+$ $[^tBu_2AlCl_2]^-$. Additional tmeda may displace the remaining halide to give the base-stabilized cation with halide counterion, $[^tBu_2Al(\text{tmeda})]^+[Cl]^-$. This is referred to as halide displacement or symmetric cleavage. Cationic complexes can also result from ligand redistribution as in the formation of the first aluminocenium cation $[Cp^*_2Al]^+$ $[Cp^*AlCl_3]^-$ from reaction of Cp^*_3Al and $AlCl_3$ (equation 30).[22]



(30)

These synthetic approaches typically yield base-stabilized cations with coordination numbers at aluminum of four or more. Complexation and increased coordination number at aluminum moderates the desired increase in Lewis acidity of the cationic reagent. For this reason, the alkyl, hydride, or halide abstraction route dominates recent attempts to prepare base-free organoaluminum cations with two- or three-coordinate aluminum centers. Strategies parallel those employed for generating cationic metallocene complexes of the early transition metals, with the most common abstracting agents being $B(C_6F_5)_3$ or trityl salts of weakly coordinating $[B(C_6F_5)_4]^-$, $[B\{3,5\text{-}(CF_3)_2C_6H_3\}_4]^-$, or carborane anions. The commercial availability of these reagents and their precursors further favors their use. Abstraction with dimethylanilinium salts or $[(Et_2O)_2H]^+[B\{3,5\text{-}(CF_3)_2C_6H_3\}_4]^-$ is less frequent since these often lead to dimethylaniline or diethyl ether coordination. Reaction of $(R_3SiO)Al_2Me_5$ with $[PhMe_2NH]^+[B(C_6F_5)_4]^-$, for example, yields the aniline-stabilized salt $[Me_2Al(NMe_2Ph)_2]^+[B(C_6F_5)_4]^-$.[102] The borane $B(C_6F_5)_3$ is a useful methide abstracting reagent, although methyl transfer is reversible in solution. Nonetheless, $B(C_6F_5)_3$ was used to prepare $[Cp_2Al]^+[MeB(C_6F_5)_3]^-$ and $[R_2Al(OEt_2)_2]^+[RB(C_6F_5)_3]^-$ (R = Me, Et, octyl) by alkide abstraction (equation 31). Klosin and coworkers also used tris(perfluorobiphenyl)borane in the presence of $AlMe_3$

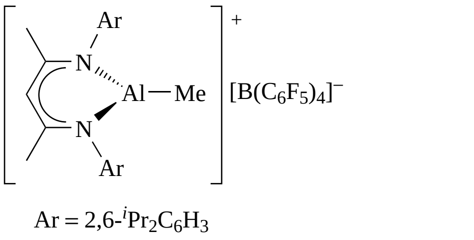


(31)

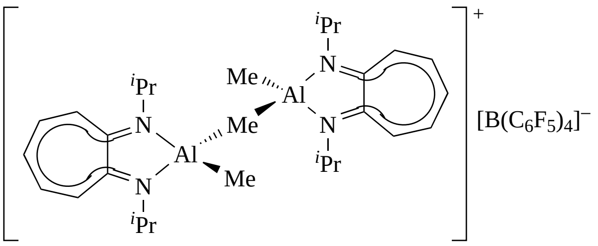
and ether to form the structurally characterized salt $[Me_2Al(OEt_2)_2]^+[MeB(C_{12}F_9)_3]^-$.[36]

Jordan and coworkers have prepared cationic aluminum complexes utilizing amidinate ligands using the alkide abstraction route.[103] Reaction of $\{MeC(N^iPr)_2\}AlMe_2$ with $B(C_6F_5)_3$ or $[Ph_3C]^+[B(C_6F_5)_4]^-$ yields the unstable cation $[\{MeC(N^iPr)_2\}AlMe]^+$. The cation can be stabilized by coordination of a Lewis base to give $[\{MeC(N^iPr)_2\}Al(Me)L]^+$ (L = NMe_2Ph, Me_3P) or with one equivalent of the starting amidinate complex to give the methyl-bridged complex $[\{MeC(N^iPr)_2\}Al(Me)(\mu\text{-}Me)Al(Me)\{(^iPrN)_2CMe\}]^+$. Jordan has structurally characterized a related three-coordinate aluminum cation supported by a β-diketiminate ligand (**39**) and a methyl-bridged dimer (**40**) supported by an aminotroponiminate ligand.[104,105] The aluminum atom in (**39**) is perturbed

slightly from planar to pyramidal by a weak interaction with the anion. The shortest contact between the cation and anion is the Al–F_{meta} interaction at a distance of 2.151(1) Å. In (**40**), the bridging methyl is trigonal bipyramidal with the hydrogen atoms residing in the equatorial plane. Aluminum–carbon distances for the bridging methyl (2.177(3), 2.120(3) Å) are significantly longer than those for the terminal methyls (1.949(3), 1.953(3) Å) as expected owing to the three-center two-electron bonding for the bridging methyl group.



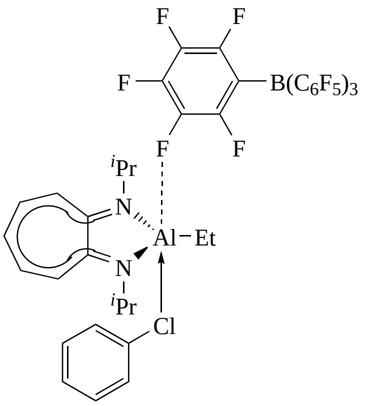
(**39**)



(**40**)

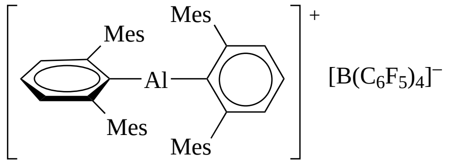
Chlorobenzene has been shown by NMR spectroscopy and X-ray crystallography to coordinate to aluminum in the cationic complex (**41**).[106] The Al–Cl distance of 2.540(3) Å is slightly longer than Al–Cl distances in chloride-bridged aluminum dimers (2.2–2.5 Å) and consistent with a coordinate covalent Cl→Al bond. The orientation of the chlorobenzene ring with respect to the diisopropylaminotroponiminate ligand suggests that π-stacking may help to stabilize the complex. The interaction between the anion and aluminum cation is very weak. The Al–F distance in (**41**) is 3.23 Å, considerably longer than the Al–F distance of 2.151(1) Å found in complex (**39**).

Many attempted syntheses of two- and three-coordinate base-free cations are unsuccessful owing to facile decomposition of the target cationic complex by aryl transfer from the borate anion to the aluminum center. Attempted synthesis of alumenium ions R_2Al^+ from reaction of R_3Al and $[Ph_3C]^+$ $[B(C_6F_5)_4]^-$, for example, results in initial formation of an unstable R_2Al^+ intermediate followed by aryl transfer to give $R_2AlC_6F_5$ and $B(C_6F_5)_3$.[37] Jordan,[103–105] Arnold,[107] and Gibson[108] have reported analogous aryl transfers from borate anions to cationic aluminum complexes supported by β-diketiminate, amidinate, and carbazolyl ligands.



(**41**)

Polyhedral borane and carborane anions are more robust and less coordinating than the perfluoroarylborates and thus may serve to stabilize reactive alumenium species. Reed and coworkers reacted $[Ph_3C]^+[CB_{11}H_6Br_6]^-$ with Et_3Al to give $[Et_2Al][CB_{11}H_6Br_6]$.[109] The molecular structure of $[Et_2Al][CB_{11}H_6Br_6]$ shows an approximately tetrahedral aluminum coordinated by two of the bromine atoms of the carborane anion with distances of 2.581(2) and 2.542(2) Å. The compound is formulated as a tight-ion pair, $[Et_2Al]^{\delta+}$ $[CB_{11}H_6Br_6]^{\delta-}$, and shows alumenium ion-like behavior. It reacts with pyridine to form $[Et_2Al(py)_2]^+[CB_{11}H_6Br_6]^-$, likely coordinates ethylene, and effects alkylation of benzene and formation of butene.



(**42**)

A two-coordinate base-free alumenium ion (**42**) was prepared by Wehmschulte using bulky terphenyl groups to provide steric protection of the aluminum center and protect against aryl transfer.[32] There is no interaction of the anion with the cationic aluminum center in the solid state. The shortest Al–F distance is 5.498 Å. There are, however, contacts between the Lewis acidic aluminum and carbons of the mesityl groups as short as 2.353(1) Å. The C–Al–C angle in (**42**) is 159.17(5)°.

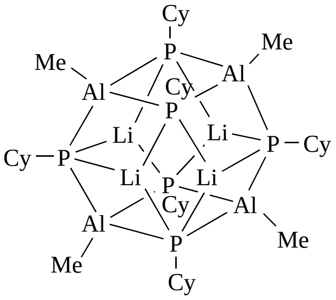
Much of the recent work on cationic organoaluminum complexes was stimulated by Jordan's report that $\{MeC(N^iPr)_2\}AlMe_2$ activated with $B(C_6F_5)_3$ polymerizes ethylene to high molecular weight polymer, although with low activity.[103] Reaction of $\{^tBuC(N^iPr)_2\}AlMe_2$ with $[Ph_3C]^+$ $[B(C_6F_5)_4]^-$ gives an analogous cationic complex but with superior activity for the polymerization of ethylene. Molecular weights of the resulting polymer were as high as 272 200

with low polydispersity. This is consistent with polymerization by a single-site catalyst. Activities are far below what is achieved with single-site transition metal complexes.

The key to using aluminum complexes to polymerize rather than oligomerize ethylene to C_8-C_{14} alkenes as in the Aufbau reaction is steric hindrance that will prevent approach of the growing alkyl chain to the aluminum center. This precludes chain termination by β-hydrogen elimination. Computational studies on the mechanism of this have been reported and some indicate that mechanisms involving two aluminum centers are plausible.[110] Following on this discovery, other nitrogen-donor ligands (*see* ***Ammonia & N-donor Ligands***) have been investigated in search of cationic aluminum complexes for the polymerization of alkenes. Gibson has briefly discussed cationic aluminum complexes for alkene polymerization in a recent review.[111] Cationic organoaluminum complexes may also function as catalysts for the ring-opening polymerization of epoxides, lactones, and lactides, but this area of research is still in its infancy and it is unclear in some cases if the polymerizations occur by a coordination/insertion mechanism or by cationic polymerization.

6 ANIONIC ORGANOALUMINUM COMPOUNDS

Organoaluminum compounds react with anionic Lewis bases to form aluminate complexes, the compositions and structures of which are diverse. Many aluminates exhibit structures in which aluminum and a metal cation are connected by one or more bridging groups, including alkyls, alkoxides, amides, halides, hydrides, and phosphides. Simple reactions of a carbanion with an aluminum trialkyl form complexes $M[R_3AlR']$. These may be monomeric as in $Na[AlR_4]$ (R = Me, Et, ^{n}Pr, ^{n}Bu) or polymeric with bridging alkyls as in $[KAlCH_2{}^iPr_4]_n$ and $[LiAlEt_4]_n$. Lithium hydridoaluminates may exhibit linear bridging hydrides as in $Na[Me_3AlHAlMe_3]$, nonlinear hydride bridges as found in many tetramers, and triply-bridging hydrides as in $[LiHAl^tBu_3]_2$. More complex structures are observed, such as the 14-atom $Li_4Al_4P_6$ cage found in $[(THF{\cdot}Li)_4(MeAl)_4(CyP)_6]$ (**43**), shown below without the THF molecules. Linton, Schooler, and Wheatley recently reviewed the structural diversity of aluminates.[112]



(**43**)

Particularly interesting are reactions of aluminum alkyls with halide or pseudohalide salts in a 2:1 ratio to form complexes $M[Al_2R_6X]$. Although some of these complexes possess linear bridges, as in the previously mentioned $K[Al_2Et_6F]$, many consist of bent structures as determined by X-ray crystallography and spectroscopy. Upon the addition of an aromatic solvent to those with bent structures and gentle heating, liquid clathrates of the formula $M[Al_2R_6X]{\cdot}n$(arene) phase-separate into a dense phase below a phase of pure solvent. Clathrate formation is dependent on the shape of the anion, the size of the cation, the lattice energy of MX, the strength of the anion-cation interaction, and the presence of arene molecules. The liquid clathrates do not form for the linear compounds or the 1:1 compounds $M[AlR_3X]$, nor do they form in the absence of an aromatic solvent. Each clathrate phase $M[Al_2R_6X]{\cdot}n$(arene) has a maximum number of solvent molecules (n) and Atwood has determined how arene to anion ratios vary as a function of cation and anion size. Interactions between the cation and the arene molecules are also important to clathrate formation and several crystal structures of these salts show π interactions between arene molecules and potassium or cesium cations. Some common components of liquid clathrate phases are shown in Table 3. Incorporation of crown ethers allows the preparation of additional liquid clathrates having the formula [M·crown ether]$[Al_2R_6X]$ $\cdot n$(arene). Some 3:1 and 4:1 complexes such as $K_2[SO_4(AlMe_3)_4]$ also form liquid clathrates in the presence of aromatic solvents. There are currently no uses for these air- and water-sensitive liquid clathrates. Further information is available in the chapter by Atwood in the text by Robinson.[10]

7 APPLICATIONS OF ORGANOALUMINUM COMPOUNDS IN SYNTHESIS

Organoaluminum compounds are used to effect a variety of organic transformations. They are excellent reducing agents and examples of reductions are shown in Table 4. Organoaluminum reagents serve as Lewis acid catalysts for Diels–Alder reactions, and they are also used to transfer alkyl groups to transition metal complexes for metal-catalyzed coupling reactions as in the coupling of alkynes to dienes. As already mentioned, hydroalumination (*see* ***Hydroboration Catalysis***) and carbalumination of alkenes followed by oxidation can be used to prepare alcohols.

Organoaluminum compounds are heavily used in organic synthesis and the pertinent literature is too extensive to be adequately reviewed here. Readers are directed to excellent articles by Eisch[8,9] for a general overview of the subject and are encouraged to search for specific transformations in the texts published by March[113] and Larock.[114] The text by Ojima cites several examples of enantioselective reactions using chiral complexes of aluminum.[115]

Organoaluminum compounds also have applications in the synthesis of inorganic and organometallic complexes of the transition metals. Since aluminum is more electropositive than most of the transition metals, aluminum alkyls are excellent alkylating agents for transition metal complexes. Alkylation followed by subsequent β-hydrogen and reductive elimination (e.g. equation 32) is a convenient means of reducing transition

$$Ni(acac)_2 + 2Et_3Al + 2COD \longrightarrow Ni(COD)_2 + 2AlEt_2(acac) + C_2H_4 + C_2H_6 \quad (32)$$

metals to lower oxidation states. In the presence of additional ligands, this reductive ligation provides a preparative route to low-valent transition metal carbonyl, phosphine, and alkene complexes as shown in equations (33) and (34).

$$WCl_6 + 3Et_3Al + CO \longrightarrow W(CO)_6 \quad (33)$$

$$Mn(OAc)_2 + {}^iBu_3Al + CO \longrightarrow Mn_2(CO)_{10} \quad (34)$$

Table 4 Organoaluminum compounds as alkylating and reducing agents

Substrate	Aluminum reagent	Product
RX	R'_3Al	R–R′
R_3COH	Me_3Al	R_3CMe
RC(O)R′	Me_3Al	$RR'CMe_2$

RC(O)H	Et_3Al	R(Et)(H)COH

8 APPLICATIONS OF ORGANOALUMINUM COMPOUNDS IN INDUSTRY

Organoaluminum compounds are best known and most utilized as cocatalysts in the polymerization of alkenes. In 1953, Karl Ziegler discovered that suspensions of $TiCl_3$, prepared by reduction of $TiCl_4$ with Et_3Al in a hydrocarbon solvent, actively polymerize ethylene and propylene to high molecular weight polymers at low pressure (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***). This catalyst system and related catalysts comprised of an early transition metal (e.g. Ti, V, Cr) and an aluminum alkyl, some supported on an inorganic support such as $MgCl_2$, became known as Ziegler–Natta alkene polymerization catalysts. Modification of Ziegler–Natta catalysts by the addition of various iodide promoters increased catalytic activity for the polymerization of butadiene to *cis*-1,4-polybutadiene. Alkene polymerizations continue to be of major commercial importance today. Annual production of polyethylene (PE) and polypropylene (PP) in 1993 exceeded 50 million tons and by 1996 worldwide production of PE and PP was 40 million and 20 million tons, respectively.

More recently, metallocene complexes activated by methylaluminoxane (MAO) were found to polymerize ethylene and propylene to high molecular weights with unprecedented control over molecular weight, polydispersity, and stereoregularity of the resulting polymer.[33,86–89] The main role of MAO is proposed to be as a methylating agent and methide abstracting reagent as shown in equation (35), but MAO is also believed to scrub oxygen, water, and other

$$Cp_2ZrMe_2 + (MeAlO)_n \rightleftharpoons [Cp_2ZrMe][Me(MeAlO)_n] \quad (35)$$

protic impurities from the system and hence protect against catalyst deactivation. Polymerization occurs by a coordination/insertion mechanism at the resulting cationic transition metal complex and the polymer properties and activity of the single-site catalyst are controlled by the steric and electronic properties of the ligands and further influenced by ion-pairing effects. Other activators such as $B(C_6F_5)_3$ and trityl salts of noncoordinating anions better stabilize well-defined cationic complexes for ease of characterization. MAO also has drawbacks including its high cost and the high aluminum content in resulting polymers owing to the use of Al:M ratios up to 1000:1 or higher. Nonetheless, MAO continues to be the activator of choice for commercial applications of both homogeneous and heterogeneous single-site alkene polymerization catalysts. This makes MAO one of the most important organoaluminum compounds currently utilized in industry.

Aluminum alkyls are used as Lewis acids and activators for several related transition metal-catalyzed reactions.[116] In the Dimersol® process, nickel complexes activated by an aluminum alkyl catalyze alkene dimerization, as in the conversion of butene to isooctene for use in preparing

plasticizers and in the dimerization of propylene/butene mixtures to form branched C_6 to C_8 products for use as fuels. Hexadiene is similarly prepared from butadiene and ethylene. Triethylaluminum activates nickel carboxylates and cobalt complexes ligated by acetylacetonate and phosphines for mild catalytic hydrogenation of arenes to cyclohexanes. Aluminum alkyls are also used to prepare molded products from poly(dicyclopentadiene) using reaction injection molding. In a process developed at Hercules, solutions of WCl_4 and $EtAlCl_2$ in dicyclopentadiene are injected into a mold and heated to form the polymer. Aluminum alkyls are also used to alkylate WCl_6 or $WOCl_4$ to form active alkene metathesis catalysts. The role of the aluminum alkyl is as an activator, presumably via alkylation, and the active catalyst is believed to be a tungsten alkylidene complex.

In all of the above processes, the organoaluminum compounds serve as cocatalysts that activate a transition metal for the desired organic transformations. There are several important processes that do not involve transition metals and in which the organoaluminum reagents acts as a catalyst or stoichiometric reagent. The two most important of these are the formation of fatty alcohols and terminal alkenes from ethylene.[7,116] These capitalize on the Aufbau reaction for formation of alkyl chains that can reach to C_{200}, but the commercially important alkyls are those from C_{14} to C_{20}. Oxidation of the aluminum alkyl followed by acidic hydrolysis yields predominately C_{14} to C_{20} alcohols and alumina (equation 36). The alcohols are converted to

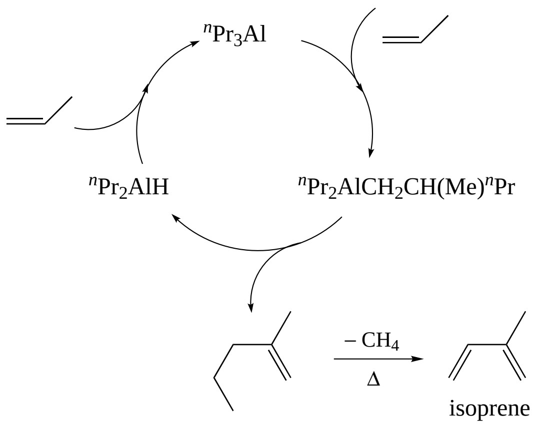
$$\{Et(CH_2CH_2)_n\}_3Al \xrightarrow[(ii)H_3O^+]{(i)O_2} 3Et(CH_2CH_2)_nOH + Al(OH)_3 \quad (36)$$

biodegradable sulfates for use in detergents and to esters for use as plasticizers. The alumina coproduct is of high quality and sold separately. In the absence of oxygen, these alkyls are heated to 280–320 °C to facilitate β-hydride elimination and formation of terminal alkenes (equation 37). This regenerates an aluminum hydride capable of further ethylene insertion, making this process catalytic. In the production of alcohols, the aluminum is a stoichiometric reagent.

$$\{Et(CH_2CH_2)_n\}_3Al \xrightarrow{280-320\,°C} 3CH_2{=}CH(CH_2CH_2)_nH \quad (37)$$

Only single insertions into an Al–C bond occur for propene and higher alkenes and this is utilized for catalytic dimerization of propene as illustrated in Scheme 3.[7,116] Insertion of propene into an Al–C bond of ^{n}Pr$_3$Al followed by β-hydride elimination yields an aluminum hydride and 2-methylpent-1-ene. Insertion of propene into the Al–H bond regenerates ^{n}Pr$_3$Al. Thermal cracking of 2-methylpent-1-ene gives isoprene, which is subsequently polymerized with a Ziegler–Natta catalyst to form the synthetic rubber, *cis*-1,4-polyisoprene.

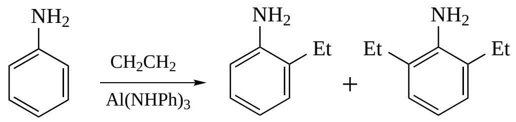
In the fine chemicals industry, (+)-citronellol for use in L-menthol synthesis has been prepared by hydroalumination



Scheme 3 Aluminum-catalyzed dimerization of propene

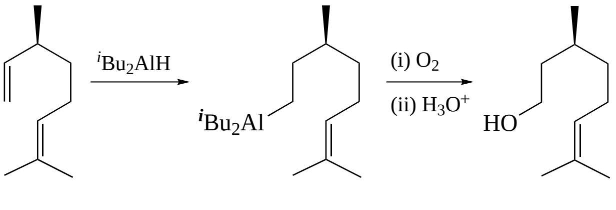
of L-citronellene followed by oxidation of the Al–C bond and hydrolysis (Scheme 4), similar to the procedure used for the preparation of fatty alcohols.[116] Note that the hydroalumination is selective for the less-substituted of the two olefinic bonds in the L-citronellene.

In another example in the fine chemicals industry, organoaluminum complexes direct the *ortho*-ethylation of anilines to form intermediates for the manufacture of the herbicides Lasso® and Dual®. In this synthesis, Et_3Al is reacted with aniline to form the active catalyst, $Al(NHPh)_3$, which subsequently reacts with ethylene to give either *ortho*-ethylaniline or 2,6-diethylaniline depending on reaction conditions (equation 38). One author has suggested that this may occur by aluminum migration from nitrogen to an ortho carbon of the arene, followed by ethylene insertion into the Al–C$_{arene}$ bond and liberation of the product upon reaction with aniline to regenerate the aluminum anilide.[116]



(38)

Another commercial application of organoaluminum compounds is as catalysts for the ring-opening polymerization of epoxides to form homopolymers of epichlorohydrin (ECH) and copolymers and terpolymers of ECH, ethylene oxide, propylene oxide, and allyl glycidyl ether.[6,117] The resulting



Scheme 4 Formation of (+)-citronellol from L-citronellene

polyether elastomers find use in automotive and industrial applications that require materials with low gas permeability, retention of flexibility at both low and high temperatures, and stability upon extended exposure to heat, hydrocarbons, and ozone. Catalysts are the so-called 'Vandenberg catalysts' prepared by partial hydrolysis of aluminum trialkyls, often with additional components such as acetylacetone. Annual production of polyether elastomers using aluminoxane-based Vandenberg catalysts was estimated at nearly 13 000 tons in 1991. Several research groups are developing organoaluminum catalysts for polymerization of epoxides, lactones, and lactides, as well as for copolymerization of carbon dioxide and epoxides.[118–122] These efforts have not yet resulted in commercial processes.

Organoaluminum compounds are also utilized as precursors for the preparation of aluminum-containing materials. Electronic-grade trimethylaluminum is sold in 99.9999% purity for the production of semiconductors (*see* ***Semiconductors***) and other electronic-grade metal alkyls. Aluminum trialkyls and a variety of organoaluminum alkoxides, halides, amides, azides, and β-diketonate derivatives continue to be studied as single-source precursors to thin films of Al_2O_3, AlN, AlGaAs, and AlGaSb by MOCVD, MOVPE and other pyrolysis methods.[123–126] High-purity films of aluminum can be deposited by thermal decomposition of aluminum alkyls, particularly those that possess a β-hydrogen.

9 SAFETY CONSIDERATIONS

The safe handling of organoaluminum compounds, particularly aluminum trialkyls, requires procedures to minimize the risk of exposure of the organoaluminum reagent to oxygen, water, halogenated solvents, excessive heat, and ignition sources.[7] Exposure to oxygen and water is minimized by handling organoaluminum compounds in dried glassware under an atmosphere of purified nitrogen or argon. This is accomplished using standard inert-atmosphere techniques on a dual-manifold Schlenk or vacuum line, or in an inert-atmosphere glove box. Liquid transfers between septum-capped reagent bottles and reaction vessels are made by double-tipped stainless steel cannula or syringes lubricated with hydrocarbon grease. Silicone greases must be avoided since they react with aluminum alkyls. Volatile compounds can be manipulated via vacuum line transfers. A glove box is essential for convenient weighing and storage of samples as well as for the preparation of samples for NMR and IR spectroscopy and X-ray crystallography. Reactions can be carried out in standard air-free glassware designed for use on Schlenk or vacuum lines, but care must be taken to avoid the use of water-cooled condensers and aqueous heating and cooling baths to avoid severe reactions in the event of glass breakage.

If a spill occurs, vermiculite or sand can be used to absorb the pyrophoric material and to slow the aerial oxidation by suffocation. Slow oxidation will continue to take place until the material is consumed. The absorbent should be disturbed periodically to expose fresh material to air. When all material appears to be oxidized, a mist of water can be used to hydrolyze any remaining organoaluminum compound. Solid waste can then be collected and disposed of in a suitable hazardous waste container.

Sand and vermiculite can also be used to suffocate a fire if the spill ignites. In the case of a fire, standard dry chemical (BC, sodium bicarbonate) extinguishers are used to suffocate the fire and suppress the burning process. Carbon dioxide extinguishers can also be used to suffocate and cool the fire. Obviously, water cannot be used.

Severe burns can occur if exposed skin comes into contact with an aluminum alkyl, either neat or in solution. The severity and depth of the burn will increase with increasing exposure time. In case of an accident, rinse the exposed skin with copious amounts of water to hydrolyze any remaining aluminum alkyl, to dilute the reagent, and to cool the skin. Rubber gloves, goggles, and a lab jacket are required when working with aluminum alkyls. A splash-protective face shield and a separate safety shield are also recommended.

Small quantities of organoaluminum distillation residues and waste solutions may be destroyed by slow addition of a 25% isopropanol solution in a hydrocarbon solvent. Safety procedures for handling large volumes of organoaluminum reagents can be obtained from commercial vendors.

Glossary

Amine complex: complex with amine ligands, other than ammonia
Ammine complex: complex with NH_3 (ammonia) as the only N-donor ligand, for example, *trans*-$PtCl_2(NH_3)_2$
Facultative ligand: multidentate ligands that are capable of arranging their donor atoms around a metal ion in a number of different ways
Homoleptic Complex: complex with only one type of ligand

Abbreviations

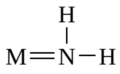
Abbreviations used are listed in *Nomenclature of Inorganic Compounds*:[1] other abbreviations will be described in the text.

1 INTRODUCTION

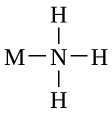
The nitrogen atom can adopt oxidation states (*see* ***Coordination & Organometallic Chemistry: Principles*** and *Oxidation Number*) from −III to +V (*see* ***Nitrogen: Inorganic Chemistry***). Consequently, there are many different types of N-donor ligands incorporating different oxidation states and different types of metal−nitrogen bonding (**1**)–(**14**) with a sometimes complicated nomenclature.[1]

Imino (nitrido) (**1**)

Imido (nitrene) (**2**)



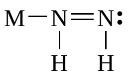
Amido (amino) (**3**)



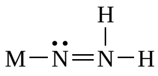
Ammine (**4**)

Dinitrogen (**5**)

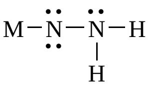
Diazenido (**6**)



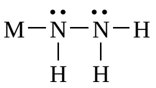
Diazene (**7**)



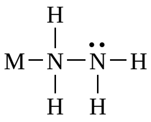
Isodiazene (**8**)



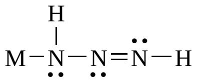
Hydrazido(2-)-N,N (**9**)



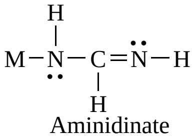
(**10**)



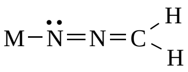
(**11**)



Triazene (**12**)



Aminidinate (**13**)



(**14**)

Nitrogen forms catenated[2,3] (*see Catenation*) ligands such as N_3^-, as well as mixed donor atom ligands such as NCS^-, NCO^-, CN^-, NO, NS, NO_2^-, NH_2OH[4–6] (*see* ***Mixed Donor Ligands***). We will restrict the present discussion to those ligands containing only N, C and, H atoms.

The equilibrium

$$R_3N\colon + H_3O^+ \rightleftharpoons R_3NH^+ + H_2O \qquad (1)$$

(protonation) constant (*see* ***Stability Constants & their Determination***) for the reversible protonation of an N-donor ligand (equation 1) is a measure of the basicity.[7] Multi-N-containing ligands have a series of such constants that can cover a considerable range (Table 1).

The interaction of an N-donor ligand with a metal ion also covers a wide range, from the very weak chelate or macrocycle-assisted association of an alkali metal cation to the very robust Co^{III} and Ru^{III} metal−nitrogen bonds. In aqueous solution, this interaction (equation 2) is essentially a substitution

$$M\text{–}OH_2^{n+} + \colon NR_3 \rightleftharpoons M\text{–}NR_3^{n+} + H_2O \qquad (2)$$

Table 1 Representative protonation constants for some N-donor ligands[7]

L	$-pK_n[H^+]$	$-pK_1[Ni(L)]^{10}$	$-pK_1$ $[Cu(L)]^{10}$
en	7.18, 9.98	7.35	10.5
dien(**159**)	4.47, 9.17, 9.96	10.7	15.9
trien(**178**)	3.6, 6.84, 9.22, 9.92	14.4	20.1
tetren(**207**)		17.4	22.8
penten(**223**)		19.1	–

reaction of a coordinated water molecule by the incoming N-ligand, and there may also be competing hydrolytic equilibria (equation 3). Such hydroxo

$$M\text{–}OH_2{}^{n+} \rightleftharpoons M(OH)^{(n-1)+} + H^+ \quad (3)$$

complexes can be much more substitution-inert, and may also result in metal ion hydroxide precipitation. The competition can be overcome to a certain extent by using nonaqueous solvents, for example, DMSO or DMF in Cr^{III} N-ligand synthesis.[8,9]

For labile systems with reasonably well defined coordination numbers, for example, first-row transition metal divalent cations, chelating and macrocyclic ligands have a greater stability than would be expected from an additive relationship, that is, from equations (4) and (5), $K_{ML} > K_{ML2}$. However, there is a simple relationship

$$M^{2+} + 2NH_2Me \rightleftharpoons M(NH_2Me)_2{}^{2+} \quad K_{ML2} \quad (4)$$

$$M^{2+} + en \rightleftharpoons M(en)^{2+} \quad K_{ML} \quad (5)$$

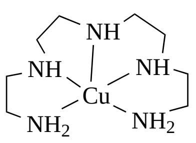
between the formation constants for $M(NH_3)_n{}^{2+}$ and $M(polyamine)^{2+}$ (polyamine = en, dien(**159**), trien(**178**), tetren(**207**), penten(**223**), i.e. the homologous series of linear polyamines increasing by $CH_2CH_2NH_2$,

$$\log K_1(\text{polyamine}) = 1.152 \log K_n(NH_3) + (n-1)\log 55.5 \quad (6)$$

equation 6). In this equation, n is the denticity (number of N atoms) of the polyamine, 1.152 is an inductive effect correction [$= pK_a(CH_3NH_2)/pK_a(NH_3)$], and $(n-1)\log 55.5$ is the entropy contribution.[10]

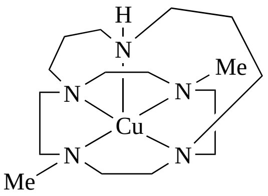
There are also systematic trends in stability constants when five-membered polyamine rings are replaced by six-membered rings, or when linear polyamine ligands are replaced by macrocyclic ligands of a similar strain (*see Chelate Effect*). These effects can be well accounted for in terms of enthalpy contributions to the formation constant.[11]

Both kinetic and thermodynamic classifications of metal–nitrogen complexes have been proposed. The former gives systems that are either coordinatively inert or labile (*see Coordinatively Inert & Labile Complexes*), with inert being defined as those that allow geometric isomers (*see Isomer, Types of*) or react (via M–N bond rupture) with half-lives (*see Radioactive Decay*) of longer than 1 min. The latter involves the hard-acid, soft-base concept[12] with the amine nitrogen being considered as a hard center (*see* ***Hard & Soft Acids and Bases***), as it binds strongly to protons, and is thus expected to bind strongly to 'hard' metal centers (good lone pair acceptors). In this classification, it is usual to compare the accessibility or stability of M–N complexes with those of analogous M–P donor ligands (a typical 'soft' donor). In both methods of classification, the boundaries are not sharp and the stability of a particular metal amine complex depends to a considerable extent on the nature of the ligand. For example, most open chain Cu^{2+} amine complexes such as $Cu(tetren)^{2+}$ (**15**) (**207**) are rapidly decomposed in acid solution, but when the Cu^{2+} is encapsulated in an N_5 polyamine cage such as L (**16**), the resulting complex is stable for days in 1 M $HClO_4$ at 50 °C[13] (*see* ***Macrocyclic Ligands***).



$[Cu(tetren)]^{2+}$

(**15**)



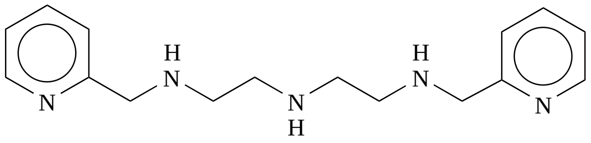
$[CuL]^{2+}$

(**16**)

Very often, amine complexes are designed to illustrate some subtle mechanistic (*see* ***Mechanisms of Reaction of Organometallic Complexes***) or stereochemical effect in coordination chemistry and much effort has been exercised in the design of specific amine ligands. For example, the reaction shown in equation (7) is very sensitive to steric effects, and the introduction of a pyridine ligand in place of an

$$CoCl(N_5)^{2+} + OH^- \longrightarrow Co(OH)(N_5)^{2+} + Cl^- \quad (7)$$

alkylamine results in a modest (45×) rate increase.[14] The incorporation of a 'flat secondary nitrogen donor' (see Section 5) in a coordinated polyamine chain results in a significant rate increase ($\sim 10^3\times$). The combination of both effects, requiring the synthesis of bispicdien (**17**), preparation of the Co^{III} complex, and characterization of the correct isomer,[15] has quite a remarkable acceleratory effect on reaction (7) (Table 2).



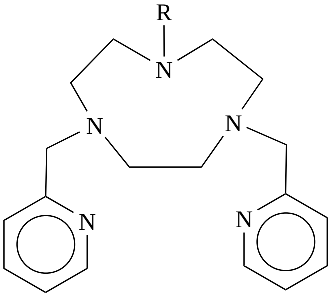
Bispicdien

(**17**)

Table 2 Structural effects on base hydrolysis rates (equation 7)[14–16]

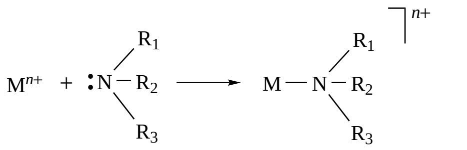
Complex	k_{OH}(25.0 °C)(M^{-1} s^{-1})
$CoCl(en)_2(MeNH_2)^{2+}$	7.3
$CoCl(en)_2(py)^{2+}$	332
cis-α-$CoCl(trien)(NH_3)^{2+}$ (**193**)	10.6
cis-β_2-$CoCl(trien)(NH_3)^{2+}$ (**195**)	4.8×10^4
$\alpha\beta$-$CoCl(bispicdien)^{2+}$ (see **218**)	2.0×10^7
t-CoCl(dmptacn)2+ (**18**)	4×10^{-2}
t-CoCl(dmpmetacn)2+ (**19**)	7×10^{-1}

An essential requirement in the SN_1CB mechanism for reaction (7) is the presence of an NH proton. There are now several polyamine ligands that have either one (**18**) or zero (**19**) such protons (see also Section 5.3). Despite having zero NH protons, $[CoCl(dmpmetacn)]^{2+}$ reacts with base at a rate proportional to the OH^- concentration and faster than $[CoCl(dmptacn)]^{2+}$ (Table 2). Proton exchange at the CH_2 position in the pyridyl arm trans to the leaving group was observed, and amido activation through the pyridine ring is believed to be responsible for the OH^- dependent rate law.[16]



(**18**) Dmptacn (R=H)
(**19**) Dmpmetacn (R=Me)

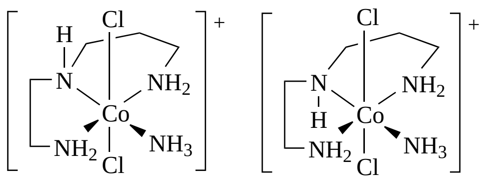
For aliphatic amines, coordination of the lone pair to a central metal ion completes the tetrahedral stereochemistry about the nitrogen atom (equation 8), and



(8)

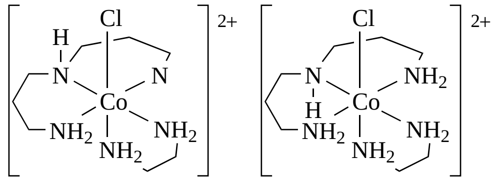
nitrogen bases with three different substituents now become potentially chiral. Inversion about the nitrogen center is generally rapid for labile complexes, but for inert complexes, both geometric and optical isomers can be isolated.[14,17,18]

Although such isomers have not been resolved for monodentate amines (suitable tertiary amines[19] are not easily coordinated to inert metal centers), the phenomenon is quite widespread with coordinated aliphatic polyamines (**20**), (**21**) and (**22**), (**23**).[20] It should be noted that current nomenclature systems[1] are not sufficient to distinguish between isomers (**22**) and (**23**) (see, however, Reference 21).



R–(**20**) S–(**21**)

Optical isomers of *trans*-$[CoCl_2(2,3\text{-tri})NH_3]^+$

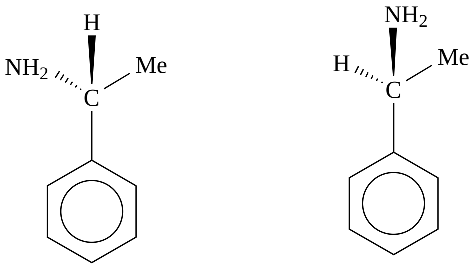


(**22**) (**23**)

Structural isomers of *mer*-$[CoCl(3,3\text{-tri})(en)]^{2+}$

The interchange of the stereochemically significant sec-NH proton in (**20**) $\rightleftharpoons$ (**21**) (inversion) or (**22**) $\rightleftharpoons$ (**23**) (isomerization) is a base-catalyzed process and takes place via a deprotonation–protonation mechanism. This interchange is one of the simplest types of 'reaction of a coordinated ligand', and proton exchange rates have been measured for quite a number of inert transition metal–amine complexes.[22] With suitable central metals (Pt^{IV})[23] or ligands,[24] the deprotonated intermediates can be isolated and characterized. Other reactions of coordinated amine ligands will be considered in Section 7.

Amines containing a *Chiral* carbon center in the aliphatic residue attached to the nitrogen atom, for example, α-methyl benzylamine (**24**), (**25**), are of considerable interest to the coordination chemist as, when coordinated, these ligands induce chirality in the metal–ligand chromophore. Methods for the resolution of more than 1000 racemic nitrogen containing organic compounds have been described.[25]



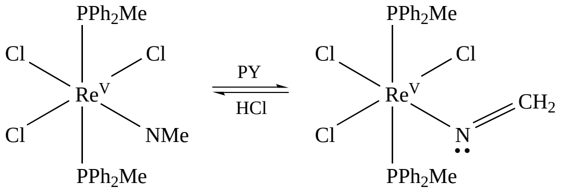
(R)–(+)–α–Methylbenzylamine (**24**) S–(–)–α–Methylbenzylamine (**25**)

Many of the simple mono- and polyamines are commercially available, but designer specific ligands[26,27] require the use of conventional organic synthetic techniques.[28,29] Methods of amine complex synthesis are usually central-metal specific, but summaries of procedures used for Cr^{III}[8,9] and Co^{III}[30] are available. In the case of the inert metal centers, geometrical isomers are frequently encountered. Fractional crystallization is still widely used for isomer separation procedures,[14] but column chromatography has the potential for separation of both optical and geometric isomers and the advantage that isomers or by-products at the 1% level can be detected and concentrated (see Section 5.2).[31–34]

Molecular Mechanics calculations can be used (1) in the analysis of disordered structures, (2) in the prediction of known structures, (3) in the prediction of isomer ratios, and (4) in the prediction of conformer ratios. The majority of studies have dealt with Co^{III} hexaamine systems,[35] but now[36,37] force fields are available for amine complexes of Co^{II}, Ni^{II},[38] Cu^{II}, Zn^{II}, Cr^{III}, Fe^{III}, and Rh^{III}.

2 LIGANDS CONTAINING ONLY ONE N-ATOM

The deprotonation of ammonia leads successively from NH_3 (Section 2.1) through NH_2^- and NH^{2-} to N^{3-}, and these anions can act as ligands.[39,40] In addition to the binding modes shown in (**1**) to (**3**), bridging and bent structures (**26**–**31**) are possible. Indeed, the amido-bridged complex, $[(NH_3)_5CoNH_2Co(NH_3)_5]^{5+}$ was isolated and characterized by Werner (*see Werner Complexes*). In many cases, the NH protons can be replaced by alkyl or more bulky $Si(Me)_3$ groups and these N donors stabilize unusually low-coordination numbers, for example, $Cr^{III}(NPr^i_2)_3$ or $Fe^{II}\{N(SiMe_3)_2\}_3$. Such alkyl systems are often more stable than their 'proton only' analogs, and bent $MNCH_3$ (**28**) species can undergo further reversible deprotonation to give methyleneamido (**31**) ligands (equation 9). These methyleneamido ($-N{=}CH_2$) or substituted ($-N{=}CR_2$) ligands can also



(9)

adopt linear (**32**) and bridged modes (**33**).[41] In (**33**), there is a striking analogy with alkenes.

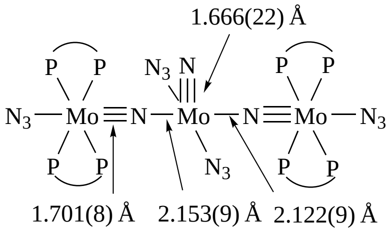
M−N−M′

(**34**)

Complete deprotonation gives the exceptionally strong π-donor N^{3-} anion (*see π-Bond*). Complexes such as $Os^{VII}Br_4N$ or $[Os^{VIII}O_3N]^-$ have Os≡N bonds in the 1.6–1.8 Å range, and the N^{3-} ligand has a strong *Trans Influence*. The available *Lone Pair* (**1**), allows such complexes to act as ligands forming bridged nitrido species (**34**). Rearrangement of the bonds leads to triangular planar N-centered systems (**29**), such as $[Ir^{III}_3N(SO_4)_6(H_2O)_3]^{6-}$ and tetrahedral M_4N^+ (**30**) arrangements, such as $[(Ph_3PAu^I)_4N]^+$ (analogous to quaternary ammonium salts). The nitrido ligand is much more prominent in second and third-row transition metal chemistry than in the first-row elements, for example, (**35**).



(**35**)

2.1 Ammonia and Ammines[42]

Metal ion complexes with ammonia are called ammines. At room temperature, ammonia is a gas, but liquid ammonia (b.p. −33 °C) is relatively easy to handle[43] and is an excellent solvent and reagent (equation 10)[44]

$$\textit{trans}\text{-}CrCl_2(2,3,2\text{-tet})^+ + NH_3(l) \longrightarrow \textit{trans}\text{-}CrCl(NH_3)(2,3,2\text{-tet})^{2+} + \textit{trans}\text{-}Cr(NH_3)_2(2,3,2\text{-tet})^{3+} \quad (10)$$

somewhat analogous to water.[45]

$NH_3(g)$ is extremely soluble and the aqueous solution is best described as $NH_3(aq)$ with the equilibrium (pK_b[25] = 4.75) written as equation (11). Thus, $NH_3(aq)$ (1 M) is an

important laboratory source of NH_3, NH_4^+, or OH^-.

$$NH_3(aq) + H_2O \rightleftharpoons NH_4^+ + OH^- \quad (11)$$

Almost all cations show some sort of interaction with the NH_3 molecule.[46] For $M(NR_3)_x{}^{n+}$ systems, the maximum x is often achieved with ammonia.

The ammine chemistry of group 2,[47] group 3,[48] Co^{III},[30,42] Cr^{III},[8,9,49] $Ru^{III/II}$,[47–51] and Os^{II},[49] has been reviewed. Synthetic procedures for many ammine complexes are given by Schlessinger.[52] Table 3 lists some (sometimes exotic) salts of representative ammine complexes, together with the average metal–NH_3 bond distance and an estimate[53] of the average M–NH_3 bond energy.

Transition metal–ammine cations have been used in the isolation of unusual anions.

Co^{III} and Cr^{III} ammines were among the first to be investigated by Reinecke, Jørgensen, Werner (Nobel prize, 1912), and Pfeiffer in the early days of coordination chemistry (*see* ***Coordination Chemistry: History***), and this work continues today (Taube, Nobel Prize, 1984). $[MX(NH_3)_5]^{n+}$ (X = anionic or neutral group) is particularly well-studied[14] and has even been used as a protecting group in peptide synthesis. Variation of M has a considerable influence on the rate of the *Solvolysis* of X (Table 4).

Two possible isomers [*trans*-(**36**), *cis*-(**37**)] for $[MX_2(NH_3)_4]^{n+}$ (M = *inert* transition metal) are usually separable, although in a number of cases only one isomeric form is known and the isolation of the other isomer is still a challenge to the synthetic chemist.

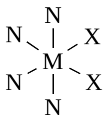
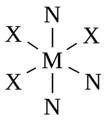
trans-(**36**)

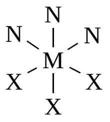


cis-(**37**)

For the triammines, there are two potential isomers [*mer*-(**38**) and *fac*-(**39**)] (these are now to be called OC-6-12 and OC-6-22 respectively, although the ranking order may change with X[1]). $[Co(NO_2)_3(NH_3)_3]$[52] should be a nonelectrolyte using Werner's octahedral coordination ideas, but should be an electrolyte according to Jørgensen's chain theory. Both schools succeeded in preparing compounds with the above stoichiometry with the Werner sample being a conductor and the Jørgensen sample a nonelectrolyte! The situation was finally resolved when it was shown that the Werner sample was heavily contaminated with $[Co(NO_2)_2(NH_3)_4{}^+][Co(NO_2)_4(NH_3)_2{}^-]$[52] and hence was conducting. Even today, it is sometimes difficult to establish the configuration of, say, $[Co(N_3)_3(py)_3]$, without resource to X-ray crystallography.



mer-(**38**)



fac-(**39**)

Despite intensive work, few metals give a complete monotonic series $[MX_{6-x}(NH_3)_x]^{(x-3)+}$, $x = 0, 1 \ldots 6$ (X = *Monodentate Ligand*). The missing member is usually the $x = 1$ compound, with the most extensive examples being $M = Cr^{III}$, $X = NCS^-$ ($x \neq 1$) or H_2O[8]; $M = Co^{III}$, $X = NO_2{}^-$ ($x \neq 1$).

Some ammine complexes are metal ion specific, for example, the dinuclear Co^{III} μ-peroxo and μ-superoxo (*see*

Table 3 Typical ammine complexes[52]

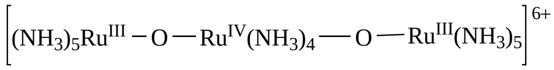
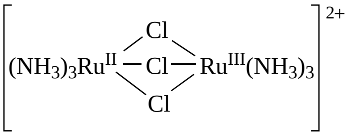
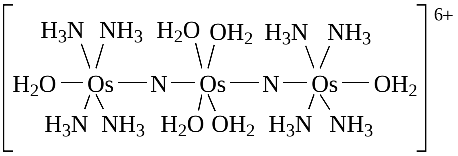
The heavier transition metal elements also form multinuclear ammine complexes, many with mixed oxidation states, for example, $[Ru_3O_2(NH_3)_{14}]^{6+}$ ('ruthenium red') (**48**), $[Ru_2(\mu Cl)_3(NH_3)_6]^{2+}$ (**49**), $[Os_3(\mu N)_2(NH_3)_8(H_2O)_6]^{6+}$ (**50**), $[Ru_2(\mu N)Cl_2(NH_3)_8]^{3+}$ (**51**), and $[Pt_2(NH_3)_8Cl_2]$ $(HSO_4)_4$ (**52**).



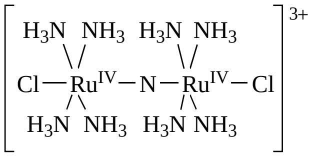
(**48**)



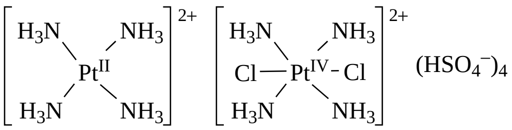
(**49**)



(**50**)



(**51**)



(**52**)

Finally, there are square-planar Pt^{II} antitumor ammine complexes (*see* ***Platinum-based Anticancer Drugs***) with the most well known being *cis*-dichlorodiammineplatinum(II) (*cis*-DDP) *cis*-$PtCl_2(NH_3)_2$. When dissolved in aqueous solution, the chloro ligands can be partially or completely substituted by either H_2O or OH^-, and the pH-dependent kinetics and equilibria have been measured.[55–61]

2.2 Monoamines

Like ammonia, the simple aliphatic monoamines are gases at room temperature, but as the length of the

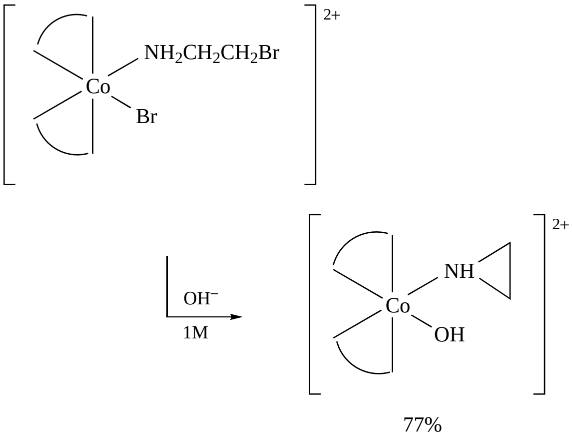
hydrocarbon chain increases, the room temperature form is a more or less malodorous, fuming liquid or waxy solid (Table 5). The neat amines strongly absorb CO_2 from the atmosphere and should be kept in well-protected screw-cap bottles.

The replacement of the six NH_3 ligands about the octahedral metal center by six alkylamine groups apparently causes considerable nonbonded interaction, but $[Co(NH_2CH_3)_6]^{3+}$, $[Ru^{II}(NH_2R)_6]^{2+}$, and $[Co(NH_2OH)_6]^{3+}$ are known.[35]

More common are the $[M^{III}X(NH_2R)_5]^{2+}$ systems (M = Co, Cr, Rh),[42] and such complexes have played a significant role in assessing the importance of steric effects on the rates of substitution reactions (*see Steric Effect*). Another extensive series of Co^{III} complexes are those of the *cis*-$[CoX(en)_2(NH_2R)]^{2+}$ type[14] but only those with R = H are known for Cr^{III}. Even in the Co^{III} series, examples of coordinated monoamines with substituents on the α-carbon atom, for example, *s*-$BuNH_2$ or $PhCH(CH_3)NH_2$, are known, but are rare, and secondary or tertiary amines are even more difficult to coordinate. Aziridine, however, seems to coordinate[62] much more freely than other secondary monoamine ligands and can be synthesized in situ according to equation (12). The larger cyclic *sec*-NH monoamines, for example, (**55**) also coordinate quite well in a series of $[CoCl(en)_2(NH(CH_2)_x)]^{2+}$ complexes.[14]

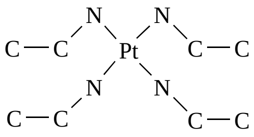


(12)

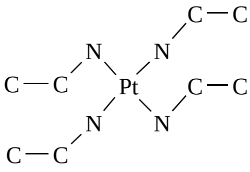
The above restrictions are not nearly so marked for square-planar Pt(II) or Pd(II) systems, and even the most sterically hindered N-donor ligands have a good chance for coordination.

Once the alkylamine is coordinated, the 'arms' can adopt a variety of conformations that appear to be controlled by packing arrangements. Thus, the two modes observed for $[Pt(NH_2Et)_4]^{2+}$ are (**53**) and (**54**).

For aniline (**56**),[63] there are steric differences that can lead to an enhanced reactivity for leaving groups in inert



(**53**)



(**54**)

systems (equation 7). For pyridine (**57**), complexes[64] such as t-$[RhCl_2(py)_4]^+$ probably represent the maximum number of py ligands that can bind to an inert central metal. Similar stereochemical restrictions probably apply to the four-coordinate Cu^{II} complexes of N-Me-imidazole[65] (see **78**) and 1,2,4-triazoles,[66] but six-coordinate $[M^{II}(LH)_6]^{2+}$ (LH = pyrazole, **77**) are known for all first-row divalent transition metal ions.[67] While the N-bonded chemistry of pyrrole (**58**)[68] is only poorly developed, that of piperidine (**55**) is quite well established.[69]

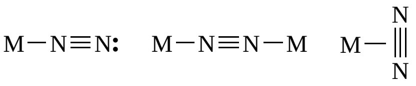
(**58**) Pyrrole

3 LIGANDS CONTAINING TWO N ATOMS

The dinitrogen complex $[Ru^{II}(N_2)(NH_3)_5]^{2+}$ (**60**), described in 1965 by Allen and Senoff, led to much subsequent research related to nitrogen fixation.[70–75] The reduction of coordinated N_2 in simple systems is shown in Figure 1, but the hydrazido(-2) (**9**) system is the only coordinated intermediate characterized in the conversion of N_2 to NH_3. The coordinated dinitrogen (**60**) may also act as a bridging ligand (**59**), (**61**), and (**62**) N_2 forms reasonably stable and well characterized complexes[74,75] with $Ru^{I/II}$, Os^{II}, Mo^0, W^0, Mn^0, $Co^{0/I}$, Ta^0, Ti^0, Ni^0, Zr^0, and Ir^I.

$$[(NH_3)_5Ru-N\equiv N-Ru(NH_3)_5]^{4+}$$

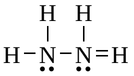
(**59**)



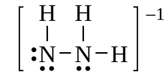
(**60**) (**61**) (**62**)

Complete protonation of dinitrogen results in hydrazine,[76] which can bind through either one (**11**) or both (bridging) N atoms, but high oxidation state metals are readily reduced.[77]

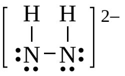
The nomenclature for substituted hydrazines is very confusing (**63**–**67**).[78] Three types of ligands are available with a formal double bond between the two N atoms (1) diazenido (**6**), obtained from diazonium compounds (ArN_2^+), (2) 1,2-diazines (**7**) (azo compounds, Ar–N=N–Ar), and (3) 1,1-diazines (**8**).



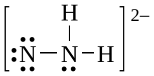
(**63**) Hydrazine



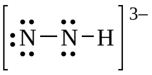
(**64**) Hydrazido(-l) (diazanido)



(**65**) Hydrazido(2-)-N,N′) (diazane-1,2-diido)



(**66**) Hydrazido(2-)-N,N (diazane-1,1-diido)



(**67**) Hydrazido(3-) (diazanetriido)

The diazenido ligand can be regarded as RN_2^+, RN_2^-, or RN_2 and when coordinated, there is a considerable range in the observed N=N stretch (2100–1440 cm^{-1}). Obviously, there is a close analogy between NO and RN_2 as ligands.[4,78] Diazines can be formed from diazenido complexes by electrophilic

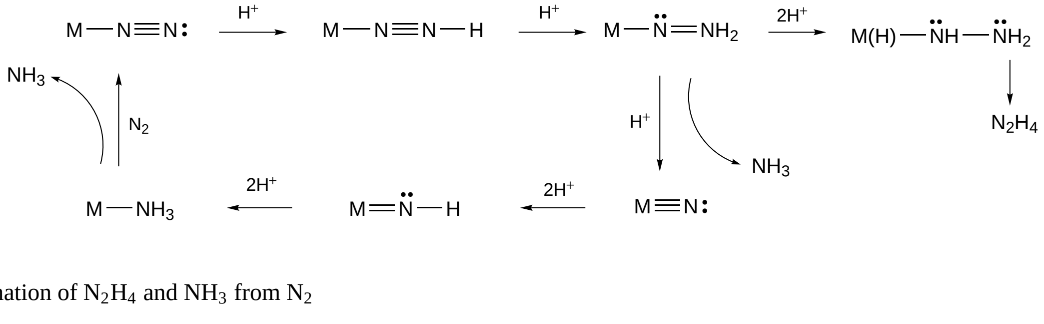


Figure 1 Formation of N_2H_4 and NH_3 from N_2

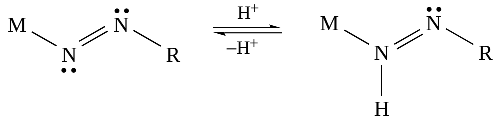
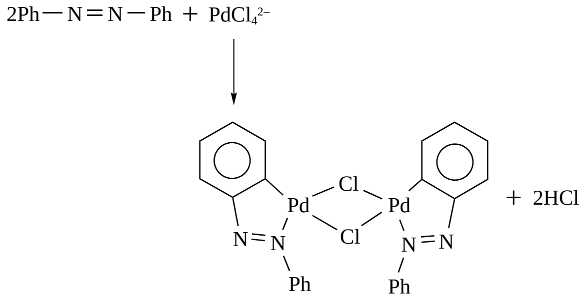
attacks (especially H^+) (equation 13).



(13)

Diazenido 1,2-Diazene

An important reaction of aryl azo ligands is *Cyclometallation* by activation of the ortho C–H proton and subsequent C–M coordination[79] (equation 14).



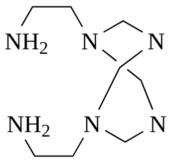
(14)

Finally, diazoalkanes $R_2C{=}N{=}N{:}$(**14**), such as diazomethane, can bind to metals but, more importantly, are a useful route to ***Carbene Complexes*** by the extrusion of N_2 (equation 15).[80]

$$OsCl(NO)(PPh_3)_3 + CH_2N_2 \longrightarrow H_2C{=}OsCl(NO)(PPh_3)_2 + PPh_3 + N_2 \quad (15)$$

3.1 Diamine Ligands

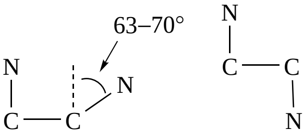
The coordination chemistry of the simplest of these, methanediamine, $NH_2CH_2NH_2$ (a fully hydrogenated form of the aminidinato (**13**) ligand), is very poorly investigated. Of more recent interest are poly(methylene) amines, for example, (**68**) formed by reaction of formaldehyde and amines in the presence of a metal ion.[81] The stability of such ligands in the absence of metal ions has yet to be established.



(**68**)

3.1.1 1,2-Diaminoethane and related ligands

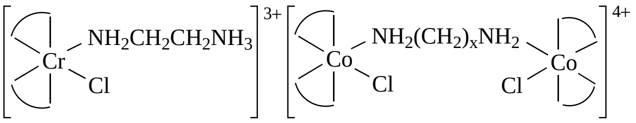
The parent ligand has played an important part in the history of coordination chemistry, as the stereochemical arrangement of bidentate bis or tris (en) complexes lead to the concept of optical activity in octahedral coordination. Ethylenediamine is commercially available either as the anhydrous (bp 118°) or monohydrate liquid forms; the vapor can cause asthma on repetitious exposure. It can adopt either the cis (*gauche*) (**69**) or trans (**70**) conformations with an energy difference of about $4\,kJ\,mol^{-1}$. Consequently, the conformation adopted in the solid state can be temperature and anion dependent.



(**69**) cis (*gauche*) (**70**) trans

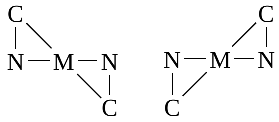
The $[enH_2^{2+}]$ cation in the $[(R,R)$-(+)-tartrate(-2)] salt adopts the trans conformation, while in the $[(R,R)$-(+)-tartrate(-1)$]_2$ salt, the *gauche* form is observed. Similarly, in $[enH_2^{2+}][Hg_2Cl_6^{2-}]$ the conformation is trans, while in $[enH_2^{2+}]_2[HgCl_4^{2-}][Cl^-]_2$ the conformation is *gauche* [69.2° in (**69**)].[82]

There are also an increasing number of examples where en (or a longer chain polyamine) is monodentate[83] or bridging[84] (**71**–**72**). Polyamine ligands, in complexes with uncoordinated NH- or NH_2-sites[85] (**71**), have been called hypodentate.[86] Such systems have the potential to produce highly charged inert cations, for example, $[Co(NH_3)_5(trenH_3)]^{6+}$.



(**71**) (**72**)

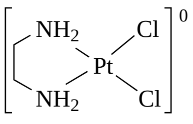
The N–CH_2–CH_2–N group forms a five-membered puckered ring with a twofold axis of symmetry as shown in (**73**) and (**74**). When undistorted, the C–C bond makes a dihedral angle of ±48.8° with respect to the N–M–N plane. The two enantiomeric conformations are labelled δ (**73**) (left-handed helicity) and λ(**74**) (right handed helicity)[87] with an inversion energy barrier of about $20\,kJ\,mol^{-1}$ that increases with N-alkylation.



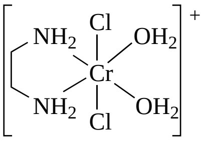
(**73**) δ (**74**) λ

Although quite a few chelated mono(ethylenediamine) complexes are known for inert transition metal centers, for

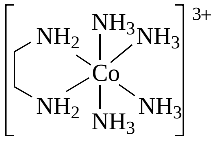
example, (**75**–**77**), it is not possible to separate the δ,λ conformational isomers as these exist in equal amounts in the solid state (see also the discussion with respect to structure (**220**)). Introduction of a second chelating ethylenediamine into the coordination sphere gives rise to two geometric isomers, *trans*-(**78**) and *cis*-(**79**), (see also (**36**) and (**37**)). The diamine rings in (**78**) and (**79**) can be either λ,λ; δ,δ or, λ,δ; in (**78**), the λ,λ and δ,δ conformations are enantiomeric and energetically equivalent, and are estimated to be about $4\,\mathrm{kJ\,mol^{-1}}$ more stable than the trans δ,λ form. In the solid state, however, the majority of the square-planar $[M(en)_2]^{2+}$ (M = Ni, Cu) and *trans*-$[CoX_2(en)_2]^{+}$ complexes adopt the δ,λ conformation.[42] *cis*-Bis(bidentate chelate) complexes like (**79**) lack a plane of symmetry and thus have the potential to be separated into enantiomeric Λ(**80**), Δ(**81**) forms. The separation of $\Delta\Lambda$-*cis*-$[CoBr(en)_2(NH_3)]^{2+}$ into the Δ and Λ forms[88] using the method of racemic modification (Werner, 1911) was perhaps one of the most significant achievements in the development of modern coordination chemistry. Approximately 10% of racemic systems like (**80**), (**81**) form conglomerates[89] on crystallization (spontaneous resolution), and such systems are under active investigation.[90]



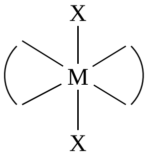
(**75**)



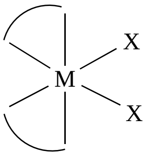
(**76**)



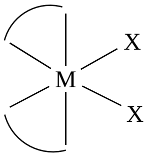
(**77**)



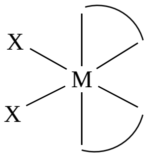
(**78**) trans



(**79**) cis

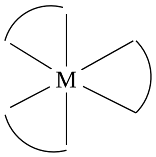


(**80**) Λ-cis

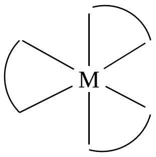


(**81**) Δ-cis

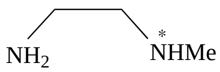
The X ligands in (**80**), (**81**) can be replaced by another chelate ring to give, for example, $[M(en)_3]^{3+}$. Now, four conformers can be constructed for each absolute configuration Λ(**82**), or Δ(**83**) *viz*, $\lambda\lambda\lambda$, $\lambda\lambda\delta$, $\lambda\delta\delta$, and $\delta\delta\delta$ with $\Delta(\lambda\lambda\lambda)$ energetically equivalent to $\Lambda(\delta\delta\delta)$. This classification is useful when separate enantiomers are available, but with the racemate, a chirality invariant nomenclature can be used. Here, the two possible chelate ring conformations are named *lel* or *ob* when the central C–C bond of the diamine ring is (approximately) paral*lel* or *ob*lique with respect to the C_3 symmetry axis of the $[M(en)_3]^{n+}$ complex.[35,87] The four conformers are symbolized as lel_3, lel_2ob, $lelob_2$, and ob_3, with lel_3 being equivalent to $\Delta(\lambda\lambda\lambda)$ or $\Lambda(\delta\delta\delta)$. In the solid state, the actual ring conformations adopted in $[M(en)_3]^{n+}$ complexes depend on the anion and are apparently related to the degree of hydrogen bonding.[35,42]



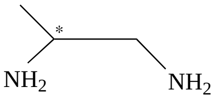
(**82**) Λ-$M(en)_3{}^{n+}$



(**83**) Δ-$M(en)_3{}^{n+}$

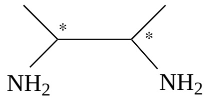


(**84**) (*R* or *S* at * when coordinated)

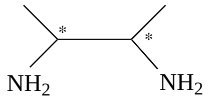


(**85**) (*R* or *S* at *)

Many N and C-substituted ethylenediamine ligands are available.[35,42] A single substituent on the N-atom will give an unsymmetrical prochiral ligand (**84**), and on the C atom the unsymmetrical ligand is racemic (**85**). Symmetrical substitution on both C atoms will give meso (**86**) and racemic ligands (**87**).



(**86**) *meso* (*R*, *S* at *)

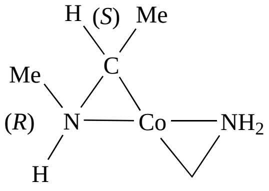


(**87**) racemic (*R,R* or *S,S* at *)

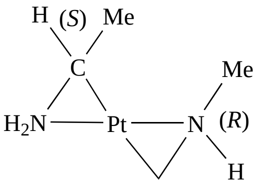
Resolution of such racemic amine ligands is frequently achieved by crystallization of the (*R*,*R*)-tartrate salt,[25] but the assignment of the absolute configuration to the resolved diamine is much more difficult especially as the sign of rotation at the Na_D lines may be pH dependent. An X-ray study[91] of racemic 1,2-diphenylethylenediamine (*RR,SS*-stien) shows the less soluble $(?)_{589}$-$[(?)_{589}$-$\mathrm{stienH_2}^{2+}][(+)_{589}(RR)\mathrm{tart}^{2-}]$ salt crystallizing from 96% ethanol to have the (*SS*)-stien absolute configuration. ORD measurements show that this salt gives $(-)_{589}$-(*SS*)-stien.

Considerable isomeric complexity results when ligands with both C and N substituents are used, for example, (**88**), (**89**).[42]

The fully N-alkylated ethylenediamine ligand, for example, 1,1,4,4-Me_4en, is not always carefully distinguished from the



(**88**)



(**89**)

fully C-alkylated isomer 2,2,3,3-Me_4en[35] in the coordination chemistry literature.

If the two amine groups are located in the 1,2- (or 1,3-)[92] positions of a cycloaliphatic ring, there is potential for both geometric and optical isomers. The most widely studied of such ligands is cyclohexane-1,2-diamine (chxn).[35] The commercially available free base is available as a (not always equal) mixture of the cis-(R,S)- and trans-(RR,SS)-isomers, conveniently separated via the Ni^{II} complexes with yellow, diamagnetic [Ni(*cis*-R,S-chxn)$_2$]Cl_2 being insoluble in MeOH. After pH adjustment, and addition of water, the mother liquor deposits crystals of blue, paramagnetic *trans*-[Ni(*trans*-(RR,SS)-chxn)$_2$(H_2O)$_2$]Cl_2. The amines can be recovered (as hydrochloride salts) from the Ni^{II} complexes by decomposition with HCl, and the *trans*-(RR,SS)-chxn can be resolved into the $(-)_{589}$-(R,R) enantiomer with $(+)_{589}$-(R,R)-tartaric acid.[93,94]

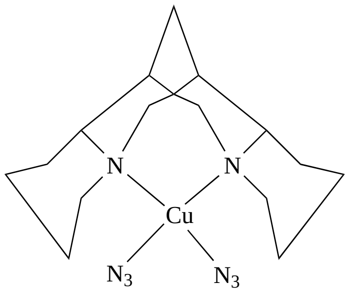
3.1.2 1,3-Diaminopropane and Related α,ω-Aliphatic Diamine Ligands

Coordination of 1,3-diaminopropane (tn) in the chelating mode results in a six-membered ring, and chair (c), boat (b), or twist (t) conformations. Simple tn complexes prefer chair or twist conformations in the solid state and there are a variety of chair orientations possible in $[M(tn)_3]^{n+}$ systems.[35,42] For labile central atoms (Cu^{2+}, Ni^{2+}, Cd^{2+}), the stability constants for metal–ligand binding are always tn < en due to a more negative enthalpy.[10] Extrapolation of these trends to inert systems might suggest that tn complexes would be less stable than the en analogs. In these cases, however, we are now discussing kinetic stability, and for Cr^{III} at least, the tn complexes are more robust than the en systems.[8,9]

In $[CoCl(N_5)]^{2+}$ systems, the replacement of en by tn almost always results in increased labilization of the coordinated chloro ligand. This effect has been attributed to greater ease of distortion for the tn complex.[14]

Among the more esoteric six-membered ring diamines is α-isospartine (**90**), and a Cu^{II} complex has been characterized.[95]

Increasing the ring size even further to α,ω-aliphatic diamines results in an increased propensity for polymerization or hydroxo formation rather than chelation. Seven membered diamine rings are found in $[Cu(bn)_2]^{2+}$ and $[Co(bn)_3]^{3+}$ (bn = 1,4-butanediamine) and with inert metal centers, complexes with several ring sizes, for example, $[Co(en)(tn)(bn)]^{3+}$ can be prepared.[42] We will see later (Section 6) how larger chelate

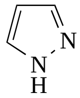


(**90**)

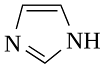
rings can be incorporated into the skeleton of polyamine ligands.

3.1.3 Heterocyclic Ligands with Two N Atoms.[96–103]

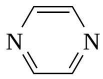
This section covers the vast field of the coordination chemistry of pyrazole (**91**), imidazole (**92**), pyrazine (**93**), pyrimidine (**94**), pyridazine (**95**), 2,2′-bipyridine (**96**), *o*-phenanthroline (**97**), piperazine (**98**), and dabco (**99**) as ligands.



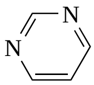
(**91**) Pyrazole



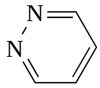
(**92**) Imidazole



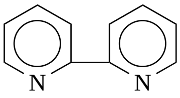
(**93**) Pyrazine



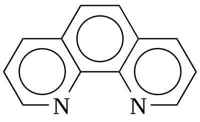
(**94**) Pyrimidine



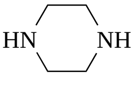
(**95**) Pyridazine



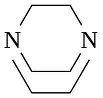
(**96**) 2,2′-bipyridine



(**97**) 1,10-phenanthroline



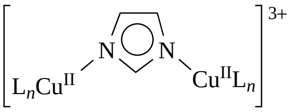
(**98**) Piperazine



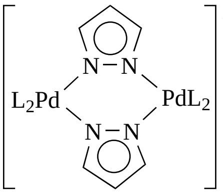
(**99**) Dabco

Many of these can only act as monodentate or bridging ligands (**91**)–(**95**),[100] (**98**), (**99**): in the bridging mode, M···M interactions can be mediated by the bridge. Such interactions are measured by magnetic coupling or electron transfer (*see* ***Electron Transfer in Coordination Compounds***), and the

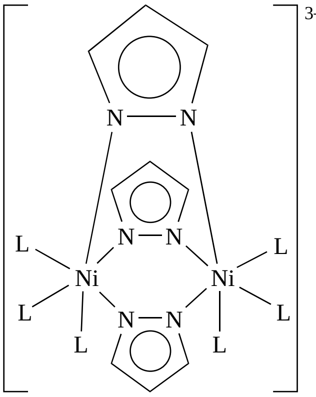
M···M distance can be closely controlled. Note, however, that pyrazole (**91**) and imidazole (**92**) can only bridge after deprotonation (**100**–**102**), and in highly substituted ligands, coordination usually takes place at the least sterically hindered nitrogen atom.



(**100**)



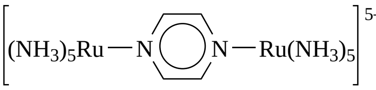
(**101**)



(**102**)

In the six-membered diazine systems, (**93**–**95**), the most widely investigated ligand is pyrazine (**93**)[96,97] in the 'model' pyrazine bridged mixed valence compound (**103**) (*see* ***Mixed Valence Compounds*** and *Creutz–Taube Complex*). The coordination chemistry of the aliphatic analog, piperazine (**98**), is not well developed.

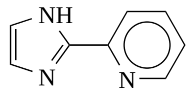
The chelating ligands, 2,2′-bipyridine (bipyridyl) (**96**)[98–100] and *o*-phenanthroline (**97**), have distinctive metal complexes. When compared to say 1,2-diaminoethane, bipy is less basic, more rigid, and larger; when coordinated, the ligand orbitals can participate in an extensive π-overlap with the metal orbitals. Consequently, not only do bipy and related ligands bind to metals that form strong complexes with en, but these ligand systems also form complexes with metal centers such as Fe^{II}/Fe^{III} that have only a poorly developed aliphatic polyamine chemistry.



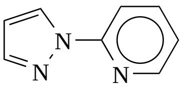
(**103**)

Of significant interest are the $Ru(bipy)_3{}^{n+}$[101] and $Cr(bipy)_3{}^{n+}$[102] complexes. The former, along with derivatives, can be used as sensitizers in photolytic systems such as the photolysis of water, and the Ru^{II}/Ru^{III} couple can be tuned by varying the nature of the bipy ligand. The $Cr(bipy)_3{}^{3+}$ cation is one of the 'standard' substances for probing excited state photochemistry (*see* ***Photochemistry of Transition Metal Complexes***).[102]

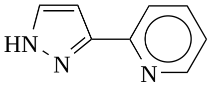
Other diimine ligands[103] are shown in (**104**–**106**) with systems containing one pyridine and one other heterocyclic mono-aza ligand, and the C atoms of the py ring can be replaced by one or more N atoms to give, for example, (**107**). Other coupled sets are: pyrazole plus pyrazole (**108**), pyrazole plus imidazole (**109**), and imidazole plus imidazole (**110**) together with coupled pyrazines (**111**), pyrimidines (**112**), (**113**), and pyridazines (**114**).



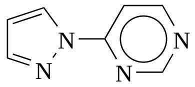
(**104**)



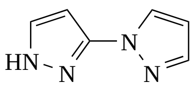
(**105**)



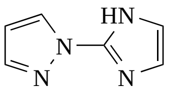
(**106**)



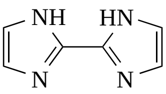
(**107**)



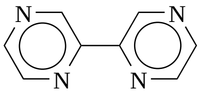
(**108**)



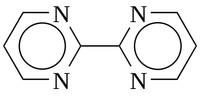
(**109**)



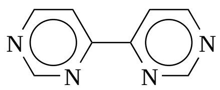
(**110**)



(**111**)

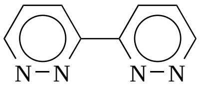


(**112**)



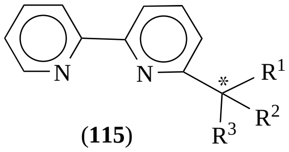
(**113**)

The combinations are limited only by imagination and the coordination chemistry of many of these systems is yet to

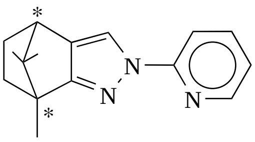


(**114**)

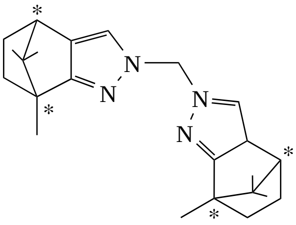
be fully developed.[98] Ligands of this type have potential in homogeneous asymmetric catalysts: (**115**–**117**) illustrate the approach.[104] Structure (**117**) shows that the chelate ring size can be expanded with no marked loss of chelating ability and all the ligands shown in (**104**–**114**) have the potential for this development.



(**115**)



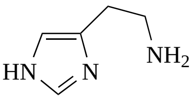
(**116**)



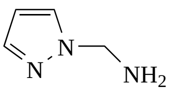
(**117**)

3.1.4 *Miscellaneous Diamine Ligands*

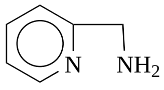
In this section, we include ligands that are heterocyclic based, but with an aliphatic 'arm', such as (**118**–**121**). The last two ligands are commercially available and may be useful in enabling a pyridine group to coordinate as part of a chelate system, when the unchelated pyridine ligand fails to bind.



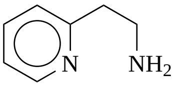
(**118**)



(**119**)

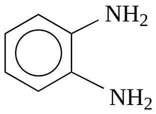


(**120**)

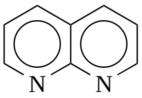


(**121**)

Also included here is 1,2-diaminobenzene (**122**) (*o*-phenylenediamine), kept separate because of its tendency for internal redox reactions (equation 19)[42] and the bidentate



(**122**)

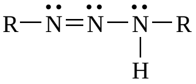


(**123**)

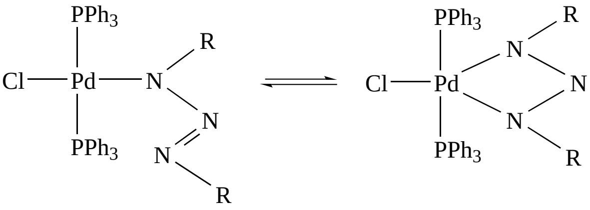
pyridine-type ligand (**123**)[96,97] that forms a very small bite angle.

4 CATENATED N ATOMS[2,3,105]

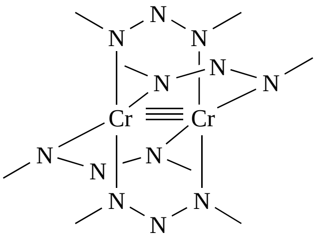
Although the parent triazine (**12**) is very unstable, aryl triazines (**124**) are commercially available, and deprotonation gives anionic ligands that can bind in monodentate (**125**), chelating (**126**), or bridging (**127**) modes. The Ni^{II} complex analogous to (**127**) has an Ni–Ni distance of 2.359 (Å) and the Cu^{II} complex a Cu–Cu distance of 2.441(Å). The Cu^{I} systems, however, form a reversible 2(dimer) (**128**) ⇌ tetramer (**129**) equilibrium. In the chelating mode (**126**), the triazine ligand forms a four-membered ring with a bite angle of 56–65° (65° in $[Co(PhN_3Ph)_3]$).



(**124**) R = Ph



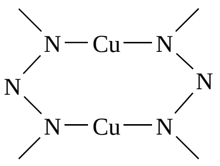
(**125**) R = p-tol (**126**) R = p-tol



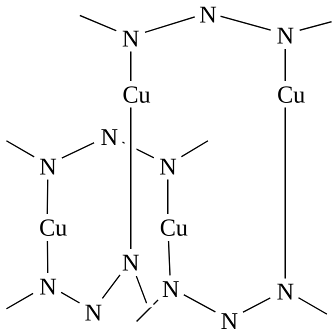
Cr≡Cr = 1.85 Å

(**127**) $Cr_2(PhN_3Ph)_4$

The central N atom in the triazine system can be replaced by the CH group to give imidines (**13**),[41,105] and complexes with structures similar to (**125**–**127**) are known,



Cu....Cu = 2.451 Å
(**128**) R = Ph



Cu....Cu = 2.66 Å
(**129**) R = Me

for example, $[Mo_2(PhNC(Ph)NPh)_4]$. However, no complexes containing fully saturated triazanes (**130**) or tetraazanes (**131**) appear to have been described. On the other hand, both tetrazines (**132**) and tetrazadienes (**133**) form stable metal complexes,[2,105] despite the fact that the parent tetrazadienes do not exist in the free state.

$R_2N—N(R)—NR_2$

(**130**)

$H_2N—NH—NH—NH_2$

(**131**)

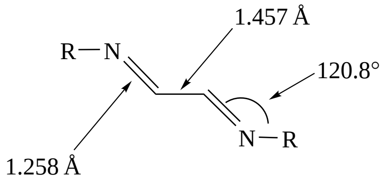
$R_2N—N{=}N—NR_2$

(**132**) R = Et

R—N=N—N=N—R

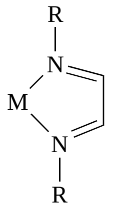
(**133**)

The N atoms in (**133**) can be replaced by C atoms to give 1,4-diaza-1,3-butadiene systems (**134**)[105] that have a close skeletal relationship to bipyridyl ligands (**96**) (Section 3.1.3).



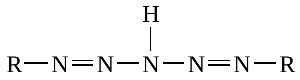
(**134**) R = Cyclohexyl

The bond lengths and bond angles in (**134**) suggest little electron delocalization in the free ligand, and rotation about the C–C bond allows coordination in the planar chelating mode (**135**).

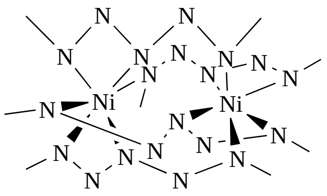


(**135**)

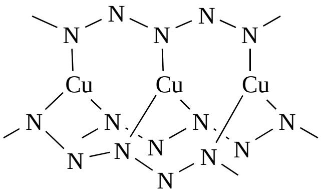
Further catenation of the nitrogen chain leads to pentazadienes (**136**) with bridging structures (**137**) and (**138**) for the Ni^{II} and Cu^{I} complexes, respectively.



(**136**) R = *p*-tol



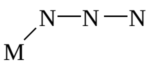
(**137**)
$[Ni_2(\mathbf{136})_4]$



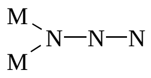
(**138**)
$[Cu_3(\mathbf{136})_3]$

4.1 Azides

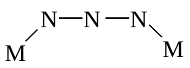
The azide ion (N_3^-) is a *Pseudohalide*[105,106] because its properties resemble those of the halides. The free ion has a linear N–N–N skeleton with equal N–N distances (1.167 Å), but the anion coordinates terminally (**137A**) with an M–N–N angle of 116–140° and an N–N–N distortion of about 4° from linearity. Other possible modes of coordination are shown in (**137B**)–(**144**). As yet, there are no examples of (**143**).



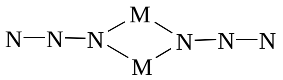
(**137A**)



(**137B**)

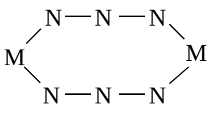


(**139**)

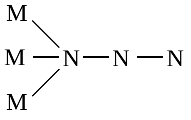


(**140**) μ-(1,1)–

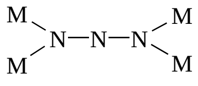
The azido ligand is particularly versatile as a leaving group, as the displacement is acid catalyzed.[107] Coordinated azide ligands also have the potential to react via 1,3-dipolar cycloaddition with organic isonitriles or nitriles to give 1- or



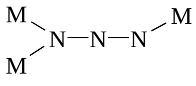
(**141**) μ-(1,3)–



(**142**) μ-(1,1,1)–

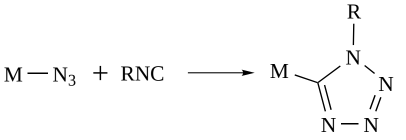


(**143**) μ-(1,1,3,3)–

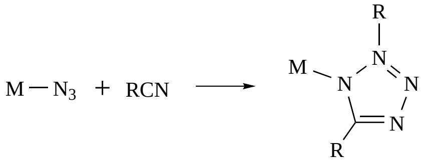


(**144**) μ-(1,1,3)–

5-substituted tetrazolate anions (Section 4.2) respectively (equations 16 and 17). Alternatively, the azide ion can be added to coordinated



(16)



(17)

isonitrile or nitrile ligands to give the same products.[108] The rate of reaction between N_3^- and RCN is considerably enhanced by coordination of the nitrile (Section 7).

4.2 Cyclic Catenated N Ligands[3,97]

Three adjacent N-atom carbocyclic systems are found in triazine (**145**) and triazole (**146**) with the coordination chemistry of the former being poorly investigated. There are, however, many derivatives (**147**–**148**) of the weak acid 1,2,3-triazole (pK_a = 9.26) (**146**). Triazoles (**146**) and the conjugate anion generally bind through N(3) for the parent and N(1) for the anion, but all three N atoms can exhibit metal–nitrogen binding (**149**–**154**). The reaction of 8-azaadenine (**148**) and $CuCl_2$ in HCl results in a six-membered ring opening to give (**155**). Extension of the nitrogen chain gives tautomeric tetrazoles (**156**), (**157**) that are quite strong acids (pK_a 4.8) but neutral molecules (**158**) with weaker base strengths can be formed. Monodentate coordination through the N(1), N(2), and N(4) positions has been observed and N(3)–N(4) bridging is the most common. The N(2)-isomer of $[Co(5\text{-}CN\text{-}tetrazole)(NH_3)_5](ClO_4)_2$ is a commercial explosive.

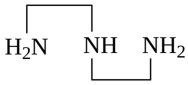
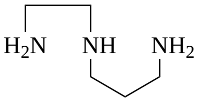
5 POLYAMINE LIGANDS

5.1 Triamine Ligands[27,42,96,97]

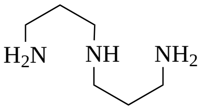
Structures (**159**–**176**) illustrate representative ligands. Some, such as (**164**–**166**) are restricted to *fac* (**39**) coordination, others (**167**)–(**172**) to *mer* (**38**), and the rest are facultative. For the aliphatic triamine ligands (**159**–**163**), (**168**),[109] there are potentially three geometric isomers in bis(tridentate) octahedral coordination, and when the ligand is unsymmetrical (**160**, **162**, **163**), there is the potential for optical isomers at the coordinated *sec*-NH center (**20**) (**21**). Spermidine (**163**), together with spermine (**182**), are important biologically occurring polyamines[110,111] with the potential to form large ring coordination compounds,[42] but the longer side-arm may not always be chelated.[112]



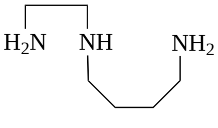
(**159**)



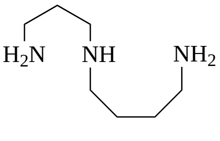
(**160**)



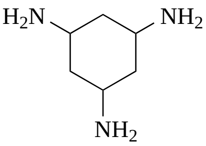
(**161**)



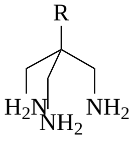
(**162**)



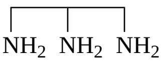
(**163**)



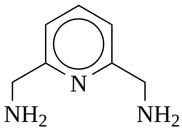
(**164**)



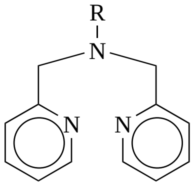
(**165**) tame



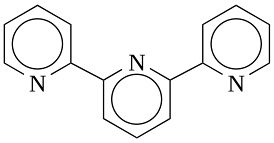
(**166**)



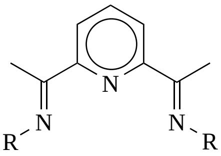
(**167**)



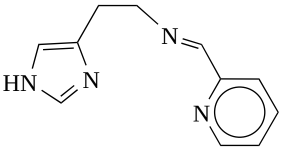
(**168**)



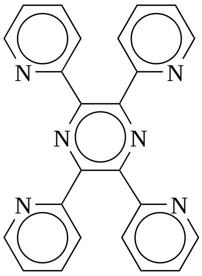
(**169**)



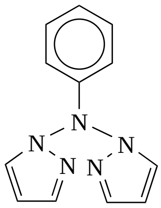
(**170**)



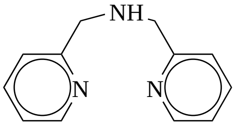
(**171**)



(**172**)



(**173**)

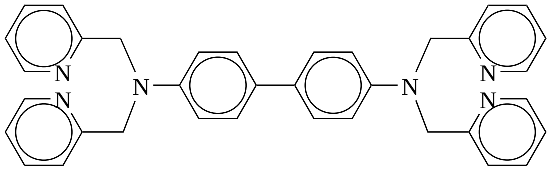


(**174**)

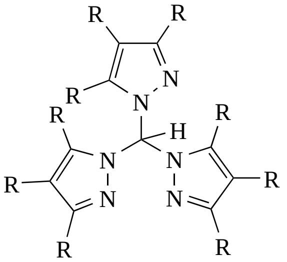
In ligands like (**169**) and (**174**), the pyridine 'arms' can be replaced with N-linked pyrazole (**91**)[113,114] (see **173**, **176**), C-linked imidazole (**29**)[115–117] (see **177**), N-linked 1,2,4-triazole,[118] or C-linked pyrimidine (**94**).[119] Similar 'arm' replacement in (**165**) has been achieved with pyrazole to give (**176**).[120,121] For some formal hexaamines, like (**172**) and (**175**), the rigidity of the ligand restricts the coordination to triamines.[122] A triamine can also be formed by adding an imidazole 'arm' to an N atom in 1,5-diazacyclooctane (**177**).[123]

5.2 Tetraamine Ligands[42,96,97]

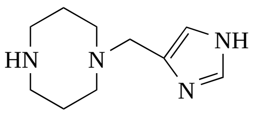
Of the potential *Quadridentate Ligands* shown in (**178**–**192**), spermine (**182**) is a naturally occurring polyamine



(**175**)

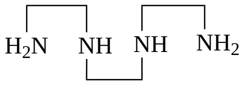


(**176**)

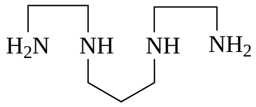


(**177**)

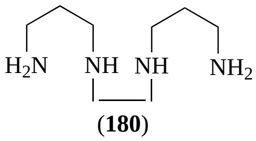
and others like (**178**), (**179**), and (**183**) are commercially available or relatively easily prepared.[42] The unsymmetrical ligands (**181**) and (**182**) are less common. A useful (but nonspecific) polyamine synthesis has been devised where polyalcohol(polybenzenesulfonates) are reacted with neat diamines[124] or NH_3(l)[125] at boiling temperature (Figure 2). After distillation of the excess diamine, the crude polyamine product mixture is complexed with Co^{III} or Cu^{II}, and the complexes are separated using cation-exchange resins. The hydrochloride salts of the free ligands can be obtained from the column fractions by treating the Cu^{II} complexes with HCl, or the Co^{III} and Cu^{II} complexes can be characterized directly.[126]



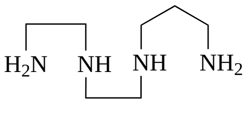
(**178**)



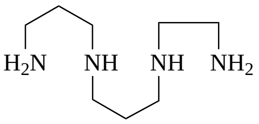
(**179**)



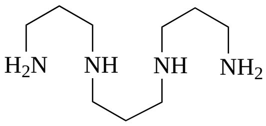
(**180**)



(**181**)

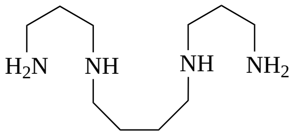


(**182**)



(**183**)

The amine (**186**) in $[CoCl(en)(LH)]^{3+}$ binds as a monoprotonated fac triamine, (**187**) in *trans*-$[CoCl_2(LH_2)]^{3+}$ as a



(**184**)

square-planar diprotonated tetraamine, (**188**) in $[(CuCl)_2L]^{2+}$ as a dinuclear tetraamine, and (**189**) in *trans*-$[CoCl_2(L)]ClO_4$ as a square-planar tetraamine that crystallizes as a conglomerate (see Section 3.1.1).

The planar quaterpyridine ligand (**190**)[127,128] can coordinate in a somewhat strained square-planar arrangement with Cu^{II}, Co^{III}, Co^{II}, Ni^{II}, Cr^{III}, and Pd^{II} but with potentially tetrahedral metal centers such as Cu^{I} or Ag^{I}, a subtle interplay of steric factors (metal and ligand) allows the formation of dinuclear dibridged helical structures (see Section 8).[26]

The quadridentate ligand, trien (**178**), played an important role in demonstrating the stereochemical significance of the s-NH proton in octahedral complexes with inert metal centers (Figure 3).

For example, the complete isomeric set of $[Co(trien)(NH_3)_2]^{3+}$ has been isolated, and only the meso–trans isomers (**197**–**198**) with two different axial ligands, remain to be distinguished. There is also an extensive chemistry of N and C-alkylated derivatives of (**178**–**180**)[42] as *cis*-$[Co(OH)(trien)(OH_2)]^{2+}$ assists the hydrolysis of amino acid esters, amino acid amides, and peptides to form *cis*-β_1 (**194**) and *cis*-β_2-$[Co(ON)(trien)]^{2+}$ (**195**)(ON = amino acid) complexes. Chiral alkylated trien ligands have the potential for chiral stereospecificity in such reactions.

The quadridentate *Tripodal Ligand*, tren (**191**), is often found as an impurity in commercial samples of trien (**178**) and this has sometimes led to isomeric misinterpretation. Techniques for the separation of these isomers are available when mixtures are suspected.[42] The coordination chemistry of tren and its 'longer arm' analogs has been reviewed.[129]

The crystal structures of $[Cu(\mathbf{183})](ClO_4)_2$ and $[Cu(\mathbf{184})](ClO_4)_2$ show that all N atoms are coordinated and the central ring lies above the plane of the two-chair six-membered rings.[42]

Of the tetraamine ligands (**199**–**206**), some like (**199**), (**200**), (**202**),[130] and (**205**)[131] require two metal centers to accommodate all the N-donor atoms.

5.3 Pentaamine Ligands

Some pentaamine ligands are shown in (**17**), (**19**), and (**207**–**215**). Commercially available technical 'tetraethylenepentamine' is a mixture of linear tetren (**207**) and branched chain trenen (**208**), so five-coordinate $[Cu(trenen)]^{2+}$ and octahedral $[CoCl(tetren)]^{2+}$ can be obtained in reasonable yields from the same polyamine mixture.[132] Alternatively, these ligands can be synthesized in situ from Co^{III} complexes of tren (**191**) or trien (**178**), and coordinated amino-acetaldehyde.[42,133]

The alternative (chirality independent) nomenclature[21] is based on X having a higher priority than Y

cannot bend to form octahedral arrangements as shown in Figure 4, but can adopt planar five-coordinate complexes such as [Ag(**210**)] PF_6, coordinate in a square plane with one 'arm' free, or bridge between two metal centers.[128] Ligands such as (**214**)[134] and (**215**)[135] have one and zero NH protons respectively and the base hydrolysis rates of the $[CoClN_5]^{2+}$ complexes would be of interest. In this regard, [CoCl(**212**)]$^{2+}$ has one of the slowest base hydrolysis rates on record.[136]

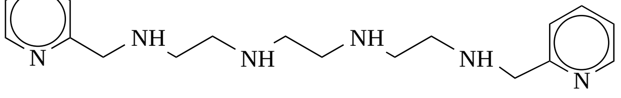
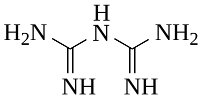
6 MISCELLANEOUS NITROGEN DONOR LIGANDS[141]

This section deals with nonmacrocyclic ligands containing only C, H, and N atoms.

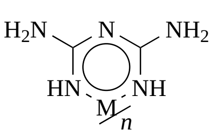
A well-developed coordination chemistry of the chelating biguanide (**234**) (big) ligand has been reviewed,[41,142,143] but the prevalence of hydrates and the acid-base properties of the coordinated ligand has caused confusion in the structural assignment. The two series of salts $[M(big)_3]\cdot xH_2O$ and $[M(bigH)_3]X_3$ ($X = Cl^-$, Br^-, $1/2SO_4^{2-}$ etc.) are best represented as (**235**) and (**236**).



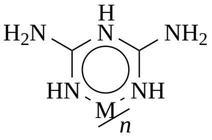
(**233**) Bpytrien



(**234**)

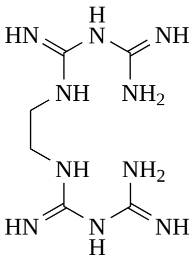


(**235**) $[M(big)_n]$



(**236**) $[M(bigH)_n]X_n$

Quadridentate ligands such as (**237**) are prepared by what must be one of the first (1944) uses of metal ion template ligand synthesis (Figure 5).[143]



(**237**)

In the biologically relevant, usually monodentate, adenine[144] (**238**) and related ligands (**239**–**241**), it is often difficult in deciding if binding takes place at the N-1 or N-7 sites, and it is possible[144] that the binding position for adenine may be metal ion specific: Ni^{II}, Cu^{II}, Co^{II}, Cd^{II} at N-7; Zn^{II} at both; Hg^{I} and Mn^{II} at N-1 (*see* ***Nucleic Acid–Metal Ion Interactions***).

The incorporation of many-membered chelate rings into the metal ion coordination sphere is possible with ligands that

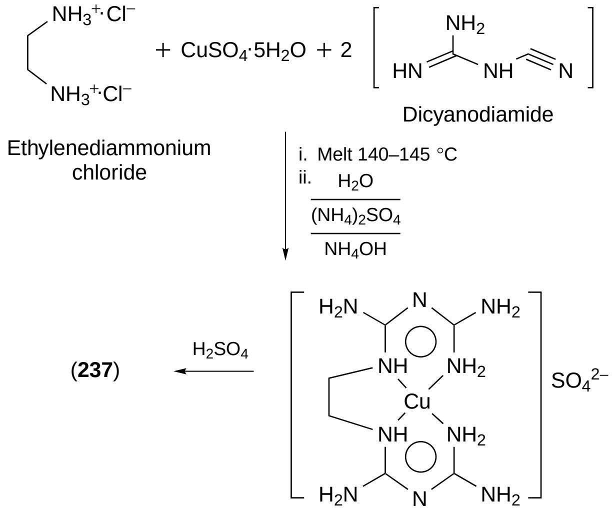


Figure 5 Synthesis of $[Cu\{en(big)_2\}]SO_4$

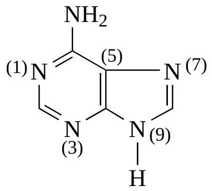
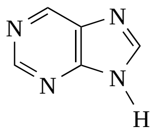
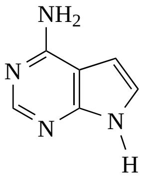


(**238**) Adenine

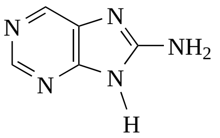


(**239**) Purine

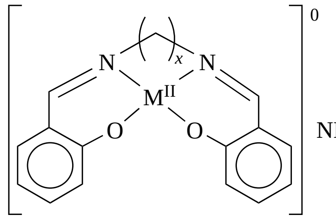
have chelating groups at either end of the long hydrocarbon chain (**242**–**243**). While most work has been done with salicylaldehyde-diimine[145] type systems (**242**), there are also polyamines (**243**) with similar potential.



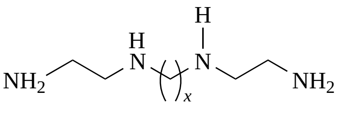
(**240**)



(**241**)



(**242**)



(**243**)

Complexes of aminopolymers[146] such as polyvinylpyridine[14] (PVP) or poly(ethyleneimine) (PEI) are known, for example, *cis*-$[CoCl(en)_2PVP]Cl_2$ has been prepared with up to 108 repeat units and up to 50 Co^{III} atoms, and Ni^{II} complexes of PEI are readily formed in solution.

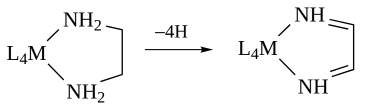
7 REACTIONS OF COORDINATED NITROGEN LIGANDS

A variety of reactions can take place with coordinated nitrogen ligands. In many instances, the products are controlled by the template effect (*see Templating*). In other cases, coordination can induce a dramatic increase in the reaction rate.

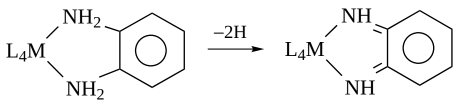
7.1 Coordinated NH_2

7.1.1 Dehydrogenation

Oxidation of coordinated diamines (especially for Ru or Fe)



(18)



(19)

$$L_5M–NH_2CH_2Me \xrightarrow{-4H} L_5M–N{\equiv}C–Me \quad (20)$$

can yield imines or nitriles (equations 18–20) if the M–N bond is sufficiently inert.

7.1.2 Condensation[13,147,148]

More commonly, the coordinated – NH_2 group can undergo condensation reactions with carbonyl compounds to form imines (Figure 6) in both labile and inert metals. Dicarbonyl systems can bridge between two independent NH_2 groups to form linear or macrocyclic ligands (equation 21) (*see* ***Macrocyclic Ligands***). The resulting imines can then be

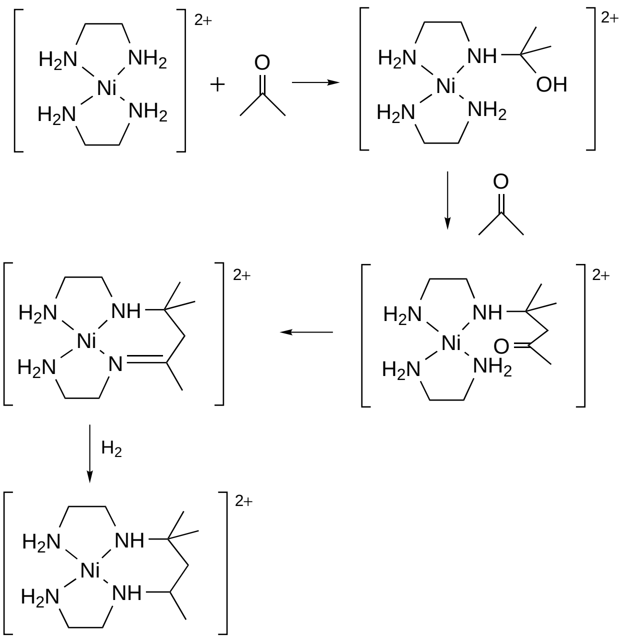


Figure 6 Carbonyl condensation

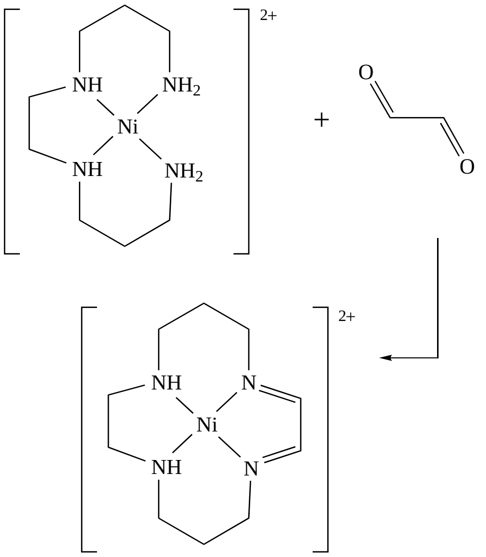
hydrogenated to give saturated amines.



(21)

Oxidative deamination followed by carbonyl condensation is thought to be the pathway by which *mer*-tridentate imine systems are isolated from diamine precursors (Figure 7) using Co as the metal center.[149]

7.1.3 Deprotonation

A number of reactions of inert metal complexes are nicely explained by a preliminary deprotonation of the NH_2 ligand. These include base hydrolysis (equation 7), NH $\rightleftharpoons$ ND exchange,[22] s-NH racemization, and some N–C bond formation reactions (equation 12). In every case, the rate of the reaction is proportional to the OH^- concentration and, as mentioned earlier (see Section 1), in favorable cases the deprotonated species can be isolated and characterized.[23,24]

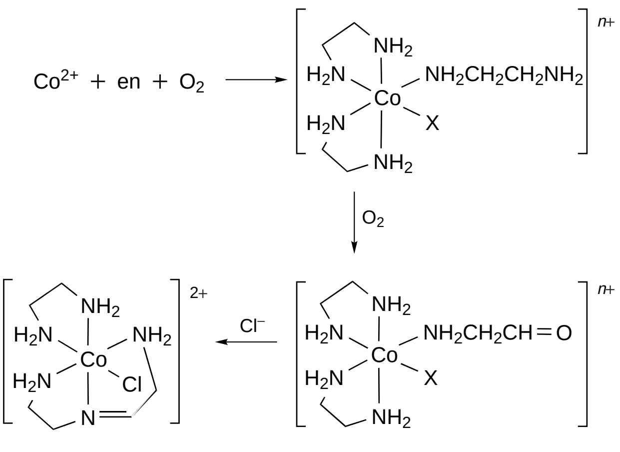


Figure 7 Imine formation

7.2 Other Reactions

Equations (16) and (17) show how coordinated azides can be expanded to give coordinated tetrazoles, and coordinated nitriles can be hydrolyzed to give amides (equation 22).[150,151]

$$[(NH_3)_5Co{-}N{\equiv}C{-}R]^{3+} + OH^- \longrightarrow [(NH_3)_5Co{-}NH{-}C(=O){-}R]^{3+} \qquad (22)$$

Finally, reactions of coordinated ligands can produce amines. These include oxidation of coordinated thiocyanate (equation 23) and hydrolysis of coordinated cyanate (equation 24).[152]

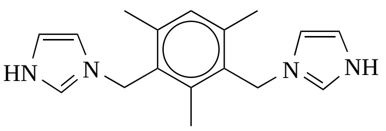
$$trans\text{-}[Co(NCS)Cl(en)_2]^{2+} \xrightarrow{[O]} trans\text{-}[CoCl(NH_3)(en)_2]^{2+} \qquad (23)$$

$$[Cr(NCO)(NH_3)_5]^{2+} \xrightarrow{H+} [Cr(NH_3)_6]^{3+} \qquad (24)$$

$$Cr(NO_3)_6 \cdot 9H_2O + urea \xrightarrow[130\,^\circ C]{melt} [Cr(NCO)(NH_3)_5]^{2+} \qquad (25)$$

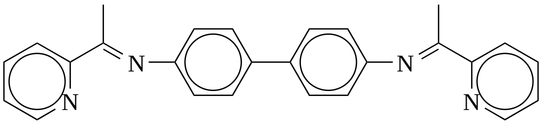
8 SUPRAMOLECULAR ASSEMBLIES[153–156]

While much of the earlier work in polyamine chemistry focused on chelate formation, there is now a growing interest in the use of more rigid amine ligands to produce geometric clusters[153–157] (*see* ***Self-assembled Inorganic Architectures***). Such arrangements include triangles,[158] squares,[159] cubes, tetrahedra, boxes, ladders, and helicates.[160,161] The strategy is based, not only on the ligand design, but also on the stereochemistry of the coordinated metal ion.[157] For example, using the ligand (**244**), an M_2L_2 cyclic dimer is formed with Ag^I (linear N_2 geometry) and an M_4L_4 cage with Pd^{II} (square-planar N_4 geometry). With Zn^{II} (tetrahedral) and Co^{II} (octahedral), one-dimensional zigzag chains and infinite one-dimensional polymacrocyclic networks are formed respectively.[162]



(**244**)

To construct a tetrahedral M_4L_6 cluster, four octahedral metal centers with threefold symmetry and six rigid bis-bidentate ligands of twofold symmetry are needed. (An M_2L_3



(**245**)

triple helix is an alternative outcome.[159]) The tetrahedral M_4L_6 arrangement has been achieved with (**245**) and Zn^{II}.[163]

9 CONCLUSION

In such an enormous variety of N-donor ligands, we can only cover most of the core systems, but the nature of the ligand can be changed in an almost limitless fashion by the addition of substituents, for example, 6-Me-purine (**239**) or 2-Me-pyrazine(**93**). Such substituents can change the donor properties of the ligand via both electronic and steric factors, and the chemistry of the metal complex may or may not follow that of the unsubstituted parent. Since we are not yet in a position to predict the magnitude of these changes, we are provided with a fascinating field of chemical discovery.

1 INTRODUCTION

The analytical chemistry of the transition elements (*see Transition Metals*), that is, those with partly filled shells of d (*see d^n Configuration*) or f electrons (*see f-Block Metals*), should include that of the first transition period (Sc, Ti, V, Cr, Mn, Fe, Co, Ni, and Cu) and that of the second transition series (Y, Zr, Nb, Mo, Tc, Ru, Rh, Pd, and Ag). The third transition series embraces Hf, Ta, W, Re, Os, Ir, Pt, and Au, and although it formally begins with lanthanum, for historical reasons this element is usually included with the lanthanoids (rare-earth elements) (*see* ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***; *Rare Earth Elements*). The actinoid elements (*see* ***Actinides: Inorganic & Coordination Chemistry***) are all radioactive (*see Radioactive Decay*) and those with atomic number (*see Atomic Number*) greater than uranium ($Z = 92$) are artificial; the analytical chemistry of these elements is too specialized to consider here.

Chemical analysis originally sought to determine what elements were present in a particular sample and their concentrations, that is, answers to the questions 'What's in it?' and 'How much?' were sought. As time went on the questions became more searching and the analyst had to address considerations of speciation, that is, the form in which the element is present, its oxidation state, or its occurrence as a specific chemical compound. When the element in question is not distributed uniformly throughout the matrix, the question of its location, for example, at a particular site in a solid catalyst (*see Catalysis*) or grain boundary (*see Grain Boundary*) of an alloy (*see* ***Alloys***), becomes of special interest.

Since the analyte is often present in quite a complex matrix comprising other elements or substances that may or may not interfere with any projected method of determination, and may indeed be quite a minor constituent of the whole sample, these considerations will effectively dominate the working details of any analytical procedure. There can therefore be no case for prescribing a single definitive method for (say) nickel that would be universally applicable to its determination in alloys (*see* ***Alloys***), organometallic compounds (*see Organometallic Complexes*), inorganic salts (*see Ionic Bonds*), or coordination compounds (*see Coordination Complexes*), to its presence as a trace constituent (*see Trace Element*) in maize or other plant products, or in natural waters or effluents.

The environmental scientist will often wish to distinguish between the total mercury in a sample of sea-water and the amounts of methylmercury compounds in it (*see* ***Metal Ion Toxicity***). Other factors that influence the choice of an analytical method for a particular element and the details of procedure stem from the actual reasons for carrying out the analysis in the first place. Do we need the highest possible precision and accuracy, as when assessing the purity of gold and silver or a material for use in semiconductors? Are routine analyses to be conducted on large numbers of samples of very similar type? Is the desired level of precision one set by the eventual use of the analytical result purely for quality control? Is the speed of obtaining a result of overriding importance, as when analyzing the molten contents of a furnace? Or the need to limit the cost of each analytical determination? Or the need to use semi-skilled labor? Other factors that affect the choice of analytical method and the details of procedure depend on the amount of sample available and perhaps its unique character. These considerations apply with special force to the elemental analysis of archaeological artifacts[1] and museum specimens.[2]

For the above reasons it seems appropriate to describe the methods available for analyzing, in particular, the transition metals and to do so in rather broad outline; details of procedure have thus been relegated to representative specialist textbooks[3–6] and research publications. Major reference works include the multivolume *Treatise on Analytical Chemistry* series,[7] the ongoing *Wilson and Wilson's Comprehensive Analytical Chemistry* series (now up to volume 43),[8,9] the *Encyclopedia of Analytical Science* (10 volumes),[10,11] and the recent *Encyclopedia of Analytical Chemistry* (15 volumes).[12] The latter work provides an outstanding source of information on the theory, instrumentation, and applications of modern analytical chemistry.

2 HISTORICAL PERSPECTIVE

2.1 Introduction

As soon as chemical substances of plant or mineral origin became the objects of commerce, the need for what we nowadays think of as 'quality control' became evident, for the realities of human nature soon ensured that problems of adulteration, false weights, and even plain deception had to be taken into account. Thus, Pliny (23–79 AD) recorded that the adulteration of copper sulfate by iron sulfate could be detected by testing a solution with a strip of papyrus soaked in gall-nuts, which blackened if iron was present.

In the absence of mineral acids only 'dry' methods could be employed to detect fraud or defeat the counterfeiters, who became active from the very early days of jewellery and precious vessels of gold and silver. In the earliest references to fire assay, found in cuneiform tablets, the King of Babylon complained to the Egyptian Pharaoh Amenophis IV (reigned 1375–1350 BC), 'Your Majesty did not look at the gold which was sent me last time ... after putting them in the furnace this gold was less than its weight.' The Bible contains many references to fire assaying, for example, 'As the fining pot for silver, and the furnace for gold; so is a man to his praise' (Prov. **27**, 21); '. . . for he is like a refiner's fire, . . . and he shall purify the sons of Levi, and purge them as gold and silver' (Mal. **3**, 2–3); 'As they gather silver, and brass, and iron, and lead, and tin, into the midst of the furnace, to blow the fire upon it, to melt it . . .' (Eze. **22**, 20); 'And I will turn my hand upon thee, and purely purge away thy dross, and take away all thy tin' (Isa. **1**, 25).[13,14]

The separation of silver from gold was a difficult task, and Pliny refers to an essentially chemical method in which the alloy is roasted with iron sulfate and common salt in the presence of brick dust, which absorbs the silver chloride formed and leaves pure gold. However, some 250 years earlier, Hieron, King of Syracuse (200 BC), had asked Archimedes to examine the composition of a new golden crown that he suspected might have been made from a gold–silver alloy. Since the density of gold (19.3) is nearly twice that of silver (10.5) the composition of the crown was easily determined by a purely physical method, probably the first use of a nondestructive method in analysis.

The process of fire assay is essentially quantitative in the sense that it concerns a change in weight before and after some heat treatment. The essential balance was a familiar piece of equipment employed by generations of traders, as evidenced by the fact that weights used in Babylon in 2600 BC are still in existence.

The process of assaying gold was current from early times and in the thirteenth century it was clearly described in the *Summa perfectionis magisterii* (ascribed to Geber). This also described the preparation of aqua fortis (nitric acid), which was known to dissolve silver but not gold, and aqua regia, prepared from a mixture of nitric acid with ammonium chloride, which even dissolved gold and separated the silver as its insoluble chloride. By the fourteenth century, cupellation had become a statutory method for assaying gold, and Charles I of Hungary decreed in 1342 AD that a special laboratory for this purpose (*domus regalis*) should be set up in every mining town.[13] However, problems arising from unreliable analysis did not go away so easily and even in the nineteenth century astute dealers in France found that they could make a tidy profit by buying silver with a 'low assay' from some laboratories and selling it elsewhere where they knew they could receive a 'high assay'. In 1829 the embarrassed administration sought for a solution by offering a prize for a simple and rapid method of analysis with an error of less than 4 to 5 parts in 10^4 that could be universally accepted. Joseph Gay-Lussac was the successful prizewinner with his method of adding a standard solution of sodium chloride to a solution of the silver in nitric acid until one drop of the dilute standard solution no longer produced further turbidity due to the precipitation of silver chloride. With minor improvements for detecting the endpoint, this simple method is still in use 175 years later.[13]

During the fifteenth century the metals zinc, antimony, bismuth, and probably cobalt were discovered, together with many new reactions now used in quantitative analysis.[13,14] For example, A. Libavius (1540–1616) noted how ammonia in water could be determined by the blue color formed with a copper salt. Robert Boyle (1627–1691) was the first to use a solution of hydrogen sulfide (which he made from flowers of sulfur, potash, and ammonium chloride) as an analytical reagent, and he noted the black precipitate it formed with lead, gold, and mercury.

Chemical analysis came into being to meet the demands of early technology. The need for metals in the eighteenth century led to the shortage of the wood and charcoal needed for smelting iron. Replacing them by coal gave a brittle product and it was not until about 1750 that careful analytical work revealed the reason. More mining exploration led to the discovery of new minerals and produced additional problems for the analysts who had to devise new qualitative and quantitative methods, particularly in those countries with the richest mineral deposits, and notably in Sweden. M. H. Klaproth's contributions (1743–1817) in Germany were especially noteworthy, for he originated the technique of alkali fusion for opening up minerals and used silver or gold vessels for the purpose. He realized that foreign materials could be introduced into his samples when they were finely ground in a mortar and he made appropriate corrections. He made significant advances in the analysis of mixtures of iron, manganese, aluminum, and chromium in solutions containing phosphates and arsenates.[13]

2.2 Blowpipe Methods

An important technique developed in the mid-eighteenth century was to miniaturize large-scale metallurgical operations by adapting the blowpipe, which had long been used by glassblowers and goldsmiths, to provide an indispensable

adjunct for the examination of minerals in the laboratory and especially in the field. In the hands of Gahn and Cronstedt in the eighteenth century it became a simple instrument for directing a fine and concentrated flame into a small portion of the powdered sample in a hollowed-out block of charcoal. With the aid of fluxes such as borax, soda, and sodium ammonium phosphate ('microcosmic salt'), many metal oxides could be reduced and valuable information gained from the color and reactions of the bead that remained. Bergmann was a great exponent of this technique and his book *De tubo feruminatorio* (1779) summarized all the knowledge of his time. J. J. Berzelius disseminated it widely through his book *Abhandlung om Blasrorets awendende i kemien och mineralogien* (1820) and its translations into many European languages. This technique, which was once a stable feature of every course on qualitative analysis, fell into disuse around 1910.[14]

2.3 Titrimetry and Gravimetry

At first, quantitative analysis by titrimetry was confined to such problems as measuring the strength of vinegar and the basic articles of commerce such as sulfuric acid, hydrochloric acid, and solutions of chlorine in water. Thus, the amount of alkali in pearl ash was arrived at by measuring the number of teaspoonfuls of a dilute solution of nitric acid needed before effervescence ceased; detection of the endpoint by a change in the color of litmus was a later improvement by William Lewis (1767). Titrimetry took a step forward when F. A. H. Descroizilles (1757–1825) introduced the first form of 'burette' and a crude 'standard flask' described as a 'small jug ... in the neck of which a mark is made with a diamond indicating the place up to which the vessel contains just 2 dl.'[13–15] In about 1846, F. Margueritte introduced potassium permanganate for the titration of iron and Penny's process (1850) extended this with a standard solution of potassium chromate since permanganate could not be used when the iron was taken into solution with hydrochloric acid.[16] Later developments in titrimetry centered around the use of electrochemical methods, these being especially useful for detecting the endpoint since they could be adapted to recording devices and automatic control.[14] Complexometric titrations (see Section 6.3) for many metals date from G. Schwarzenbach's work in the early 1940s.

Classical analysis by gravimetry (see Section 5) took a new turn when L. H. Tschugaeff reported the novel use of a new organic reagent, dimethylglyoxime, in 1905, but several decades passed before other reagents such as cupferron (*see Cupferron*), 8-hydroxyquinoline, 1-nitroso-2-naphthol, the alkyl- and arylarsonic acids, and so on, became firmly established.[14,15]

2.4 Physical Methods

Physical methods such as spectroscopy (1925), atomic absorption (A. Walsh, 1955) (see Section 9), atomic fluorescence (T. S. West, 1966) and X-ray fluorescence (XRF) (1923) (see Section 10.1), and optical absorption spectrophotometry (ca. 1940) (see Section 7) gained increasing importance as the relevant apparatus became more refined and commercially available.[14] Although radiochemical methods began to be exploited from the early years of the last century, a new and major analytical technique, that of neutron activation analysis (see Section 11.1), had to await the availability of nuclear reactors as neutron sources, following the stimulus of the Second World War. This also provided the stimulus for many analytical procedures based on liquid–liquid extraction (or 'solvent extraction'), although its potential had been realized as early as the beginning of the twentieth century.[14]

3 PRETREATMENT OF THE SAMPLE

When the desired element is present in the sample at quite a low concentration, it may be necessary to take a large amount for analysis and this raises the important question of securing a truly representative sample if the initial material is not homogeneous.[17] An aliquot portion of a solution can be obtained with suitable accuracy, but this does not solve the problem of how to obtain a homogeneous solution of the original specimen without introducing large amounts of reagents that cannot readily be removed and may complicate the subsequent procedures. The rate of dissolution is always increased if the sample to be analyzed is presented in the form of a fine powder and such comminution has been achieved by a variety of techniques contrived to disperse the specimen without contamination by the equipment, vessels, or reagents used.[3,4]

Although fusion with alkaline or acidic fluxes such as KHF_2, $K_2S_2O_5$, or Na_2CO_3 (with or without KNO_3) is usually effective, it may introduce materials that subsequently produce complications. HNO_3 and HF are often used for Zr, Hf, Ta, Nb, Ti, and other metals, refractory oxides (*see* ***Oxides: Solid-state Chemistry***), borides (*see* ***Borides: Solid-state Chemistry***), carbides, and nitrides (*see* ***Nitrides: Transition Metal Solid-state Chemistry***). The removal of unwanted material, especially organic matter, by dry- or wet-ashing demands special care, as unacceptable losses of certain elements may arise from these processes.[18] For voltammetric analyses, where the analyte must be in an ionic form, organic material must be removed completely, as well as interfering substances such as oxygen, hydrogen peroxide, complexing agents, surfactants, and any substances that might be adsorbed on the electrode surfaces.

The modern trend has been to carry out digestions in closed vessels of quartz using suitable mineral acids (HNO_3, HCl, H_2SO_4, or $HClO_4$) or in glassy carbon or Teflon-lined bombs (for HF). The digestions are often carried out under high pressure (up to 30 bar) and high temperature (up to 320 °C). Microwave heating is increasingly used to speed the process

and avoid any possible contamination from flames or other heat sources.[19] In a modern UV digestor, samples containing a small volume of pure hydrogen peroxide are arranged in stoppered quartz vessels around a high-pressure mercury-vapor lamp which generates OH radicals that degrade organic matter. A typical digestion of an hour or less at 90 °C is used in the determination of Ni (~1 μg dm^{-3}) or Cu (~30 μg dm^{-3}) in lake water or municipal waste water.

4 QUALITATIVE ANALYSIS

The discovery of so many elements up to the beginning of the twentieth century led to innumerable schemes for their qualitative analysis, with special regard to the circumstances that frequently occurred in complex mixtures, so that some degree of separation was mandatory. Contemporary advances in analytical methods have made much of this work of historical or pedagogical interest only.[20]

Immense effort was at one time devoted to devising 'spot-tests' to enable a specific element or chemical group to be identified in a minute amount of analyte.[21] With the advent of techniques that permit of the simultaneous identification of the components of a complex mixture, these too are less widely used except in special circumstances.

5 GRAVIMETRIC ANALYSIS

5.1 Classical Gravimetry

In classical methods of gravimetric analysis[22] the desired element was separated completely from the matrix and weighed as such or precipitated from aqueous solution as a sulfide or hydroxide (whence a stoichiometric oxide was obtained by ignition) or as a suitable inorganic or organic salt. The conditions governing the quantitative precipitation of the analyte, its freedom from contamination by adsorption or inclusion, and its drying to constant weight required a meticulous observance of the prescribed experimental details and demanded trained experimental skills and were thus time-consuming and costly. The development of homogeneous precipitation (or 'precipitation from homogeneous solution'), which ensured a low rate of precipitation by slow generation of the effective precipitant *in situ* (*see In Situ Reaction*), did much to provide experimental conditions whereby precipitates could be produced under the most favorable conditions.[23]

5.2 Organic Reagents for Metals

With the introduction of dimethylglyoxime by Tschugaeff in 1905 and the later development of a variety of new organic reagents, it became feasible to precipitate a desired element as a metal coordination compound (*see Coordination Complexes*) that often had a low solubility and a favorably high equivalent weight.[24] Organic precipitating reagents are generally bidentate (*see Bidentate Ligand*) chelating ligands (*see Chelating Ligands*), with O, N, and S being the most commonly encountered donor atoms (*see Donor Atom*). At first it was hoped that it would be possible to synthesize a reagent *specific* for each element, thus obviating the need for elaborate separation procedures. This now seems to have been an impossible goal and the best that can be achieved is provision of a reagent which, under carefully specified reaction conditions (e.g. control of pH and the presence of certain auxiliary complexing agents), shows a high *selectivity*.

There appears to be no specific and quantitative precipitant for scandium, the first of the transition metals. The principal difficulty is that of separating scandium from the other metals, since it occurs in practically all yttrium and lanthanum minerals, in smaller amounts in tin, tungsten, zirconium, beryllium, titanium, and niobium minerals, and in minute amounts in almost all rocks. Many of the classical gravimetric procedures depend on the precipitation of its hydroxide or oxalate and subsequent ignition to Sc_2O_3, which unfortunately has a high gravimetric factor. If interfering elements are first removed, it gives a precipitate with oxine

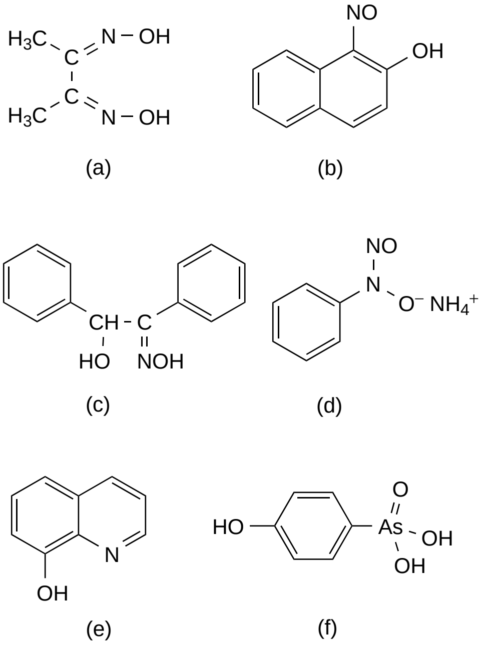

Figure 1 Selection of typical organic precipitating agents (commonly precipitated transition metal ions given in parentheses): (a) dimethylglyoxime (Ni^{2+}, Pd^{2+}), (b) 1-nitroso-2-naphthol (Fe^{3+}, Co^{2+}, Zr^{4+}, Pd^{2+}), (c) α-benzoin oxime ('cupron') (Cu^{2+}, $MoO_2{}^{2+}$, $WO_2{}^{2+}$), (d) ammonium N-nitroso-N-phenylhydroxylamine ('cupferron') (Ti^{4+}, $VO_2{}^{+}$, Fe^{3+}, Zr^{4+}, Ce^{4+}, U^{4+}), (e) 8-hydroxyquinoline ('oxine') (TiO^{2+}, Fe^{3+}, Cu^{2+}, Zr^{4+}, $MoO_2{}^{2+}$, $WO_2{}^{2+}$, Th^{4+}, $UO_2{}^{2+}$), (f) 4-hydroxyphenylarsonic acid (Ti^{4+}, Zr^{4+})

(8-hydroxyquinoline) from a buffered acetate solution at pH 6.5–8.5 of composition $Sc(C_9H_6NO)_3{\cdot}C_9H_7NO$ (M_r 622.7) having a low gravimetric factor.[25]

Gravimetric methods for other transition metals are detailed by several authors in reference texts;[3,4,24,26,27] a representative selection of well-known organic reagents and their common analytes is given in Figure 1.

6 TITRIMETRIC ANALYSIS

6.1 Advantages of Titrimetry

Whereas in gravimetric analysis a reagent is added in excess to a solution of the analyte and the resulting precipitate is collected, washed, dried, and weighed, in titrimetry (formerly 'volumetric analysis') a reagent of precisely known concentration is added to the test solution in just sufficient amount as to be stoichiometrically equivalent to the amount of analyte. No excess is used and the endpoint is detected visually (by a change in color or fluorescence (*see Fluorescence*) of a suitable indicator) or instrumentally (e.g. photometrically or by some electrochemical method). Titrimetric methods are intrinsically quicker than gravimetric procedures and demand less operator skill. The whole procedure can be automated, conducted on a small scale (with volumes down to a few microliters), and adapted to work with highly radioactive materials (*see Radioactive Decay*).[3,4,28]

6.2 Individual Determinations

In a back-titration of silver by chloride ions, potassium chromate can be used to indicate the endpoint (Mohr's method) but with potassium thiocyanate as titrant, ammonium iron(III) sulfate ('ferric alum') is preferred. In the direct titration (Gay-Lussac's method) the location of the 'turbidimetric' endpoint has been improved in detail.[3,4]

A number of transition metals can be determined conveniently if their cations undergo a definite change of oxidation state (*see Oxidation Number*) on titration with a standard solution of potassium permanganate, potassium dichromate, cerium(IV) sulfate, or ammonium hexanitratocerate(IV). Several visual indicators have been proposed, including diphenylamine and its derivatives, xylene cyanole FF, and especially *N*-phenylanthranilic acid and tris(1,10-phenanthroline)iron(II) sulfate ('ferroin'). Solutions of Cr^{II} have been used in the determination of iron, copper, titanium, vanadium, molybdenum, tungsten, mercury, gold, silver, and bismuth, and standard solutions of V^{II} and V^{IV}, Sn^{II}, U^{IV}, W^{III} and W^{V}, and Mo^{V} have also been proposed as reductants. In the indirect determination of chromium, $PbCrO_4$ is precipitated and its lead content determined titrimetrically. Molybdenum and tungsten have been determined similarly by measuring the calcium content of precipitated $CaMoO_4$ and $CaWO_4$.[26,28]

6.3 Complexometric Titrations

A titrimetric procedure for the determination of most of the transition metals using a common titrant could obviously be of considerable value. This possibility arose from the pioneering work of G. Schwarzenbach in 1945.[29]

If we consider the determination of a transition metal M by the reaction $M + L \rightarrow ML$ (where L is an organic ligand (*see Ligand*) and the charges on the various species are omitted in the interests of generality), a successful analytical method must meet the following requirements: (i) the reaction must be sufficiently fast; (ii) it should lead stoichiometrically to a single product ML without any intermediate reactions or by-products; (iii) there should be a large increase in free energy (*see Gibbs Energy*), so that the reaction is effectively complete, that is, the stability constant (*see* ***Stability Constants & their Determination***) K_{ML} must be large;[30] (iv) the ligand L must be readily available and give stable standard solutions; and (v) there must be some simple means of monitoring the course of the reaction, that is, for following changes in the concentration [M] or [ML]. These conditions are generally met if L is the conjugate base of an aminopolycarboxylic acid such as ethylenediaminetetraacetic acid (EDTA, H_4Y), which is known to form very stable 1:1 complexes with a large number of metals (Table 1) by coordinating to the central metal atom through its nitrogen and oxygen atoms to give up to five chelate rings (*see Chelating Ligands*) of optimum size (five atoms).[27] The structure of a representative transition metal–EDTA complex is illustrated in Figure 2.

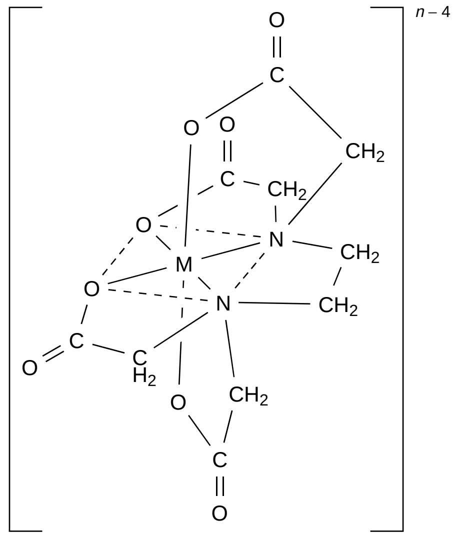

Figure 2 Typical structure of the 1:1 complex formed between a transition metal ion M^{n+} and EDTA (H_4Y)

Table 1 Metal–EDTA complexes: typical values[a] of log K_{ML}

[a]Data at 20–25 °C and $I = 0.1–1.0$ M.[30]

The pure salt $Na_2H_2Y{\cdot}2H_2O$ is commercially available; it is readily soluble in water and its high molecular weight (372.16) facilitates the preparation of standard solutions that keep extremely well in hard glass, borosilicate (Pyrex), or polythene containers, although they are aggressive toward soft glass.[29] Complexation proceeds rapidly except in the case of Cr^{III}. A few cations tend to form polynuclear complexes in alkaline solution and react sluggishly with EDTA at room temperature; several problems are overcome by heating with a known excess of EDTA, then adjusting the pH and back-titrating. The endpoint is detected visually with a variety of metallochromic indicators, which change color when [M] decreases to a small value, or electrochemically with, for example, a mercury drop or amalgamated gold foil electrode. Titrimetric methods have been proposed for all the metals listed in Table 1. For example, plutonium can be determined by complexation with excess EDTA at pH 2.5 and the excess back-titrated with Th^{IV} using Alizarin S as indicator. Molybdenum and tungsten are determinable through the calcium content of $CaMoO_4$ and $CaWO_4$, and chromium through the lead content of $PbCrO_4$ or other means. Good methods are available for all the lanthanoids, and although no really satisfactory method has been established for gold and the individual platinum group metals (PGMs), silver is readily obtained in terms of the nickel ion displaced in the reaction $2Ag^+ + K_2[Ni(CN)_4] \rightarrow 2K[Ag(CN)_2] + Ni^{2+}$.[28,29,31]

7 SPECTROPHOTOMETRIC ANALYSIS

The absorption of radiant energy when a beam of light traverses a solution in a cell of length l is given by $A_\lambda = \varepsilon_\lambda lc$, where c is the molar concentration of the solution and ε_λ is the molar absorption coefficient at a specified wavelength λ (Beer's law). This linear relationship between the absorbance (formerly 'optical density') and the concentration forms the basis of innumerable methods for determining the concentration of solutions that absorb in the visible or UV regions (*see UV–Visible Spectroscopy*). Since values of A_λ are additive, procedures are readily found for evaluating the composition of mixtures provided there is no interaction between the molecules.[32–34]

The absorption coefficients of the transition metal cations themselves are seldom large enough to permit a satisfactory spectrophotometric (absorptiometric) determination, but complexation of copper with amines (*see* ***Ammonia & N-donor Ligands***) (blue color) or iron(III) with thiocyanate (red color) has long been exploited. Innumerable organic compounds have been found to give coordination compounds of high ε values and 2,2′-bipyridyl, 1,10-phenanthroline and 2,4,6-tris(2′-pyridyl)-1,3,5-triazine and their derivatives (*see* ***Ammonia & N-donor Ligands***) are of special value in the determination of iron(II). Bathocuproine (2,4-dimethyl-4,7-diphenyl-1,10-phenanthroline) is a very sensitive and selective reagent for determining copper(I) in the presence of considerable amounts of iron since for steric reasons (*see Steric Effect*) it does not coordinate to Fe^{II}.[27]

1,5-Diphenylthiocarbazone ('dithizone') forms intensely colored complexes with, for example, Mn, Fe, Co, Ni, Cu, Zn, Pd, Ag, Cd, Pt, Au, and Hg, which are soluble in CCl_4 and $CHCl_3$, a property which facilitates their separation and individual determination.[35,36] Solutions of most metal dithizonates in organic solvents have the interesting property of being photochromic (*see Photochromism*), and the relatively long half-life of the photoexcited mercury(II) dithizonate complexes ($t_{1/2}$ ca. 1 min) has facilitated their investigation by conventional spectroscopic techniques.[37]

8 ATOMIC EMISSION SPECTROSCOPY

The fact that every element can give rise to characterizing spectra when suitably excited was known early in the nineteenth century,[13,14] but the numerous practical applications

for qualitative and quantitative analyses, especially for quality control in industry and for research purposes, developed with the growing demands of analytical chemistry and the availability of more efficient and sophisticated instrumentation. The source of excitation transforms the sample into a plasma of atoms, ions, and molecular radicals that can be excited electronically (*see Excited State*). The decay of these excited species (*see Electronic Transition*) involves radiation of light quanta which can be sorted by wavelength in a suitably designed spectrometer, and this emission spectrum, recorded in the early days photographically, is now digitally captured using photomultiplier tubes or diode arrays.

Excitation by flame is less effective than by electric arc or spark, glow, or plasma discharge, or by lasers which produce a more line-rich spectrum; on the other hand, these advantages can only be exploited by instruments capable of higher resolution.[6]

8.1 Arc and Spark Excitation

One of the most convenient sources of excitation is the low voltage (10–150 V d.c.), high current (1–35 A) discharge between two electrodes. The finely powdered sample is contained in a cup machined from a pure graphite rod (usually the anode) and a pointed graphite rod forms the counter electrode. When the arc is struck, the temperature of the conducting channels between the electrodes ranges between 4000 and 7000 K and although the emission lines for any given element appear simultaneously, the elements in a sample matrix do not vaporize at the same rate and various factors determine their sequential emission. In some techniques the separation of a volatile element from others less volatile is deliberately enhanced (e.g. when determining trace impurities in uranium) by the addition of such substances as silver chloride ('carrier distillation method'). In other applications the arc temperature is stabilized to promote uniform and simultaneous evaporation by mixing the sample with a spectrochemical buffer such as lithium carbonate, which supplies the arc with a constant supply of ions and electrons. Detection limits for some typical elements range from 0.1 to 1.0% for Nb, Ta, and W, from 0.01 to 0.1% for Bi, Cd, La, Y, Zn, and Zr, from 0.001 to 0.01% for Au, Fe, Ir, Mo, and Sn, and from as little as 0.0001 to 0.001% for Ag, Co, Cr, Cu, Ni, Os, Pd, Pt, Rh, and Ru.[6,38]

With high (1000 V) or medium voltages, events occur very rapidly in spark discharges. The spectra depend not only on the physical conditions of operating but on that part of the spark gap actually viewed by the spectrograph and also on the selected time interval during the discharge. Owing to such factors and purely matrix effects which affect the absolute intensity of lines emitted by elements in a sample, quantitative measurements normally involve a comparison of the spectra of the analytical sample with those of artificial standards containing the desired elements at comparable concentrations in as closely a similar matrix as possible, with sample and standards being excited under precisely the same conditions.[6,38]

8.2 Inductively Coupled Plasma (ICP) Sources

Since 1974, the inductively coupled plasma (ICP) torch has become commercially available and is among the most effective sources for emission spectroscopy in use today. An ICP discharge is produced by the effect of a radio frequency field (typically 27 to 40 MHz), which creates a magnetic field inside a stream of argon which is first made conducting by a pilot electric spark, arc or Tesla discharge. A spectrally intense plasma at a temperature of 9000 to 10 000 K is obtained in the annulus of an ICP discharge operating at 1–2 kW input power. Samples are introduced as powders, gases, or liquids using the type of spray chamber already made available in flame spectroscopy.[6] Because of the inert atmosphere of the ICP discharge, some of the difficulties encountered in flame excitation are avoided: for example, the air–acetylene flame favors the formation of neutral atoms, while the very hot nitrous oxide–acetylene flame contains high concentrations of CN and NH species and produces a strongly reducing atmosphere. Chemical interferences of this kind, leading to the formation of stable compounds in flames, are almost negligible in the ICP discharge and spectra arising from molecular species such as CN are minimized. Simultaneous determination of as many as 35 elements in a single sample can be carried out without modifying the conditions for each element: less than 5 cm^3 of sample solution is generally required. Detection limits are generally in the range 0.02–2 ppb (ppb $= 10^{-7}$%).[39,40]

9 ATOMIC ABSORPTION SPECTROSCOPY

The Maxwell–Boltzmann distribution law shows that the ratio of the number of atoms N_u in an excited upper state (*see Excited State*) to the number in the ground state N_o increases exponentially with temperature. For example, the ratio N_u/N_o for Cs (resonance line at 852.1 nm), Ca (422.7 nm), and Zn (213.8 nm) increases from 4.44×10^{-4}, 1.21×10^{-7}, and 7.29×10^{-15} at 2000 K to 2.98×10^{-2}, 6.04×10^{-4}, and 1.48×10^{-6} at 4000 K. Even so, this means that for many transition metals only a small fraction of the vaporized atoms are in an excited state capable of emitting a line spectrum, even at the temperature of an ICP.

In 1955, A. Walsh[41] recognized this and showed how the absorption from the great preponderance of unexcited molecules could be exploited analytically.[42–44] Thus, in atomic absorption spectroscopy (AAS) the light from a (usually modulated) source emitting the spectrum of the desired analyte element is passed through a sample atomization cell (such as a flame or graphite tube furnace), a monochromator (to isolate the desired source emission line) and finally into a detector to allow measurement of the change in source line

intensity due to absorption by sample atoms. The narrow waveband (0.001–0.005 nm) light source is usually a hollow cathode discharge lamp prepared with the desired element, although some multielement lamps are now available. In the sample atomization cell a fraction of light from the essentially monochromatic source is absorbed by atoms from the sample, which is sprayed as a solution into the flame by a pneumatic nebulizer, or vaporized electrothermally from a solid in a graphite furnace. The amount of radiation remaining can then be monitored, the concentration of atoms in the path of the light beam being determined by Beer's law. Calibration is achieved with standard solutions containing known concentrations of the element being determined.

In the case of flame atomization, fuel–oxidant mixtures like acetylene–air are used for most easily atomized elements; for the less easily atomized elements, for example, those that exist mainly as monoxides, the analytical sensitivity can be greatly enhanced by going to a higher-temperature flame, such as acetylene–nitrous oxide, thus shifting the equilibrium $M + O \rightleftharpoons MO$ toward the metal.

The development of nonflame atomization systems, particularly the graphite tube furnaces, resulted in a significant improvement in the analytical sensitivity for many elements.[45] While the flame-based technique is capable of measuring sample concentrations down to 100 ng cm^{-3} (parts per billion), graphite furnace devices offer detection limits of the order of 0.1 ng cm^{-3}, a 1000-fold gain. These devices consist of a graphite tube, into which a small amount of sample is placed, which is then heated electrically to a high temperature, vaporizing and atomizing the sample. They are particularly useful when the amount of sample available is limited, since sample volumes are usually in the microliter range. Unfortunately, these devices often suffer from matrix effects and exhibit relatively poor precision because of the small sample size. However, a typical detection limit for many elements using furnace AAS is 10^{-13} g.

In general, as an analytical technique for trace metal (*see Trace Element*) determinations, AAS has important advantages. It has high sensitivity for many elements, with perhaps 60 or so elements measurable with flame atomization in the ppm range ($\sim$0.1–10 µg cm^{-3}, or $\sim 10^{-7}$–10^{-5} g on an absolute basis), and more than half of these measurable at significantly lower concentrations with nonflame atomization. In addition it is simple, rapid, and relatively low cost and can be highly specific, exhibiting few interferences.

9.1 Applications of AAS

In considering the applications of AAS,[46] the technique has made the biggest contribution to the determination of nonferrous metals and for the transition elements Cu and Ag, in particular, whose measurement is completely free from interferences due to Zn, Cd, Hg, Sn, Pb, Bi, or Sb. Blood sera and other body fluids are analyzed after deproteination using concentrated HCl, while for the analysis of plants, milk, and wine the samples are commonly mineralized by incineration or by wet-ashing with acids. In metals and alloys these elements are frequently present in somewhat higher concentrations and these materials may, therefore, be analyzed directly after dissolution in appropriate acids.

The ferrous metals, which include Co, Ni, Cr, Mn, and Mo, besides Fe, all have line-rich spectra and with the exception of iron all are used as alloying elements in steels. No specific interference effects have been observed for Fe, Co, or Ni; for Cr and Mn the effects are only slight; for Mo they can be considerable. The tendency to exhibit interference effects corresponds to the tendency to form oxides in the flame and is, therefore, predominantly due to the formation of nonvolatile compounds and may be eliminated by using releasing elements. Thus, for example, the depressive effect of Si on Cr and Mn may be eliminated by the addition of Ca or Sr to the solution sprayed.

The sensitivity of AAS is usually sufficient to allow determination of these elements in steels after simply dissolving the sample. Most often a mixture of hydrochloric and nitric acids is used, but sometimes sulfuric and phosphoric acids with several drops of nitric acid to facilitate oxidation are preferred. In any case, the volumes of acids in all the solutions sprayed must be kept constant, because generally the acids have a depressive effect. For the analysis of organic materials, plants, fertilizers, and so on, the ash is often digested with acids and the undissolved residue filtered off.

A special group of materials analyzed are crude and lubricating oils. Ni, V, and Fe act as poisons on cracking catalysts (*see Catalysis*), and the wear of mechanical parts of engines can be indicated by the content of trace elements (*see Trace Element*) in lubricating oils. Their determination is therefore an important task. To eliminate the tedious mineralization of the samples, they can be analyzed directly after dilution with some nonpolar solvent, usually xylene, or methyl isobutyl ketone (MIBK).

Among the noble metals, Au and Pd are most easily accessible to AAS determinations. Both are easily atomized in the flame and are not subject to any specific interference effects, so that their determination is sensitive and without complications. Pt, Rh, Ru, Ir, and Os may be determined, but with several specific interference effects, especially in low-temperature flames.

10 X-RAY METHODS

The bombardment of a metal target with a beam of high-energy electrons produces X rays with a line spectrum characteristic of each element present. This is virtually independent of chemical combination or physical state and, for example, the K_α lines from molybdenum appear at the same place whether the target is the oxide, sulfide or the element

itself; the frequency ν is related to the atomic number Z by Moseley's law, $\nu = k(Z-1)^2$.[6]

By focusing an electron beam of moderate energy (10–50 keV) on a very small area of the sample the X ray characteristic of the local elements are excited (electron probe microanalysis, EPMA), enabling details of surface structure such as inclusions and grain boundaries (*see Grain Boundary*) to be examined.[47] A further development following on from this is scanning electron microscopy (SEM) (*see Electron Microscopy*).[48] On the other hand, if a material is irradiated with X rays it is possible to measure the energy of electrons ejected from the sample, and this leads to a method of analysis known as X-ray photoelectron spectroscopy (XPS) (*see* ***Photoelectron Spectroscopy of Transition Metal Systems***) or electron spectroscopy for chemical analysis (ESCA) (*see Electron Spectroscopy for Chemical Analysis*),[49] particularly suitable for the nondestructive study of the composition of solid surfaces (*see* ***Surfaces***).

10.1 X-ray Fluorescence (XRF) Analysis

When a beam of X rays is absorbed in an element, electronically excited atoms (*see Excited State*) are produced and those with vacant K-shells return to the ground state by a series of electronic transitions (*see Electronic Transition*) manifested by the emission of XRF. Proportional counters may be used to measure the intensity of a fluorescence line and by using a pulse-height analyzer with suitable electronics a form of spectrometer results in which a wavelength solution is obtained without the need for a diffracting crystal.[6] Such XRF spectroscopy is now widely applied to every type of element determination in control and research laboratories.[50] Solids or liquids are generally held in shallow metal or plastic containers covered with a thin Mylar window transparent to X rays. For trace analysis a sample is suitably diluted to reduce matrix effects to negligible proportions. Preconcentration may involve ion-exchange resins or papers (*see Ion Exchange*) or the use of appropriate chelating agents (*see Chelating Ligands*).[27]

The accuracy and precision of XRF methods, which can be applied for constituents ranging from a few ppm to almost 100% by weight, are related to the care taken in preparing the sample and standards, the quality of the apparatus, and the use of the appropriate correction factors. In industrial control analysis a relative analytical accuracy of 1% is not unusual.[50]

11 ACTIVATION ANALYSIS

When a target nucleus $^{A}_{Z}\mathrm{X}$ is bombarded with a stream of particles $^{a}_{z}\mathrm{x}$, there is a definite probability measured by the capture cross-section σ of producing a new compound nucleus $^{A+a}_{Z+z}\mathrm{B}$ which rapidly rearranges to give a new nuclide $^{A+a-1}_{Z+z-1}\mathrm{C}$. This process always occurs in less than 10^{-12} s so that the concomitant prompt radiation cannot be measured while the irradiation is still in progress. The product nuclide C is a radioactive species which starts decaying as soon as it is produced, with a characteristic half-life $t_{1/2}$ and the emission of α, β, and γ rays in the usual way.[6,51,52]

11.1 Neutron Activation Analysis

If the irradiation is carried out for t seconds in a stream of neutrons of flux f (neutrons cm^{-2} s^{-1}), the resulting activity due to W g of sample is given by

$$A(\text{disintegrations s}^{-1}) = \frac{f\sigma\theta W N_A[1-\exp(-0.693t/t_{1/2})]}{M}$$

where M is the atomic mass of the isotope of abundance θ, σ is its capture cross-section (cm^2), and N_A is the Avogadro constant, 6.023×10^{23}. The values of σ for different nuclei cover a wide range from about 0.07 up to several thousand barns (1 barn $= 10^{-24}$cm^2), and values of $t_{1/2}$ range from seconds to many years (e.g. 1662 years for ^{9}Be).[6,51]

In practice, the sample of analyte and a standard containing about the same mass of the element of interest are irradiated simultaneously in the same neutron flux f and for the same time t before being removed to the counting laboratory. A period of 'cooling' may be allowed to let any high activity from extraneous elements die away. If the resulting sample emits γ-rays, counting is carried out with a scintillation spectrometer which is especially effective when a number of elements are to be determined simultaneously and where a nondestructive analysis is essential.[2,53] If chemical separations are required to obtain a radiochemically pure specimen for β-counting, various carriers may have to be employed but since these will not be radioactive, no blanks are thereby introduced; this is one of the great advantages of the neutron activation procedure.[52] We can estimate the sensitivity of neutron activation analysis by calculating the smallest mass of a given element that can be determined after irradiation of a sample to saturation in a flux of 1.5×10^{12} neutrons cm^{-2} s^{-1}, assuming that 2 hours had elapsed between irradiation and counting and that the limit of detection was 10 counts min^{-1} (Table 2).[51] The value of the method in the case of the less common elements will be obvious.

11.2 Charged Particle and Gamma Photon Activation Analysis

In addition to activation by thermal (~0.04 eV), epithermal (>0.1 eV), or fast neutrons (14 MeV), a variety of charged particles (p, d, α, etc.) and γ-rays have been used when special sources are available.[6,51,52] For example, 1–5 MeV protons from a van de Graaff electrostatic generator produce X rays from the excited intermediate $^{A+a}_{Z+z}\mathrm{B}$ in a technique designated by the acronym PIXE (proton-induced X-ray emission),[54]

Table 2 Estimated sensitivity of neutron activation analysis[51]

Sensitivity (g)	Element
1×10^{-12}	Dy, Eu
5×10^{-12}	Au, Ho, Lu
1×10^{-11}	In, Mn, Re, Sn
5×10^{-11}	As, Kr, La, Pr, Sc, Tb, Tu, W, Yb
1×10^{-10}	Sb, Br, Cu, Er, Ga, Pd, Na, Ta, Yt
5×10^{-10}	Al, Cs, Co, Gd, Hf, Nd, Li(n,α), P, Rb
1×10^{-9}	Ba, B(n,α), Cd, Ce, Hg, Os, Pt, K, Ru
5×10^{-9}	Cl, Ge, I, Ag, Te, Th, Sn, U, Xe, Zn
1×10^{-8}	Mo, Ni, Si, Th
5×10^{-8}	Bi, Se
1×10^{-7}	Cr, Fe, Sr, Zr
5×10^{-7}	Ca, S

which gives better discrimination between similar elements and is particularly suited for the simultaneous determination of a large number of elements in many varied specimens. Disadvantages of charged particle methods are the low flux of particles and the small penetration depth.

12 ELECTROCHEMICAL METHODS

There is a whole gamut of electrochemical methods available for the determination of the transition elements.[55] Electrogravimetric methods are available for large numbers of metals (e.g. Cu, Ag, Cd, Co, Ni, Sn, Zn, Pb, and Tl) provided these are available in weighable amounts. Controlled potential electrolysis at a mercury pool electrode is best suited for separations (e.g. Cu, Cd, and Pd from uranium) or removing traces of metallic impurities when preparing very pure electrolytes for use in polarography.[6]

Polarography (discovered by Jaroslav Heyrovský in 1922)[56] is a technique in which the potential between a dropping mercury electrode and a reference electrode is slowly increased at a rate of about 50–200 mV min^{-1} while the resultant current (carried through an auxiliary electrode) is monitored; the reduction of metal ions at the mercury cathode gives a diffusion current proportional to the concentration of the metal ions. The method is especially valuable for the determination of transition metals such as Cr, Mn, Fe, Co, Ni, Cu, Zn, Ti, Mo, W, V, and Pt, and less than 1 cm^3 of analyte solution may be used. The detection limit is usually about 5×10^{-6} M, but with certain modifications in the basic technique, such as pulse polarography, differential pulse polarography, and square-wave voltammetry, lower limits down to 10^{-8} M can be achieved.

Especially for those metals that form amalgams (e.g. Cu, Pb, Cd, In, Bi, and Zn), the sensitivity can be increased 10- to 1000-fold by preconcentrating the analyte electrochemically in a hanging mercury drop (or on a solid electrode surface) and then plotting the current–potential curve of the stripping voltammogram (anodic stripping voltammetry, ASV).[57]

13 PLATINUM GROUP METALS (PGMs)

Owing to great similarities in chemical properties and their association together in Nature, the second and third triads of groups 8–10 of the periodic table (Ru, Rh, Pd and Os, Ir, Pt) present many difficulties for the analyst. Their comparative rarity and intrinsic value demand their recovery from spent catalytic converters in the petroleum and many other chemical industries, from the increasing number of pollution control units in motor vehicles, from scrapped jewellery and the scrap of the electronics industry, as well as material from geochemical exploration, the exploitation from mineral deposits, and ‘sweeps’. The first requirement is to collect a homogeneous alloy (*see* ***Alloys***).[58,59]

Often a friable alloy can be produced simply by melting with aluminum; this can then be ground into a powder. Collection by fire-assay methods involving the use of tin and iron–nickel–copper alloys has been extensively studied and collection by melting with nickel sulfide, copper sulfide, and copper alone has its advocates. Lead oxide, as used in the fire assay of gold and silver, is less suitable for isolating platinum and palladium and still less so for rhodium, ruthenium, and iridium, while osmium is largely volatile in the cupellation stage. The optimum procedure is naturally highly dependent on the nature of the sample and in many cases some form of acid digestion is preferable.[58,59]

With modern instrumentation it is often possible to make determinations of individual elements without the necessity for any chemical separations, but while mutual interferences for AAS and ICP emission spectrometry are often small the sensitivity, for example, for iridium, may be unacceptably low and chemical separations are required.[60] The separation of rhodium from iridium is one of the most challenging analytical tasks. Ruthenium and osmium are most commonly separated from other PGMs and matrix elements by distillation of their tetroxides.[59]

Separation of PGMs by solvent extraction or using cation exchangers (*see Ion Exchange*) is well documented[58,59] and gravimetric and titrimetric methods are prominent, especially in the older monographs.[61] The most important instrumental techniques include emission spectroscopy, XRF, AAS, and, of course, the use of activation analysis (see Section 11).[58,59]

1 INTRODUCTION

1.1 History, Occurrence, Use, and Isotopes

Antimony compounds were known to the ancients. In Egypt and other ancient oriental cultures, Sb_2S_3 (stibnite) was used as medicine and for cosmetic purposes, for example, as a component of black eye makeup. The names of the element in different languages originate from the Latin words stibium and antimonium. The former was used in 50 BC by Pliny for Sb_2S_3. It is probably of Egyptian origin. For the word antimonium, there are several more or less fantastic etymologies (against the monks, against loneliness etc.). Probably it is a retranslation of the Arabic word for stibium into Medieval Latin.

Antimony is among the less abundant elements in the earth's crust (0.6 ppm). The most important antimony ore is stibnite, which occurs in large quantities in China, South Africa, Bolivia, and other countries. Other antimony sulfide ores are tetrahedrite ($Cu_3Sb_2S_3$), wolfsbergite ($CuSbS_2$), and jamesonite ($FePb_4Sb_6S_{14}$). Weathering of stibnite leads to valentinite (Sb_2O_3).

It is not very difficult to recover stibnite from other minerals because the melting point of this antimony mineral is low (546 °C). Heating in the range of 550 to 600 °C results in selective melting of the stibnite, which can be collected as crude concentrate. Roasting in air produces Sb_2O_3 that can be reduced with coke. Another method is to reduce the Sb_2S_3 concentrate directly with scrap iron to give elemental antimony (equation 1), which can be purified by melting with sodium nitrate and sodium carbonate.[1]

$$Sb_2S_3 + 3Fe \longrightarrow 2Sb + 3FeS \qquad (1)$$

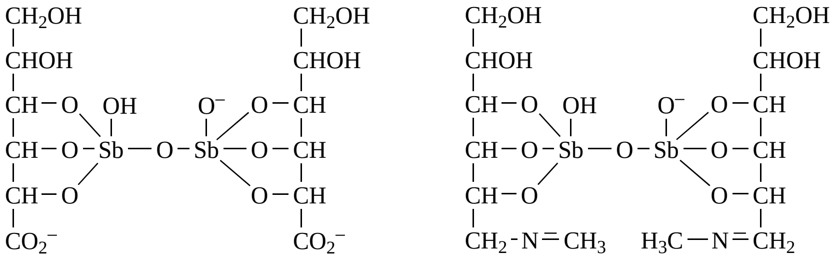
More complex antimony ores can be treated by leaching with alkali hydroxide or sulfide and by electrolysis of the resulting solution of sodium thioantimonate, Na_3SbS_4. Elemental antimony can also be recovered from the flue dust of lead smelters.

The dominant use of antimony is as an alloying element to harden lead, notably for grids in motor car batteries.[1] Pb–Sb alloys have also been used for ammunition or for movable types in printing presses.[1] Antimony is a component of many bearing alloys, like Babitt metal (an alloy of antimony, tin, copper, and other metals), which are useful as bearings because they are soft and slippery. Sb_2O_3 can be applied in chemicals used to impregnate plastics, textiles, rubber, and other materials as a flame retardant. The orange–red form of Sb_2S_3, which is obtained from Sb(III) and H_2S, has been used for pyrotechnical articles and as a pigment in paints, plastics, or rubber. An important medicinal use of antimony compounds is the treatment of tropical diseases caused by parasites like leishmaniasis or bilharziasis.[2,3] Therapies include potassium antimony(III) tartrate, sodium antimony(V) gluconate (Pentostam®) or *N*-methyl-glucamine antimonate(V) (Glucantime®). Proposed structures are shown in Schemes 1 and 3. It is thought that Sb(V) is reduced to Sb(III) *in vivo*. Potassium antimony(III) tartrate (tartar emetic) is an emeticum. It is also used in the therapy of infections in veterinary medicine.

Natural antimony consists of the isotopes ^{121}Sb (57.3%) and ^{123}Sb (42.7%). Important artificial isotopes include ^{122}Sb ($\tau_{1/2} = 2.8$ days), ^{124}Sb ($\tau_{1/2} = 60.4$ days), and ^{125}Sb ($\tau_{1/2} = 2.7$ years).

1.2 Elemental Antimony

The form of elemental antimony that is stable at normal temperatures and pressures is the gray, metallic rhombohedral α-form, mp 630.7 °C, bp 1587 °C, density 6.70 g cm^{-3}. Crystals are lustrous. They have a relatively high electrical resistivity (41.7 µΩ cm at 20 °C). The structure of α-Sb consists of sheets of covalently bonded antimony stacked in layers, which are formed of puckered six-membered rings. Each antimony forms three shorter bonds (2.91 Å) in the same layer as well as three longer bonds (3.36 Å) to antimony atoms in the adjacent layer. In addition to the α-form, other allotropes include a very unstable yellow form and black forms obtained electrolytically or by condensing the vapor on cold surfaces. Two crystalline allotropes are made by high-pressure techniques. At 85 kbar, a modification with a primitive cubic lattice is formed where each antimony atom is in an octahedral environment of six equidistant (2.96 Å) neighbors. Further



Sodium antimony(v) gluconate (Pentostam®)

N-methyl-glucamine (Glucantime®)

Scheme 1

increase in the pressure to 90 kbar gives a hexagonal close-packed form with Sb–Sb distances of 3.28 Å for the 12 nearest neighbors. Thin films of amorphous antimony on surfaces of $AuSb_2$ and MoS_2 contain crystalline structures of Sb_4 tetrahedra.[4] Antimony vapor consists of Sb_2 and Sb_4 molecules. The calculated Sb–Sb bond length in Sb_4 tetrahedra is 2.687 Å.

Elemental antimony is stable in air and moisture at room temperature but oxidizes upon heating to give Sb_2O_3, Sb_2O_4, and Sb_2O_5. It reacts with Cl_2 to give $SbCl_5$ and also reacts with the other halogens and with sulfur. Antimony is not soluble in HCl or dilute H_2SO_4. Hot concentrated H_2SO_4 gives $Sb_2(SO_4)_3$ and concentrated HNO_3 gives hydrated Sb_2O_5.

1.3 General Aspects of Antimony Chemistry

The ground state electronic configuration of antimony is [Kr] $4d^{10}5s^25p^3$. Its covalent radius is 1.4 Å and its ionic radii are 0.76 and 0.60 Å for six-coordinate Sb(III) and Sb(V) respectively. Both the +3 and the +5 oxidation states are stable for antimony. Compounds with a formal oxidation state of +4 such as Sb_2O_4 and $SbBr_6^{2-}$ are diamagnetic, containing equal amounts of Sb(III) and Sb(V). Negative oxidation states are found in alkali metal antimonides. The most frequently encountered coordination numbers are 3 (e.g. trigonal pyramidal in SbH_3), 4 (tetrahedral in $Sb(CH_3)_4^+$, ψ-trigonal bipyramidal in $(CH_3)_2SbBr_2^-$), 5 (square pyramidal in SbF_5^{2-}, $SbPh_5$, trigonal bipyramidal in SbF_5), and 6 (octahedral Sb in $SbBr_6^{3-}$, SbF_6^-). Also, coordination numbers 1 (Sb≡Sb) and 2 (stibabenzene, C_6H_5Sb, RSb=SbR, $RSb{=}CR_2$, Ph_2Sb^-) are known.

2 ANTIMONY HYDRIDES

The most important antimony hydride, stibine, SbH_3 is a malodorous, extremely toxic gas (bp −18 °C, mp −88 °C) formed from soluble antimony compounds and hydrogen in statu nascendi (equation 2), by reaction of Mg_3Sb_2 with dilute hydrochloric acid, or, at best, by reaction of $SbCl_3$ with $NaBH_4$ (equation 3) in hydrochloric acid.

$$Sb(OH)_3 + 6H \longrightarrow SbH_3 + 3H_2O \quad (2)$$

$$SbCl_3 + 3NaBH_4 \longrightarrow SbH_3 + 3NaCl + 3BH_3 \quad (3)$$

The structure is pyramidal with a H–Sb–H angle of 91.54°, and an Sb–H bond length of 1.70 Å.[5] SbH_3 is an endothermic compound ($\Delta H_f^\circ = 145.1\ kJ\,mol^{-1}$) decomposing at room temperature to metallic antimony and hydrogen. As a side product of the syntheses of SbH_3, small amounts of distibine Sb_2H_4 were also detected. SbH_3 is used in Metal Organic Chemical Vapor Deposition (MOCVD) processes, but because of its instability, it has to be generated on site.[1] SbH_2, H_2SbOH, and $HSbO_2$ are products of the photolysis of SbH_3 and O_3 in an Ar matrix at 12 K.[5]

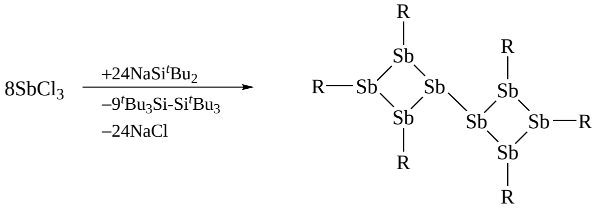
3 ANTIMONIDES

Reduction of antimony by alkali metals or by other methods leads to alkali metal antimonides (Zintl anions) of various types. Known antimonides include isolated Sb^{3-} ions (in Li_3Sb, Na_3Sb), dumbbells Sb_2^{4-} in Cs_4Sb_2, discrete antimony chains, for example, Sb_6^{8-} in $SrSb_3$, infinite spirals $(Sb^-)_x$ (in NaSb, RbSb), planar four-membered rings Sb_4^{2-} in $K(crypt)_3Sb_4$, Sb_7^{3-} cages in Cs_3Sb_7 or $Na_3Sb_7{\cdot}3TMEDA{\cdot}3THF$ (TMEDA = tetramethylethylenediamine, THF = tetrahydrofuran), and net shaped anions Sb_3^{2-} in $BaSb_3$.[6,7] Also, transition metals, lanthanides and actinides, form a variety of intermetallic compounds with antimony. Typical transition metal/antimony intermetallics are MSb_2 (M = Ni, Pd, Pt, Au) with Sb_2 units and MSb_3 (M = Co, Rh, Ir) with Sb_4 rings.

4 ANTIMONY GROUP 13 METAL (Al, Ga, In) AND GROUP 15 METAL (Si, Ge, Sn, Pb) COMPOUNDS

Important intermetallics are the III−V semiconductors for infrared detectors AlSb (band gap, 2.2 eV), GaSb (band gap, 0.7 eV), and InSb (band gap, 0.2 eV), which can be used as diodes and Hall effect devices. Precursors of these semiconductors are products obtained by reactions of $Sb(SiR_3)_3$ and alkyl derivatives of group 13 metals, for example, Lewis acid−base adducts $R_3M–Sb(SiR_3)_3$ (M = Al, Ga, In; R = alkyl) or heterocycles $[R_2MSb(SiMe_3)_2]_n$ ($n = 2, 3$).[8–11]

Known molecular compounds with bonds between antimony and group 15 metals (M = Si, Ge, Sn, Pb) include organometal stibines $(R_3M)_3Sb$, distibines $(R_3M)_4Sb_2$, or the silyl antimonide $[(DME)LiSb(SiMe_3)_2]$.[9,12–16] The reaction of the latter with iPr$_3$SiCl yields the mixed stibine iPr$_3$SiSb(SiMe$_3$)$_2$.[9] Sodium tri(*tert*-butyl)silanide reacts with $SbCl_3$ to form the bicyclic stibine R_6Sb_8 (**1**) (equation 4).[17]



(4)

R = Si^{t}Bu$_3$ (**1**)

Exchange reactions of $(Me_3Si)_3Sb$ with Me_3MCl give $(Me_3M)_3Sb$ (M = Ge, Sn, Pb). $(Me_3Pb)_3Sb$ decomposes with the formation of $(Me_3Pb)_2$ and $(Me_3Pb)_4Sb_2$.[18] Organosilylstibines $(R_3Si)_3Sb$ generally adopt molecular structures with pyramidal antimony. The distibines $(R_3M)_4Sb_2$ are remarkable for the unusual red color of their crystalline phases where the molecules in the trans conformation are aligned to linear chains through short intermolecular Sb···Sb contacts.[14]

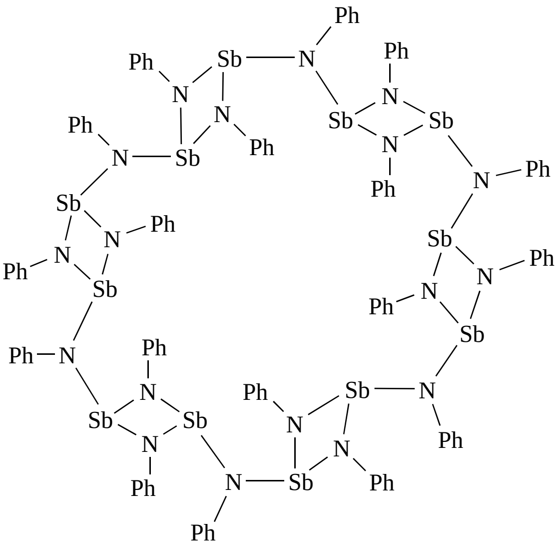
5 ANTIMONY PNICOGEN (N, P) COMPOUNDS

Although antimony−nitrogen bonds are unstable to hydrolysis, many well-characterized compounds where antimony atoms are bonded exclusively to nitrogen atoms are known.[19–24] They include tris-amido species, for example, $Sb(NR_2)_3$, formed by the reaction of $SbCl_3$ with secondary amines (equation 5).

$$SbCl_3 + 6R_2NH \longrightarrow Sb(NR_2)_3 + 3R_2NH_2Cl \qquad (5)$$

Other examples are dinuclear imido−amido compounds $Sb_2(NR_2)_2(\mu\text{-NR})_2$ and a range of species based on anions, for example, $[Sb(NR)_3]_3^-$, $[Sb_2(NR)_2(\mu\text{-NR})_2]_2^-$, or $[Sb_3(NR_2)_2(\mu\text{-NR})_4]$.[23] The reaction between $SbCl_3$ and Li[NHPh] affords the remarkable twenty-four-membered imido antimony metallacycles $Sb_{12}(NPh)_{18}$ (**2**).[23,24]

The reaction of $SbCl_3$ with $[(PNR)_2(NRLi·THF)_2]$ leads to a polycyclic cage complex of the formula $[(PNR)_2(NR)_2Sb]Cl$ where antimony is bonded to three nitrogen and one chlorine atom.[25] Antimony in a square planar environment of four nitrogen atoms exists in porphyrins and related macrocycles.[26,27] Sb–N bonds also exist in antimony azides. The mixed chloride diazide $SbCl(N_3)_2$ is formed from NaN_3 and $SbCl_3$ at room temperature.[28]



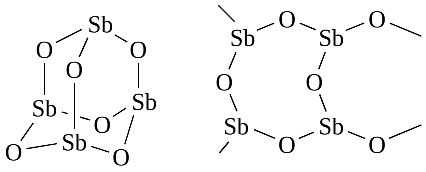
(**2**)

Molecular compounds with Sb–P bonds are very rare. One example is the anion $[cyclo\text{-}(RP)_4Sb]^-$, which is formed by reactions of $Sb(NMe_2)_3$ with primary phosphines.[7,29]

6 ANTIMONY CHALCOGEN (O, S, Se, Te) COMPOUNDS

6.1 Antimony Oxygen Derivatives

Antimony(III) oxide Sb_2O_3 occurs in two forms, cubic senarmontite containing discrete tetrahedral Sb_4O_6 molecules and orthorhombic valentinite (Scheme 2). The vapor phase consists of discrete Sb_4O_6 molecules. Senarmontite contains Sb_4O_6 units with each Sb having three Sb–O intramolecular bridging bonds (1.98 Å) and three intermolecular Sb···O distances (3.8 Å). Upon heating to 606° the cubic form is transformed into the valentinite form, which consists of infinite Sb–O double chains, the opening antimony atoms of which are bridged by oxygen in such a



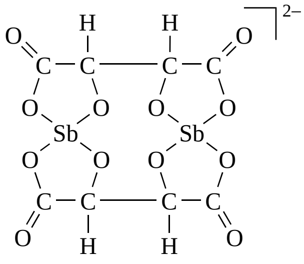
senarmontite valentinite

Scheme 2

way that strongly puckered eight-membered rings are formed.[30]

$Sb_2O_3$is insoluble in water or dilute nitric or sulfuric acids. It is regarded as amphoteric because it is soluble both in strong acids, which form complexes with Sb(III) such as hydrochloric acid, and in bases. In concentrated sulfuric acid, it is dissolved with the formation of $(SbO)_2SO_4$ or $Sb_2(SO_4)_3$. Sb_2O_3 dissolves in base to form antimonates(III), mostly, with polymeric structures. By fusing the oxides of sodium and antimony(III), one obtains Na_3SbO_3, which has a tetrameric structure. An example for antimony(III) incorporated in a polyoxometalate is the anion $(SbW_9O_{33})^{9-}$.[31,32] The presence of Sb_2O_3 and organic acids leads to soluble complexes of Sb(III). The best known example is tartar emetic, dipotassium bis[μ-D-tartratodiantimonate] trihydrate where tartaric acid acts as a tetradentate bimetallic ligand. The environment of antimony is a highly distorted Ψ-trigonal bipyramid. The axial oxygen atoms are from the carboxylate moiety and the equatorial oxygen atoms are hydroxyl derived (Scheme 3).

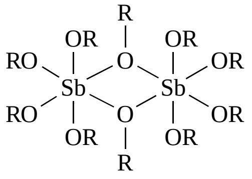
Antimony(V) oxide can be obtained by reaction of Sb_2O_3 with oxygen at high pressures and temperatures or by hydrolysis of $SbCl_5$ with aqueous ammonia. Sb_2O_5 is polymeric, with octahedrally coordinated antimony atoms. A third antimony oxide, Sb_2O_4 is best described as antimony(III) antimonate(V) $Sb^{III}Sb^{V}O_4$. It consists of layers of SbO_6 octahedra sharing vertices and Sb(III) centers between the layers. A simple oxo anion $SbO_4{}^{3-}$ is not known. Instead, the anion $Sb(OH)_6{}^-$ with six-coordinate octahedral antimony(V) is generated in basic solutions of Sb(V), for example, by treating $SbCl_5$ with aqueous sodium hydroxide. The sodium salt $NaSb(OH)_6$ is the least soluble of the alkali metal salts. The soluble potassium salt $KSb(OH)_6$ is used as a reagent for the precipitation of Na^+ as $NaSb(OH)_6$. Other antimonates(V) include $[Mg(H_2O)_6][Sb(OH)_6]_2$ and $[Cu(NH_3)_3(H_2O)_3][Sb(OH)_6]_2$. Dehydration of these hydrates affords edge-sharing polymeric octahedra $[SbO_6]_n{}^{n-}$.



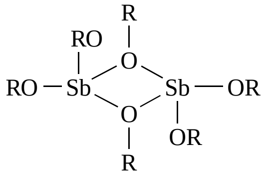
tartar emetic

Scheme 3

Alkoxides of Sb(III) or Sb(V) with known structures are compounds of the types $Sb(OR)_3$ (**3**) and $Sb(OR)_5$ (**4**). They are both dimeric in the solid state, with bridging alkoxy groups and trigonal pyramidal geometry or octahedral coordination about antimony.[33,34]

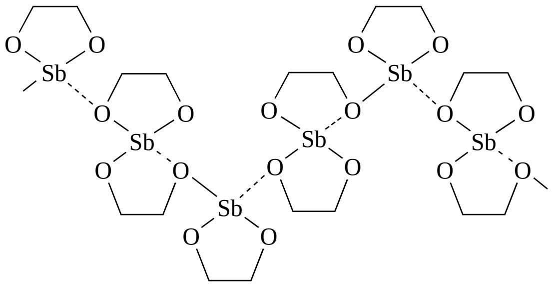


(**3**)



(**4**)

Homoleptic antimony(III) β-diketonates $Sb(thd)_3$ (Hthd = tetramethylheptanedione) and $Sb(fod)_3$ (Hfod = dimethylheptafluoroheptanedione) are obtained from $Sb(OEt)_3$ and three equivalents of the appropriate ligand. The compounds are monomeric in the solid state with ψ-seven coordination at antimony.[35] A polymeric structure is adopted by antimony (III) ethylene glycolate $[Sb_2(OCH_2CH_2O)_3]_n$ (**5**).[36]



(**5**)

Monomeric Sb(III) dialkylcarbamato complexes $Sb(O_2CNR_2)_3$ form in reactions between trisamidostibines and CO_2 (equation 6).[37]

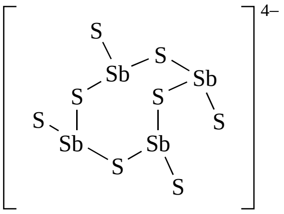
$$Sb(NR_2)_3 + 3CO_2 \longrightarrow Sb(O_2CNR_2)_3 \qquad (6)$$

6.2 Antimony Sulfides, Selenides, Tellurides

Antimony(III) sulfide is the most important sulfur compound of antimony, which occurs naturally as the

mineral stibnite often forming a beautiful array of black crystalline needles. There is also an amorphous red-bronze form. Preparation of Sb_2S_3 in the laboratory by passing H_2S into acidic solutions of Sb(III) or Sb(V) gives the orange–red form of Sb_2S_3, which is also obtained by the combination of Sb and S. Heating the orange form in the absence of air gives the gray-black form. The structure of stibnite consists of indefinite Sb_4S_6 ribbons, which may be described as zigzag chains of face sharing Sb_4S_4 cubes.[30] Antimony(III) selenide is a gray material formed by fusion of the elements. It has a chain structure involving short Sb–Se bonds (2.58–2.77 Å), the chains being held in pairs by weaker bonding (2.9 Å). These pairs are bonded into sheets with Sb–Se interactions of 3.26 Å and the sheets are held by Sb···Se interactions of about 3.46 Å. Antimony telluride is a gray material formed by direct syntheses from the elements at elevated temperatures, and adopts a layer structure. The bond lengths Sb–Te lie between 2.98 and 3.17 Å. With band gaps of 1.7 eV, Sb_2S_3; 1.3 eV, Sb_2Se_3; and 0.3 eV, Sb_2Te_3, these compounds are of importance as semiconductors.

Great structural diversity is displayed by metal derivatives of thio- or seleno-antimonates $[SbS_3]^{3-}$, $[SbSe_3]^{3-}$, $[SbS_4]^{3-}$, $[Sb_4S_8]^{4-}$, $[Sb_6S_{10}]^{2-}$, which can be prepared by various methods.[38–43] In $Cr(en)_2SbS_3$ (en = ethylenediamine), the pyramidal anion $[SbS_3]^{3-}$ is coordinated as a bidentate ligand through two sulfur atoms to the chromium center, whereas $Cr(en)_2SbS_4$ contains isolated SbS_4^{3-} anions.[40] In the structure of $[Ni(C_4H_{13}N_3)_2]_2Sb_4S_8$, there are cyclic $[Sb_4S_8]^{4-}$ anions (**6**), where four pyramidal SbS_3 units share common corners to build an eight-membered ring in a chair conformation.[38]



(**6**)

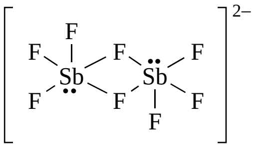
The reaction of $[CpCr(CO)_3]_2$ with Sb_2S_3 under mild reaction conditions gives a tetrachromium complex $[Cp(CO)_3Cr]_2Sb–S–Sb[Cr(CO)_2Cp]_2$.[44] The affinity of antimony(III) to sulfur is also reflected in the great number of complexes with xanthate, dithiocarbamate, dithiophosphinates, and other sulfur ligands.[45] These complexes display a great structural diversity, which ranges from monomeric to polymeric supramolecular assemblies. They are usually prepared by reactions of $SbCl_3$ and the corresponding acids or salts.

7 ANTIMONY HALIDES

7.1 Antimony(III) Halides and Sb_2I_4

Antimony trihalides SbX_3 are well known as stable compounds with X = F, Cl, Br, I.

The trifluoride, SbF_3, is a colorless crystalline solid, which can be prepared by the reaction of Sb_2O_3 with hydrogen fluoride. The structure contains pyramidal SbF_3 molecules (Sb–F 1.92 Å) linked through fluorine bridges (Sb···F 2.61 Å) to give each antimony atom a very distorted octahedral environment. SbF_3 is a useful fluorinating agent for many inorganic and organic compounds, for example, for the preparation of PF_3 from PCl_3. As strong Lewis acid, SbF_3 reacts with alkali metal fluorides with the formation of M_2SbF_5, $MSbF_4$, or other salts. The SbF_5^{2-} ion is a distorted ψ-octahedral with Sb below the basal plane of four F atoms. The SbF_4^- ion is associated through fluorine bridges to dimers $(SbF_4^-)_2$ (**7**) in $NaSbF_4$ or to tetramers $(SbF_4^-)_4$ in $KSbF_4$. More complex anions include $Sb_2F_{11}^-$, $Sb_3F_{16}^-$, $Sb_4F_{17}^-$, and $Sb_4F_{13}^-$.[46]



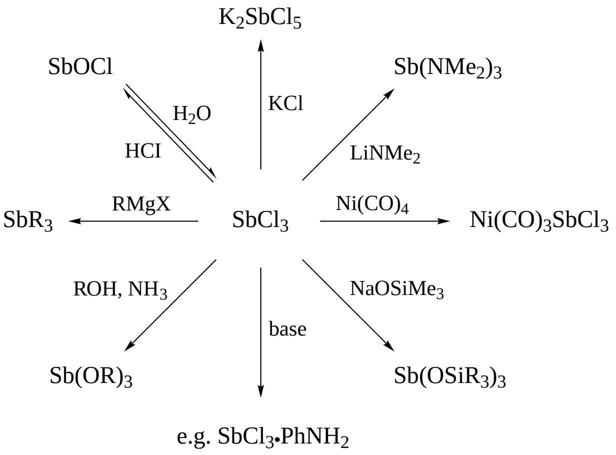
(**7**)

Antimony trichloride, $SbCl_3$, is made by reaction of Sb_2O_3 with hydrochloric acid. The crystals of $SbCl_3$ (mp 73 °C) are hygroscopic. They form a clear solution in water. Dilution results in the formation of insoluble oxy chlorides through the sequence of reactions shown in equation (7).

$$SbCl_3 \xrightarrow[H_2O]{\text{limited}} SbOCl \xrightarrow[H_2O]{\text{more}} Sb_4O_5Cl \xrightarrow{460\,^\circ C} Sb_8O_{11}Cl_2 \qquad (7)$$

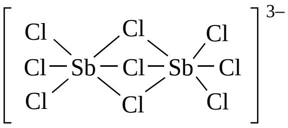
The structure of SbOCl consists of polymeric sheets of the composition $Sb_6O_6Cl_4^{2+}$ formed by linking Sb atoms through oxygen and chlorine bridges. The positive charge in the SbO_6Cl_4 sheet is balanced by layers of chloride ions. Melts of $SbCl_3$ (bp 223 °C) can be used as nonaqueous solvents, particularly for chloride transfer reactions. However, its self-ionization to give $SbCl_2^+$ and $SbCl_4^-$ is very low (conductivity 1.4 $10^{-6}\,\Omega^{-1}\,cm^{-1}$). $SbCl_3$ has a pyramidal structure in the gas phase. In the solid state, there are strong intermolecular Sb···Cl interactions.[46] $SbCl_3$ is an important antimony reagent. Some reactions are shown in Scheme 4.

$SbCl_3$ is a weak electron pair donor but an excellent acceptor and many complexes of $SbCl_3$ with donor molecules L are known.[47,48] There are complexes of the types $LSbCl_3$ or L_2SbCl_3 with bisphenoidal or tetragonal pyramidal structures respectively. Addition of Cl^- to $SbCl_3$ gives bisphenoidal



Scheme 4

$SbCl_4^-$, square pyramidal $SbCl_5^{2-}$, and octahedral $SbCl_6^{3-}$. The successive additions of Cl^- are made trans to Cl in pyramidal $SbCl_3$, probably, using the vacant Sb–Cl σ^* orbital as acceptor orbital. The resulting Cl–Sb–Cl units can be treated as 3 center, 4 electron systems. Octahedral coordination is also observed in the bifacial bioctahedral anions $Sb_2Cl_9^{3-}$ (**8**).[46]



(**8**)

Colorless $SbBr_3$ (mp 96.6 °C, bp 288 °C) and red SbI_3 (mp 171 °C, bp 400 °C) can be made from the elements or by reaction of HX with Sb_2O_3. In SbI_3, the Sb atom occupies octahedral interstices in hexagonal close-packed assemblies of I atoms (3 Sb–I 2.87 Å, 3 Sb···I 3.32 Å). Many complex derivatives of SbI_3 are known (e.g. $Sb_2I_9^{3-}$, $Sb_3I_{11}^{2-}$, $Sb_5I_{18}^{3-}$, $[SbI_4^-]_x$, $[Sb_2I_7^-]_x$).[46] A binuclear Sb(III) complex with bridging iodine and sulfur atoms of the type LSb(μ-I)$_2$(μ-S)SbL is formed by reacting antimony powder with diiodine and ($SPPh_2NHPPh_2S$) (HL).[49]

Sb_2I_4 is formed in SbI_3 melt at 230 °C according to equation (8).

$$4SbI_3 + 2Sb \rightleftharpoons 3Sb_2I_4 \quad (8)$$

7.2 Antimony(V) Halides

Known halides of Sb(V) are SbF_5 and $SbCl_5$. Antimony pentabromide and antimony pentaiodide are unknown because Sb(V) is too strongly oxidizing for these heavier halogens.

Antimony pentafluoride, SbF_5, is a colorless, very viscous liquid (mp 8.3 °C, bp 141 °C) formed by reaction of HF with $SbCl_5$. The viscosity is probably a result of the polymeric chains of cis-bridged SbF_6 octahedra, [*cis*-SbF_4(μ-F)]$_x$. In the crystalline state, SbF_5 exists as a tetramer $(SbF_5)_4$. Antimony pentafluoride is a very powerful Lewis acid and readily abstracts fluoride ions from metal fluorides (MF) to form $M^+SbF_6^-$ or with additional SbF_5 complexes of the type $[F_5Sb–F–SbF_5]^-$ forms $[F_5Sb–F–SbF_5–FSbF_5]^-$. The low nucleophilicity of these anions is useful for the stabilization of salts like $O_2^+SbF_6^-$, $Me_3C^+SbF_6^-$, $AuXe_4^{2+}[Sb_2F_{11}^-]_2$, $[XeCl][Sb_2F_{11}]$, $[Pt(CO)_4][Sb_2F_{11}]_2$, and $S_4^{2+}(Sb_3F_{11}^-)_2$.[50–52]

SbF_5 is also the key ingredient of the strongest known protonic acids (super acids). Addition of SbF_5 to liquid HF or HSO_3F substantially increases its acidity owing to the formation of $H_2F^+SbF_6^-$, $H_3F_2^+SbF_6^-$, $H_2F^+Sb_2F_{11}^-$, or $H[F_5SbOSO_2F]$. Superacid solutions derived from $SbF_5/HSO_3F/SO_2$ and HF/SbF_5 are useful for the protonation of very weak bases such as formaldehyde to give H_2COH^+ or of carbonic acid to give $C(OH)_3^+$. Crystals of $C(OH)_3^+SbF_6^-$ were obtained by reaction of carbonic acid trimethylsilyl ether with HF/SbF_5 (equation 9).[53]

$$OC(OSiMe_3)_2 \xrightarrow[-\ Me_3SiF]{HF/SbF_5} C(OH)_3^+\ SbF_6^- \quad (9)$$

Antimony pentachloride, $SbCl_5$, is a liquid (mp 4 °C, bp 140 °C dec.), which can be obtained by reaction of $SbCl_3$ with elemental chlorine. Solid $SbCl_5$ exists in two modifications: above – 54.1 °C, it is trigonal bipyramidal, below this temperature, it changes reversibly into a double chlorine-bridged dimer.[54] $SbCl_5$ decomposes at 140 °C with formation of $SbCl_3$ and Cl_2. It is a Lewis acid with a strong tendency to interact with a ligand (L) to give octahedral complexes $LSbCl_5$.[55] Reactions with chloride ion donors lead to ionic compounds with $SbCl_6^-$ anions and unusual cations. Examples are shown in equations (10) and (11).

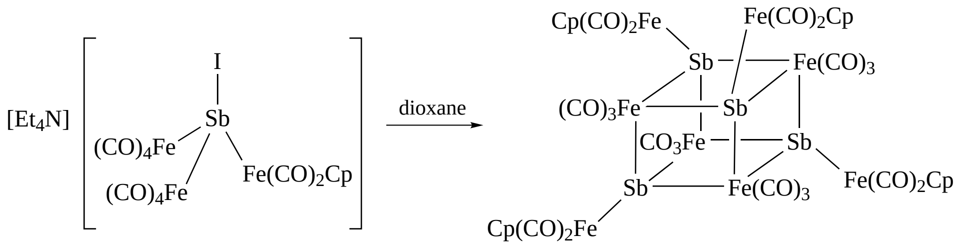
$$AlCl_3 + SbCl_5 \longrightarrow AlCl_2^+SbCl_6^- \quad (10)$$

$$PCl_5 + SbCl_5 \longrightarrow PCl_4^+SbCl_6^- \quad (11)$$

Methyl sulfonic acid reacts with antimony(V) chloride and water to yield $Cl_3SbO(OH)(O_2S(O)CH_3)SbCl_3$, a binuclear complex with bridging sulfonato groups.[56] Binuclear Sb(V) complexes are also formed from $SbCl_5$ and diphenylphosphoric acid or benzylphosphonic acid alkyl ester in water.[57,58]

8 TRANSITION-METAL COMPLEXES WITH Sb$_n$ LIGANDS

The coordination of ‘naked’ antimony atoms Sb$_n$ is achieved in complexes with Sb, Sb_2, *cyclo*-Sb_3, and *cyclo*-Sb_5 ligands.[59] Terminal Sb ligands exist in the anionic



Scheme 5

complexes of the type $(CO)_nM{\equiv}Sb^-$ ($n = 6$, M = Cr, Mo, W; $n = 5$, M = Fe). These unstable species are obtained by reactions of transition-metal carbonyls with the anion Sb_2^- formed by the laser ablation of elemental antimony.[60] $[\{Cp^x(CO)_2Fe\}SbCl_2]$ ($Cp^x = \eta^5$-$C_5H_3{}^tBu$) reacts with Mg to give $[Sb\{Fe(CO)_2Cp^x\}_3]$ or with $Na_2[Fe(CO)_4]$ to give the clusters $[\{SbFe(CO)_2Cp^x\}_3\{Fe(CO)_3\}_4]$ and $[\{Fe_3(CO)_9\}\{SbFe(CO)_2Cp^x\}_2]$.[61,62]

Oxidation of $[NEt_4]_2[Ni_{15}Sb(CO)_{24}]$ with $SbCl_3$ leads to the $[Ni_{31}Sb_4(CO)_{40}]^{6-}$ hexa anion, which displays four semi-interstitial Sb atoms.[63] The $[Fe_2Sb(CO)_5Cp]_4$ ($Cp = C_5H_5$) cluster is formed by thermolysis of $[Et_4N][\{Fe(CO)_4\}_2\{Fe(CO)_2Cp\}SbI]$ (Scheme 5). The cluster contains the cubane $[Fe_4Sb_4]$ core.[64]

The reaction of $SbCl_3$ with $[Ni_6(CO)_{12}]^{2-}$ gives the cluster anions $[Ni_{15}Sb(CO)_{24}]^{2-}$ and $[Ni_{11}Sb_2(CO)_{18}]^{3-}$.[65] Sb_2, *cyclo*-Sb_3, and *cyclo*-Sb_5 units are stabilized as ligands in transition-metal complexes, for example, the tetrahedranes $Sb_2[Mo(CO)_2Cp^*]_2$ and $Sb_3[Mo(CO)_2Cp^*]$, or in the triple-decker $Cp^xMo(Sb_5)MoCp^x$.[66,67]

1 INTRODUCTION

The first organoantimony compound, triethylstibine, was reported in 1850. Since then, a wide range of compounds with antimony mainly in the +3 and +5 oxidation states was studied. In this article, the focus is mainly on the results published between 1993 and 2003. Several general overviews of the chemistry of organoantimony compounds were presented in this period in books and annual reviews.[1–5]

2 TRIVALENT ANTIMONY

2.1 Tertiary Stibines

A common method for the synthesis of tertiary stibines with alkyl, aryl, or other organic groups is the reaction between Grignard reagents and $SbCl_3$ (equation 1) in diethylether or tetrahydrofuran.

$$3RMgX + SbX_3 \longrightarrow R_3Sb + MgX_2 \qquad (1)$$

However, when trimethylstibine is synthesized in this way, it is difficult to separate the product from the solvent. Pure trimethylstibine can be obtained together with $MeSbBr_2$ by a scrambling reaction (equation 2) of Me_2SbBr in the absence of a solvent.[6]

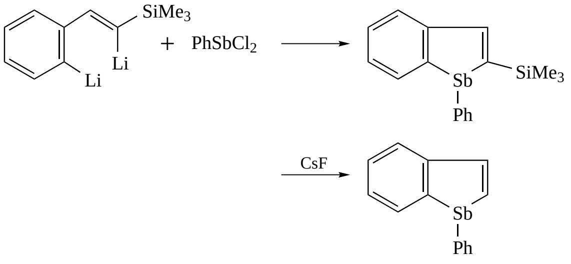
$$2Me_2SbBr \longrightarrow Me_3Sb + MeSbBr_2 \qquad (2)$$

Me_3Sb is also formed in very low yield by the process of biomethylation of Sb_2O_3 or other antimony compounds by the wood rotting fungus *Phaeolus schweinitzii*.[7]

Other useful organometallic reagents for the preparation of tertiary stibines or related heterocyclic compounds are compounds of lithium, aluminum, tin, copper, zirconium, and other metals.[8–13] In most cases, these metal compounds are reacted with antimony chlorides or bromides. Good yields of tertiary stibines were, however, also obtained by the interaction (equation 3) of trialkylaluminium reagents and tris(dimethylamino)stibine.[11]

$$6R_3Al + 2Sb(NMe_2)_3 \longrightarrow 2R_3Sb + 3[R_2AlNMe_2]_2 \qquad (3)$$

A dilithium reagent is used for the synthesis of a stibaindol (**1**) (equation 4).[13]



(4)

(**1**)

Tertiary stibines are volatile liquids or solids. The aryl derivatives are air-stable but the trialkyl stibines are air-sensitive compounds, with at least the lower members being spontaneously flammable in air. They are strong reducing agents and can be used for the removal of halogen atoms from many substrates.

Triphenylstibine Ph_3Sb and, less frequently, trialkylstibines or bi- and tridentate stibine ligands, for example, $CH_2(SbPh_2)_2$ and $CH_3C(CH_2SbPh_2)_3$ are used as donor ligands in transition metal complexes.[14,15] $(CF_3)_3Sb$ is exceptional because it does not act as a donor but as an electron pair acceptor in the reaction with a carbene (equation 5).[16]

$$(CF_3)_3Sb + {:}\overline{CN(Mes)C_2(Cl)_2N}Mes \longrightarrow (CF_3)_3Sb{-}\overline{CN(Mes)C_2(Cl)_2N}Mes \qquad (5)$$

2.2 Organoantimony(III) Halides and Pseudohalides

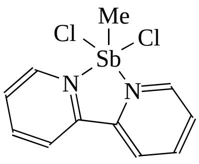
Methods to synthesize organoantimony(III) halides include the thermal elimination of organohalides from organoantimony(V) dihalides or trihalides, redistribution reactions, or

partial substitution of halogens in antimony trihalides using organometallic reagents.[17,18] The latter method was used in the reaction of tris(trifluoromethyl)phenyl lithium and antimony trichloride, which yields the corresponding chlorostibine (equation 6).[19]

$$2RLi + SbCl_3 \longrightarrow R_2SbCl + 2LiCl \quad (6)$$
$$R = 2,4,6\text{-}(CF_3)_3C_6H_2$$

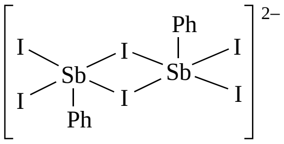
A racemic monochloride with a chiral antimony center, RR′SbCl [R = 2-(Me_2NCH_2)C_6H_4, R′ = CH($SiMe_3$)$_2$], is formed by the reaction of R′$SbCl_2$ with RLi. The compound is stable to inversion up to 160 °C in solution.[20] Alkylantimony(III)chlorides of high purity are formed by reacting alkylphenylstibines with gaseous HCl. This method was used for the synthesis of Me_2SbCl from $PhSbMe_2$. Subsequent halide exchange with NaI gives crystalline Me_2SbI.[21]

Many organoantimony(III) halides are Lewis amphoteric. They have acidic sites on the Sb atoms and they are also basic through the lone pairs of electrons on the halogen atoms. A frequently encountered consequence of this dual nature is the formation of coordination polymers in the solid state. The resulting structures formed through self-assembly of molecules were considered in a book and in a review article.[22,23] The Lewis acidity of organoantimony halides is also reflected in the tendency to form stable adducts with neutral donors or with halide anions. The 1:1 adduct (**2**) is formed by reaction of methylantimony dichloride with 2,2′-bipyridine.[24]

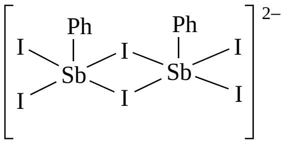


(**2**)

Intramolecular N··Sb interactions exist in $RSbCl_2$ [R = 6-Me-2-Pyr(Me_3Si)$_2$C].[25] The addition of tetramethylstibonium iodide to $PhSbI_2$ leads to the salts $[Me_4Sb]_2[Ph_2Sb_2I_6]$. The dianions $[Ph_2Sb_2I_6]^{2-}$ (**3**) form as cis- and trans-isomers.[26]



trans-(**3**)



cis-(**3**)

Self-association occurs also in organoantimony pseudohalide derivatives. K[PhSb$(SCN)_3$] has a polymeric structure in which the S atoms of one SCN are in bridging positions between pairs of Sb atoms.[27]

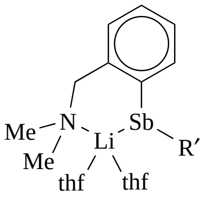
2.3 Diorganoantimony Cations and Anions

Diorganoantimony cations R_2Sb^+ with six valence electrons at antimony are unstable species. Coordination of donors leads to stable cationic adducts. One example is $[SbPh_2\{OP(NMe_2)_3\}_2]PF_6$, where two hexamethylphosphoric acid triamide molecules are coordinated to the cationic antimony center.[28] Intramolecular coordination of both amine arms of the aryl ligands leads to the stabilization of $[SbR_2][PF_6]$ (R = 2-$Me_2NCH_2C_6H_4$).[28] Cationic Sb(III) compounds exist also as sandwich complexes in $[Cp'_2Sb][AlCl_4]$(Cp′ = C_5Me_5, $C_5H_2{}^tBu_3$-1,2,4).[29]

Anionic diorganoantimony species, that is, diorganoantimonides R_2Sb^- are formed by cleavage of tertiary stibines with alkali metals or by metalation of primary stibines. Cleavage of a Sb–C bond of triarylstibines with formation of diarylantimonides is easily achieved in solutions of sodium in liquid ammonia (equation 7).[30]

$$R_3Sb + 2Na \longrightarrow R_2SbNa + RNa \quad (7)$$

Metalation of RR′SbH with BuLi gives the chiral lithium antimonide RR′SbLi [R = 2-($Me_2NCH_2C_6H_4$, R′ = CH($SiMe_3$)$_2$] (**4**) that forms RR′SbNa after transmetalation with ^{t}BuONa in the presence of tetramethylethylenediamine.[20] The pendant amine arm of (**4**) is coordinated to the alkali metal center.



(**4**)

2.4 Organoantimony Hydrides

The chemistry of organoantimony hydrides (primary stibines, $RSbH_2$, or secondary stibines, R_2SbH) has been discussed in a recent review article.[31] Hydrides with smaller organic groups tend to be less stable and result in lower yields, whereas those with bulkier groups are more stable and yields of 50% and above are common. Comparatively stable monomeric species of the type $RSbH_2$ and R_2SbH have been formed with substituents R, which may be either an alkyl group containing no β-hydrogen atoms, for example, Me_3CH_2, Me_3SiCH_2 (Me_3Si)$_2$CH, or bulky aryl groups. The primary stibine 2,6-$Trip_2C_6H_3SbH_2$ (Trip = 2,4,6-triisopropylphenyl) is of extraordinary stability. It is a white crystalline solid that decomposes at 195 °C and is indefinitely stable at room temperature under N_2 in the absence of light.[32] The reaction with BuLi gives 2,6-$Trip_2C_6H_3$(Li)SbH.

The most frequently used synthetic procedure for organoantimony hydrides is the reaction of an organoantimony

halide with lithium aluminum hydride at low temperatures in an ether solvent. Isobutylstibine $Me_2CHCH_2SbH_2$ is formed in 59% yield by this method.[33] Not only a primary stibine $RSbH_2$ but also a distibine R(H)Sb–Sb(H)R [R = $(Me_3Si)_2CH$] is formed when bis(trimethylsilyl)methylantimony dichloride is reacted with $LiAlH_4$.[34] The distibine is a yellow crystalline compound that exists in the meso form in the solid state. A racemic chiral stibine RR′SbH R = $(Me_3Si)_2CH$, R′ = CH_3 is formed from $RSbH_2$ and MeI in the presence of a base.[34]

Other methods of organoantimony hydride synthesis are reactions of R_2SbLi with $(Me_3NH)Cl$ or methanolysis of silylstibines $RSb(SiMe_3)_2$ or $R_2SbSiMe_3$. Vinyl stibine $H_2C{=}C(H)\text{-}SbH_2$ is obtained from vinyl tributylstannane on successive reactions (equation 8) with $SbCl_3$ and Bu_3SnH.[35]

$$H_2C{=}C(H)\text{–}SnBu_3 \xrightarrow{SbCl_3} H_2C{=}C(H)\text{–}SbCl_2 \xrightarrow{Bu_3SnH} H_2C{=}C(H)\text{–}SbH_2 \qquad (8)$$

Arylstibines $RSbH_2$, R = Ph, *p*-Tol react with a range of organic substrates, for example, styrene, alkynes, prochiral ketones, with transfer of the hydrogen atoms.[36] $RSbH_2$ (R = Me_3SiCH_2) can be used together with trimethylindium to deposit thin films of InSb at 450 °C.[37]

2.5 Group 13–15 Element Derivatives of Sb(III)

Organoantimony compounds with bonds between Sb and group 13 elements were discussed in a recent review.[38] They are known as Lewis acid–base adducts $R_3Sb\text{-}MR_3$ (M = Al, Ga, In) and as four- or six-membered heterocycles $(R_2Sb\text{-}MR_2)_n$ ($n = 2, 4$). Pyrolysis of these compounds leads to the semiconducting materials AlSb, GaSb, and InSb.

Organoantimony group 14 element compounds include organometallic stibines of the types R_2SbMR_3 and $RSb(MR_3)_2$ (M = Si, Ge, Sn). They are formed by reactions of R_2SbLi with R_3MCl (M = Si, Ge, Sn), by dehalogenation of $RSbBr_2$ and Me_3MCl with Mg, or by exchange reactions.[39,40] The silyl derivatives R_2SbSiR_3 and $RSb(SiR_3)_2$ are useful reagents for the synthesis of compounds with Sb–H, Sb–Sb, or Sb–metal bonds.[41]

Nitrogen derivatives of organoantimony(III) are known as moisture-sensitive amides R_2SbNR_2, $RSb(NR_2)_2$, and stibino amines $(R_2Sb)_3N$. The amides are obtained from the reactions of organoantimony(III) mono- and dihalides with $LiNR_2$ or R_2NH in the presence of Et_3N.[42,43] Tris(diphenylstibino)amine $(Ph_2Sb)_3N$ is formed by ammonolysis of Ph_2SbCl in liquid NH_3.[44] It contains an almost planar Sb_3N core.

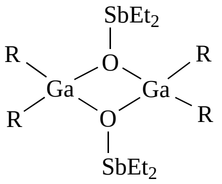
2.6 Chalcogen Derivatives of Sb(III)

The principal organoantimony(III) chalcogen derivatives of Sb(III) are compounds of the types $(RSbE)_n$, $(R_2Sb)_2E$, $[(R_2Sb)_3E]^+$, $RSb(ER)_2$, and R_2SbER, (E = group 16 element).

A four-membered heterocycle *trans*-$(RSbO)_2$ [R = 2,4,6-$((Me_3Si)_2CH)_3C_6H_2$] is formed by reaction of single crystals of RSb=SbR with atmospheric oxygen with retention of crystallinity.[45,46] Hydrolysis of $RSbCl_2$ [R = $(Me_3Si)_2CH$] leads to *cyclo*-$(RSbO)_n$ ($n = 3, 4$). The core of crystalline *cyclo*-$[(Me_3Si)_2(CHSbO)_4\cdot H_2O]$ is a boat-shaped 8-membered Sb_4O_4 ring with the organic substituents in trans positions.[47] Distibine oxides of the type $R_2SbOSbR_2$ are obtained by hydrolysis of diorganoantimony halides or by oxygenation of distibines. $(Me_2Sb)_2O$ is best prepared by reaction of Me_2SbBr with aqueous NaOH. In the solid state, the molecules are arranged as *zigzag* chains through intermolecular Sb–O interactions (Figure 1).[48]

Oxygen in the environment of three antimony atoms exists also in the planar oxonium salt $[(Me_2Sb)_3O]Br$, which is formed by reaction of $(Me_2Sb)_2O$ with Me_2SbBr.[49] Tetraaryldistibine oxides are formed by air oxidation of the corresponding distibines.[50]

The most common method for synthesizing organoantimony(III) mono and di alkoxides is the reaction of R_2SbX or $RSbX_2$ with the appropriate sodium alkoxide. Related organometallic compounds are the group 14 element derivatives $RSb(OMR_3)_2$ (M = Si, Ge, Sn; R = alkyl, aryl).[51] $[R_2GaOSbEt_2]_2$ (**5**), a compound where oxygen is in the environment of two Ga atoms and a Sb center, is formed by reaction of R_3Ga (R = Me_3SiCH_2), Et_4Sb_2, and oxygen.[52]



R = (Me_3SiCH_2)

(**5**)

Organoantimony derivatives of the heavier chalcogens of the types $(RSbE)_n$ (E = S, Se, Te) are formed by

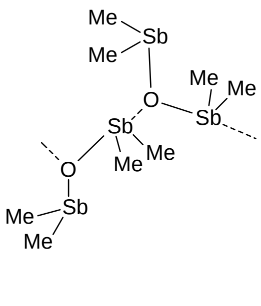


Figure 1 Chains in the crystals of $Me_2SbOSbMe_2$

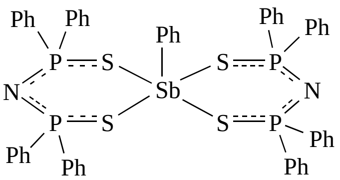
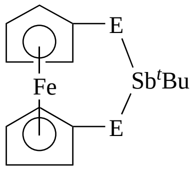
elimination of salt from $RSbCl_2$ and Na_2E. Reaction of $RSbH_2$ with sulfur provides the cyclic polysulfides $RSbS_n$ (R = 2,4,6-[$(Me_3Si)_2CH]_3C_6H_2$, $n = 5$, 7).[53] The binuclear chalcogenides $(R_2Sb)_2E$ are obtained by insertion of elemental chalcogens into the Sb–Sb bonds of distibines or by reaction of R_2SbCl with Na_2E.[54,55] Reaction of distibines with disulfides, diselenides, or ditellurides give monochalcogentate R_2SbER (E = S, Se, Te), which undergo redistribution to dichalcogenates and other products like $RSb(ER)_2$.[54,56,57] The affinity of antimony to sulfur is reflected in the stability of organoantimony(III) complexes with bidentate sulfur ligands, for example, dithiocarbamates and phosphinates.[54] The dithiophosphinate $Me_2SbS_2PMe_2$ has a polymeric chain structure with intermolecular Sb···S contacts. It is formed by reaction of $Me_2SbSbMe_2$ with $[Me_2P(S)S]_2$.[58] The reaction of $PhSbCl_2$ with $K[(SPPh_2)_2N]$ gives $PhSb[(SPPh_2)_2N]_2$ (**6**), a complex where the Sb center is in a square pyramidal environment.[59]



(**6**)

1,3-dioxa, -thia-, -selena-, tellura-ferrocenophanes (**7**) containing antimony in the central bridge position are formed by HCl elimination from $^tBuSbCl_2$ and the corresponding ferrocene derivatives containing EH or ELi bonds.[60]

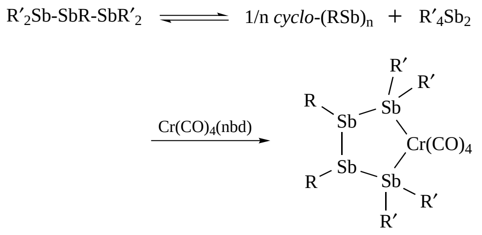


E = O, S, Se, Te

(**7**)

3 COMPOUNDS WITH Sb–Sb SINGLE BONDS

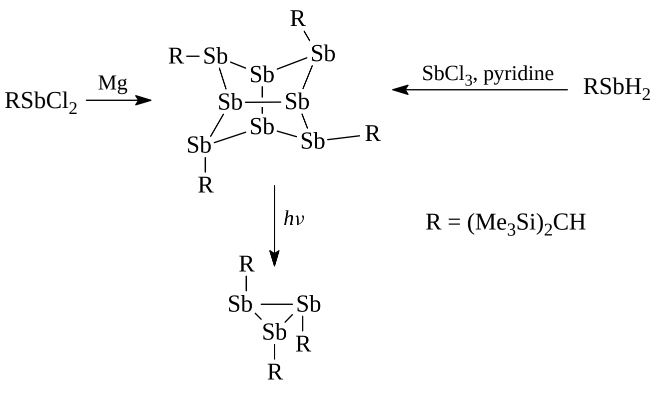
Known neutral organometallic compounds with normal covalent Sb–Sb bonds comprise distibines, R_2SbSbR_2, cyclostibines R_nSb_n ($n = 3$–6), *catena*-stibines $R_2Sb(SbR)_nSbR_2$ ($n = 1,2$), and polycycles R_nSb_m ($m > n$). Dative Sb–Sb bonds exist in the adducts R_3Sb-$Sb(R)X_2$, or in ionic species of the types R_3Sb-SbR_2^+ or $[R_2Sb$-SbR_2-$SbR_2]^+$. Also dicationic and anionic species, $[R_3Sb$-$SbR_3]^{2+}$ and $[R_2Sb$-Sb-$SbR_2]^-$, are known.[54,61–63] Distibines are formed by reaction of R_2SbBr with Mg, by elimination of dihydrogen from R_2SbH, by reactions of R_2SbNa with $BrCH_2CH_2Br$ in liquid NH_3, or by other methods. Distibines like almost all organometallic compounds with Sb–Sb bonds are yellow. However, the distibines R_2Sb-SbR_2 [R = CH_3, $R_2 = Me_2C_4H_2$] are exceptional. They form red solid phases that consist of linear chains of molecules with close intermolecular Sb···Sb contacts. Cyclostibines with known crystal structures are trimers (tristibiranes) R_3Sb_3 [R = $(Me_3Si)_2CH$], tetramers (tetrastibetanes) R_4Sb_4 [R = ^tBu, $(Me_3Si)_2CH$, Me_5C_5], pentamers (pentastiboles) R_5Sb_5 ([R = Me_3CCH_2), or hexamers (hexastibanes) R_6Sb_6 (R = Ph, Tol). *Cyclo*-R_3Sb_3 has been prepared by reaction of $RSbCl_2$ with Li_3Sb or by photochemical ring contraction of the corresponding tetrastibetane. The rings *cyclo*-R_nSb_n ($n = 4$–6) are formed from $RSbBr_2$ and Mg in THF, by air oxidation of $RSb(SiMe_3)_2$, or by elimination of hydrogen from $RSbH_2$. Several *catena*-stibines $R_2Sb(SbR)_nSbR_2$ exist as components of ring-chain equilibria (equation 9).



(9)

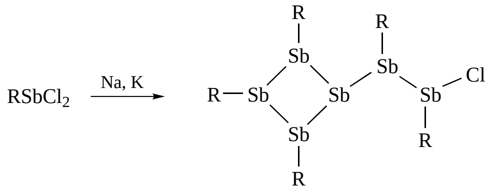
R = Me_3SiCH_2, R′ = Me, Ph; nbd = norbornadiene

Structurally established antimony polycycles include the types R_4Sb_8 and R_6Sb_8. R_4Sb_8 (R = $(Me_3Si)_2CH$) is formed by reduction of $RSbCl_2$ with Mg or by reaction of $RSbH_2$ with $SbCl_3$ and pyridine. The photochemical ring contraction of Sb_8R_4 leads to *cyclo*-$(RSb)_3$ (Scheme 1).[61,64]



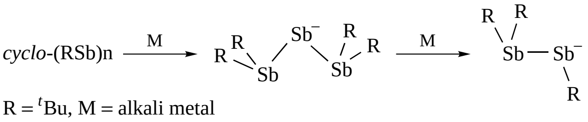
Scheme 1

A pentachloro hexastibane Sb_6R_5Cl is obtained by reaction of $RSbCl_2$ with Na/K (equation 10).[65]



(10)

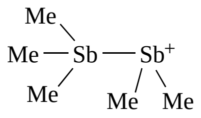
$^tBu_4Sb_4$ is a source for the syntheses of complexes with Sb_n ligands or four polynuclear antimonides.[63] Reduction of $^tBu_4Sb_4$ with alkali metals (M = Li, Na, K) in the presence of $(Me_2NCH_2CH_2)_2NMe$ gives the anionic species $^tBu_4Sb_3{}^-$ and $^tBu_3Sb_2{}^-$ (equation 11).[61,63]



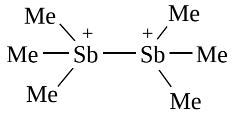
(11)

R = ^{t}Bu, M = alkali metal

Cationic species with Sb–Sb bonds are formed by scrambling reactions or addition of a stibine donor to a Lewis acidic antimony center. Scrambling reactions of Me_2SbBr lead to the ionic complex $(Me_3Sb\text{-}SbMe_2)_2(MeSbBr_2)_2$ containing cations (**8**) that consist of pyramidal Me_3Sb bonded to bent Me_2Sb units through short (2.82 Å) Sb–Sb bonds.[66]



(**8**)



(**9**)

The dicationic species (**9**) in $(Me_3Sb\text{-}SbMe_3)(SbF_6)_2$ is formed from Me_3Sb and HF/SbF_5.[67]

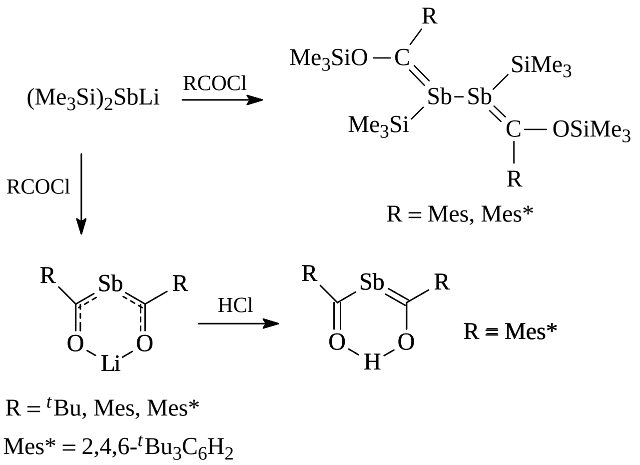
4 LOW-COORDINATION ORGANOANTIMONY CHEMISTRY

Low-coordination organoantimony compounds are species with the coordination numbers 1 or 2 at the antimony centers, for example, stibinidenes R–Sb, distibenes R–Sb=Sb–R, stibaalkenes, R–Sb=CR_2, or cyclic compounds.[45] Stable monomeric stibinidenes or stibaalkenes are not known. Complexes with stibinidene ligands are, however, well established, and trapping of a sterically hindered stibinidene, RSb, R = 2,4,6-$(Me_3Si)_2CH]_3C_6H_2$ is achieved as a cycloadduct with 1,3-butadienes.[68] Stibaalkene monomers have been considered as intermediates in various reactions. Structurally authenticated compounds with Sb=C bonds are stiba dionato complexes, stiba enols, or distibabutadienes formed from $LiSb(SiMe_3)_2$ and RCOCl. (Scheme 2).[45,69,70]

Monomeric distibenes *trans*-RSb=SbR exist with protection of very bulky aryl groups. They are formed by dehalogenation of the corresponding dihalides with Mg or by deselenation of a triselenatristibane (Scheme 3).[45,46,71,72]

With sterical protection also, a compound of the type RBi = SbR featuring a double bond between antimony and bismuth is stabilized.[72]

Known structures where two coordinate Sb centers are incorporated in aromatic ring systems are shown in Figure 2. The chemistry of these heterocycles is well documented in review articles.[45,73]



Scheme 2

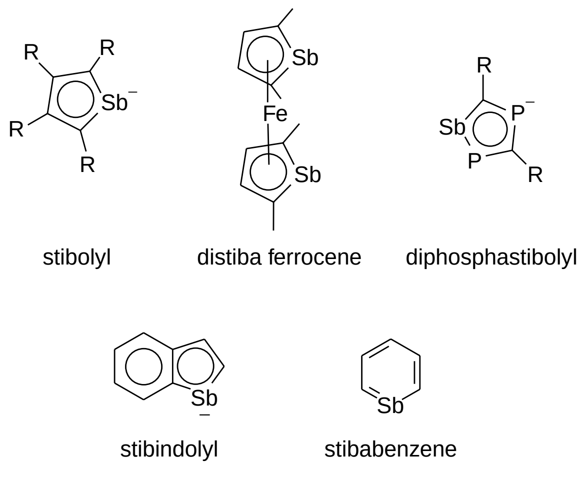


Figure 2 Heterocycles with two coordinate antimony atoms

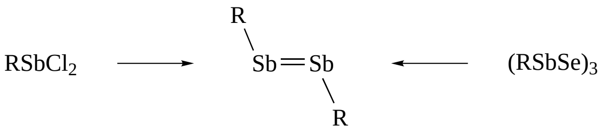


R = 2,6-$Mes_2C_6H_3$, 2,6-$(^iPr_3C_6H_2)_2C_6H_3$ R = 2,4,6-$(Me_3Si_2)_2CH)_3C_6H_2$

Scheme 3

5 PENTAVALENT ORGANOANTIMONY COMPOUNDS

Antimony forms numerous stable pentavalent organometallic compounds; among these are penta alkyls and aryls, mixed organohalides, and various chalcogen and nitrogen derivatives.

5.1 Penta Alkyls and Aryls

The pentaorgano compounds are thermally stable but air sensitive. They are generally synthesized by the reaction of Grignard or organolithium reagents with triorganoantimony dihalides and have monomeric molecular structures. Me_5Sb and Ph_3Me_2Sb are trigonal bipyramidal molecules.[74] Ph_5Sb is, however, approximately square pyramidal in the solid state.[75] The lithium salt of the octahedral $[Me_6Sb]^-$ ion is obtained from Me_5Sb and MeLi in tetrahydrofuran.[75] Reactions of R_5Sb with protic species including acids, alcohols, and thiols give R_4SbX products.

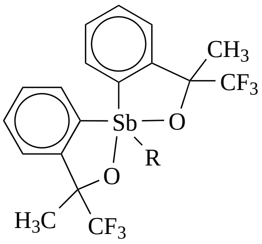
5.2 Organoantimony(V) Halides and Stibonium Salts

Examples of organoantimony(V) halides exist, ranging from $RSbX_4$ to R_4SbX. The stability decreases according to R_4SbX, R_3SbX_2, $>R_2SbX_3$ $>RSbX_4$. Tetraorganoantimonhalides R_4SbX form by addition of RX to R_3Sb.[76] They usually have ionic structures of stibonium salts, $R_4Sb^+X^-$. Ph_4SbI, however, is a molecular species with distorted trigonal bipyramidal geometry.[77] Triorganoantimony dihalides are formed by addition of X_2 to the corresponding to triorganostibines. They adopt trigonal bipyramidal structures with axial halogen atoms.[78] The reductive elimination of RX from R_3SbX_2 is an important synthetic pathway leading to diorganoantimony halides. Diorganoantimony trihalides are generally less stable than their dihalide counterparts undergoing reductive elimination to RX and $RSbX_2$ easily. They usually are strong Lewis acids and tend to form dimers with bridging halogen atoms in the solid state unless protected by bulky groups. One example for a dimeric structure is Me_2SbCl_3, where the methyl groups are on both sides of the $Cl_2Sb(\mu\text{-}Cl)_2SbCl_2$ plane and the environment of the Sb centers is octahedral. The Lewis acidic character is exemplified by the formation of a 1:1 adduct between Ph_2SbCl_3 and Ph_3SbO.[79] Organoantimony tetrahalides are the least stable in this series. However, adducts with donor ligands or the type $RSbX_4{\cdot}L$ are known.

5.3 Organoantimony(V) Chalcogen and Nitrogen Derivatives

A series of compounds analogous to organoantimony halides exist also for alkoxides and other compounds of the type $R_nSb(OR')_{(5-n)}$. Antimony tetraorganyls R_4SbOR' are formed from R_5Sb and ROH or from R_4SbCl and MOR′ (M = Na, Ag).[80] Reactions of R_5Sb with water give tetraorganoantimony hydroxides R_4SbOH.

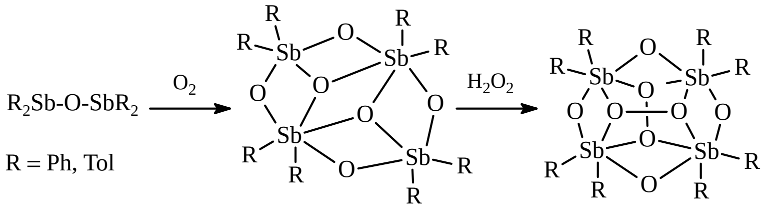
Compounds of the type $R_3Sb(OR')_2$ are usually obtained by reactions of R_3SbX_2 with NaOR′. They adopt trigonal bipyramidal structures with the oxygen atoms in axial positions. Hydrolysis of R_3SbX_2 can lead to dihydroxides $R_3Sb(OH)_2$, hydroxy halides $R_3Sb(X)OH$, or binuclear condensation products $(R_3SbX)_2O$.[81–83] Heating $R_3Sb(OH)_2$ under vacuum gives R_3SbO. A complex with intramolecular coordination of two oxygen atoms to an R_3Sb unit is the complex (**10**) that contains chiral centers at antimony and at two carbon atoms. It exists as a pair of configurationally stable diastereomers. The rates of interconversion between the diastereomers is accelerated in donor solvents and probably procedes through a hexacoordinate transition state.[84]



R = *p*-Tol

(**10**)

Alkoxides of the type $R_2Sb(OR)_3$ react with water with the formation of stibinic acids $R_2Sb(O)OH$. Their anhydrides have the formula $(R_2Sb)_4O_6$. They are molecular compounds with bridging oxygen atoms between four Sb atoms in a cage structure (**11**). The anhydrides (**11**) are formed by air oxidation of distibines $R_2Sb\text{-}SbR_2$ or by other methods.



Scheme 4

Further oxidation with hydrogen peroxide gives peroxo antimony complexes $(R_2SbO)_4(O_2)_2$ (**12**) with quadruply bridging peroxo groups (Scheme 4).[85]

A mixed anhydride of stibinic and arsinic acid has been synthesized by reaction of $(SbPh_2BrO)_2$ with $Na(O_2AsMe_2)$.[86]

Reaction of sulfur with R_3Sb or other methods give R_3SbS. R_4SbSR' or $R_3Sb(SR')_2$ is obtained from R_5Sb and HSR' or from R_3SbCl_2 and HSR in the presence of Et_3N. R_3SbBr_2 reacts with $NH_4S_2PPh_2$ to form $R_3Sb(S_2PPh_2)_2$.[87] Reaction of Se with R_3Sb leads to R_3SbSe.

Nitrogen derivatives of Sb(V) include imines $(R_3SbCl)_2NH$, diamides $R_3Sb(NR_2)_3$, and diazides $R_3Sb(N_3)_2$, which are formed by reaction of R_3SbCl_2 with NaN_3. A compound with a double-bond character of the Sb−N bond is the monomeric iminostibane $R_3Sb{=}NSO_2CF_3$ ($R = 2\text{-}MeC_6H_4$).[88]

6 TRANSITION METAL COMPLEXES WITH ORGANOANTIMONY LIGANDS

Organoantimony ligands were frequently used in the coordination chemistry of transition metals. Two recent reviews summarize this field.[14,15] The most popular antimony ligand is triphenylstibine, which is not only a good donor but also commercially available and is easy to handle. Trialkylstibines and bidentate antimony ligands like bistibino methane $(R_2Sb)_2CH_2$ are also used. An important approach is also the protection of sensitive organoantimony compounds like distibines R_2SbSbR_2, distibenes $RSb{=}SbR$, or stibinidenes RSb, in the coordination sphere of transition metal complexes.

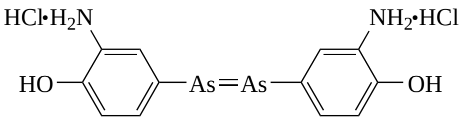
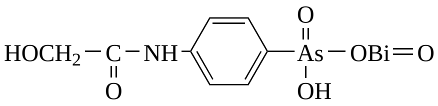
1 INTRODUCTION

Despite the popular association of arsenic to poisons, the element has found several uses. Alloys are made with Pb and to a lesser extent with Cu. The addition of small quantities of As improves the properties of Pb/Sb for storage batteries. Automotive body solder is Pb (92%), Sb (5.0%), Sn (2.5%), and As (0.5%). The III-V semiconductors especially GaAs and InAs are very important in the fabrication of LEDs, tunnel diodes, infrared emitters, laser windows, and Hall-effect devices. It also found use in agriculture as herbicide and pest controls but now is very restricted because of environmental issues. Arsenic acid, $AsO(OH)_3$, is still used in the formulation of wood preservatives but banned recently in the United States. Sodium arsenate is used to control fungi which cause measles on grapes. Sodium arsenite and monomethylarsonate are used as simple bulk weedkillers, and arsenicals such as sodium arsenate and copper acetoarsenite $[Cu(CH_3COO)_2Cu(AsO_2)_2]$ can be found in commercial household insecticides. Arsenic is also a common component of fire retardants.[1]

The toxicity of arsenic has been put into practical use in medicine. Ehrlich in 1909 developed Salvarsan, the trade name for arsphenamine (**1**), which was the first modern chemotherapeutic agent effective in the treatment of syphilis, which was eventually phased out by better organoarsenicals and latter by penicillin. Some specialist arsenical drugs are still the treatment of choice for amoebic infections like glycobiarsol (**2**).[2]

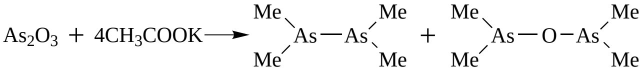


(**1**)



(**2**)

Arsenic has a prominent place in the development of modern inorganic chemistry. Lois-Claude Cadet de Gassicourt in 1757 during his experiments with arsenic-containing cobalt ores, $CoAs_2$ and $CoAsS_2$, prepared by the combination of arsenious oxide, As_2O_3, and potassium acetate, CH_3CO_2K, a red malodorous fuming liquid (Cadet's fuming liquid) that contained the first organometallic or more rigorously stated organometallioid compounds (equation 1). Latter, in the early nineteenth century it was found that the main components of the red liquid are tetramethyldiarsine (**3**) (40%) and tetramethyldiarsine oxide (**4**) (56%).[3]



(**3**) (**4**)

(1)

This article will focus on the inorganic chemistry of arsenic rather on the species that feature arsenic–carbon bonds, in which the carbon atom is part of an alkyl or aryl group, for example, (**3**) or (**4**) (these organoarsenicals may be found in the article *see* ***Arsenic: Organoarsenic Chemistry***). Only a few organoarsenicals are presented to illustrate applications or important species that were stabilized

by means of bulky organic ligands such as the arsines (**9**) and (**10**) in Section 4.1.

2 PREPARATION

The commonly encountered oxidation states of arsenic are +3, as in As_2O_3, and +5, as in As_2O_5. Formally, a −3 oxidation number can be assigned in AsH_3. But the simple ions As^{3-}, As^{3+} and As^{5+} are not known.

Arsenic is produced almost entirely as a by-product formed during the smelting of nonferrous metal ores. It occurs in appreciable amounts in a number of copper, lead, and zinc ores. The ores are treated in a manner which promotes the formation of As_2O_3. This form of arsenic sublimes at 193 °C and this physical property greatly assists in its separation and purification. The volatile arsenic compounds are collected in cooling chambers where the temperatures are gradually lowered from 220 to 100 °C or less. The condensed solids contain 90–95% arsenic trioxide. A product of very high purity can be prepared by resublimation of the solids. About 97% of arsenic produced commercially enters the commercial market as resublimed As_2O_3. Only about 3% is utilized as the metal. The free metal is prepared industrially by smelting loellingite, $FeAs_2$, or arsenopyrite, FeAsS, at 650–700 °C in the absence of air. The element is deposited under these conditions in the gas phase by condensation (equation 2).

$$\text{FeAsS} \xrightarrow{650-700\,^\circ\text{C}} \text{FeS} + \text{As(g)} \longrightarrow \text{As(s)} \quad (2)$$

In Table 1 can be found a summary of some of the more important data associated with elemental arsenic and the arsenic atom.

Table 1 Properties of elemental arsenic[1,4]

Atomic radius (calc.)	1.15 (1.14) Å
Covalent radius	1.19 Å
van der Waals radius	1.85 Å
Crystal structure	Rhombohedral
Melting point (α-As)	816 °C (at 38.6 atm)
Boiling point (α-As)	615 °C (subl.)
Density (α-As)	5.778 g cm^{-3}
Yellow As_4	1.97 g cm^{-3}
ΔH_{fusion}	369.9 kJ mol^{-1}
ΔH_{vap}	34.76 kJ mol^{-1}
Thermal conductivity	50 W m^{-1} K^{-1}
Electrical resistivity	33.3 μΩ cm (at 20 °C)
Hardness	3.5 Mohs
Electronic configuration	$[Ar]3d^{10}4s^24p^3$
Ionization energies (kJ mol^{-1})	
$M \rightarrow M^+$	947.0
$M^+ \rightarrow M^{2+}$	1798.0
$M^{2+} \rightarrow M^{3+}$	2736.0
$M^{3+} \rightarrow M^{4+}$	4837.0
$M^{4+} \rightarrow M^{5+}$	6043.0
$M^{5+} \rightarrow M^{6+}$	12310.0
Electronegativity χ (Pauling)	2.18
Stable isotopes (mass and natural abundance)	
^{75}As	74.92160 100%

At laboratory scale a useful reagent for the preparation of arsenic derivatives is arsenic (III) chloride, $AsCl_3$. A convenient synthetic method involves the reaction of As_2O_3 with sulfinyl chloride ($SOCl_2$) as shown in equation (3).[5]

$$As_2O_3 + 3SOCl_2 \longrightarrow 2AsCl_3 + 3SO_2 \quad (3)$$

3 INTERMETALLIC AND ZINTL PHASES WITH ARSENIC

3.1 Intermetallic Phases Containing Arsenic

Many metals form arsenides with interesting structures and valuable physical properties. In most cases these compounds are prepared by direct reaction of the elements in the required proportions.

The group 12 metals form intermetallics with the M_3As_2 composition. The M_3As compounds are formed with metals that are not usually thought to be univalent, for example, Ti, Zr, Hf, V, Nb, Ta, Mn. Many of the M_3As have the structure of Na_3As which is described below in the text.

With actinides one of the possible compositions found is MAs_2 like in $ThAs_2$ in which each Th atom has 9 As neighbors. Three types of structures are important with transition metals and arsenic, $CoAs_3$, NiAs and those related to FeS_2. $CoAs_3$ is a diamagnetic semiconductor that occurs in the mineral skutterudite. It has a cubic structure related to that of ReO_3 but with distortions that result in planar As_4 rings. The NiAs structure is one of the most common MX structural types. In the structure each Ni is 8-coordinate and surrounded by 6 As and by 2 Ni atoms. The As atoms form a hcp lattice in which the interstices are occupied by Ni atoms in a way that each As is surrounded by a trigonal prims of 6 Ni.[1]

Intermetallic compounds of arsenic with group 13 metals comprise the important III–V semiconductors of which GaAs along with GaP remain the most important optoelectronic emitter materials in volume production (*see* ***Semiconductors***). These include arsenides of boron, aluminum, gallium, and indium. Continuous operation at room temperature of semiconducting lasers with an operating wavelength of about 0.8 μm has been achieved with the use of GaAs/AlGaAs double heterostructure with a GaAs light-emitting layer between the AlGaAs layers. These lasers are widely used in displays and compact-disk memory-storage systems. Also InGaAsP/InP lasers with wavelengths from 1.3 to 1.5 μm are

used in optical-communication systems. For these applications the detectors are equally as important as the laser sources, and optical response at frequencies greater than 70 GHz has been achieved from a waveguide structure composed of InGaAs and InP. Intermetallic arsenides with group 14 metals form interesting materials. SnAs has a NaCl structure and it is superconductor below 3.5 K and Sn_4As_3 shows a defect NaCl structure and it is also a superconductor below 1.2 K.[6,7]

3.2 Zintl Phases with Arsenic

With arsenic, the alkaline and the alkaline earth metals form intermetallic polar compounds that are described in the literature as Zintl phases. The alkaline metals form phases with the composition M_3As whilst the alkaline earth metals form M_3As_2 phases. These compounds are not very ionic and have many metallic properties. For example, Na_3As has an hexagonal (anti-LaF_3) structure in which equal number of Na and As form hexagonal nets as in boron nitride and the remaining Na atoms are arranged in layers on either side of these nets. Each As has five neighbors at the corners of a trigonal bipyramid and six other Na atoms in a trigonal prismatic arrangement, making the total coordination number for As 11. The Na atoms have two types of environments. The Na in the NaAs net has three As atoms and six Na nearest neighbors. The structure of LiAs consists of parallel infinite spirals of As atoms (As–As distance 2.46 Å), the metallic luster and electrical conductivity indicate rather metallic bonding than ionic in this material.[1]

Ternary Zintl phases that incorporate arsenic are exemplified by Ba_4SiAs_4 (*see* ***Zintl Compounds***). The material is made of tetrahedral $SiAs_4^{8-}$ units whose charge is compensated for by the Ba cations.

Zintl phases that include transition metals and arsenic are also known. There are those that are isostructural with known main group Zintl phases. For example, Na_8TiAs_4 and Na_5HfAs_3 are isostructural with A_8SnSb_4 (A = Na, K) and Na_5SnAs_3, respectively. Other class of Zintl phases include all electronically balanced compounds that contain transition metal ions with d^0 or d^{10} closed-shell configurations. These ions are the early and late transition metals of groups 4, 5, and 6 as d^0 ions and of groups 10, 11, and 12 as d^{10} ions. There are also a couple of phases that incorporate transition metal ions with partially filled d-orbitals in which the compounds are electronically balanced, like $A_{14}MnAs_{11}$ (A = Ca, Sr, Ba, Eu). Another variant has been recently introduced with the preparation of the first examples of a mixed-valence, transition metal Zintl phase that incorporate arsenic namely, $K_{38}Nb_7As_{24}$ and $Cs_9Nb_2As_6$. The structure of $K_{38}Nb_7As_{24}$ contains isolated tetrahedra of $NbAs_4$ and two types of dimers of edge-sharing tetrahedra: dimers with only Nb^V, $[Nb_2^VAs_6]^{8-}$, and mixed-valence dimers with both Nb^{IV} and Nb^V, $[Nb^{IV}Nb^VAs_6]^{9-}$. The structure of $Cs_9Nb_2As_6$ contains only the latter dimers.[8]

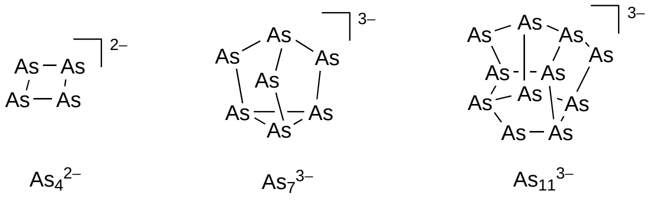


Figure 1 A few of the As_n^{m-} ions structurally characterized

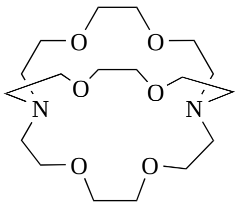
3.3 Zintl Anions with Arsenic

Reaction of group 15 elements like arsenic with alkali or alkaline earth metals forms Zintl anions of the general type As_n^{m-}. Characterization of these species has been accomplished dissolving the solids in liquid NH_3 or ethylenediamine ($H_2NCH_2CH_2NH_2$) and adding the macrocycle, 2,2,2-crypt (**5**) to complex the cations and stabilize the polyatomic anions. The fully characterized Zintl arsenic anions As_4^{2-}, As_7^{3-} and As_{11}^{3-} are shown in Figure 1.[9–12]



(**5**)

4 ARSENIC HYDRIDES

4.1 Arsine and Other Hydrides of Arsenic

Pentavalent hydrides of arsenic are not known in any form.[13] The simplest hydride of arsenic^{III}, arsine (AsH_3) is a very toxic gas (m.p. −116 °C, b.p. −62 °C) with a characteristic garlic-like odor, which in the presence of air oxidizes to As_4O_6. It is thermally unstable depositing a mirror of As in hot surfaces, a property that is used in the qualitative determination of arsenic (Marsh test).

In the laboratory, convenient synthetic routes to prepare AsH_3 is the reduction of $AsCl_3$ with $LiAlH_4$ in diethylether or THF solutions at low temperature and the reaction between arsenite and KBH_4 in acid solution (equation 4). Arsenides of electropositive metals (Na, Mg, Zn, etc.) upon treatment with acidic solutions also afford AsH_3.[1,9,14]

$$4As(OH)_4^- + 3BH_4^- + 7H^+ \longrightarrow 3H_3BO_3 + 7H_2O + 4AsH_3 \quad (4)$$

Arsine reacts with HBr and HI in the gas phase forming the corresponding onium salts $[AsH_4]Br$ and $[AsH_4]I$ (equation 5). Arsonate formation does not occur with HF and HCl because these acids have stronger H–X bonds than their heavier group 17 congeners.[15]

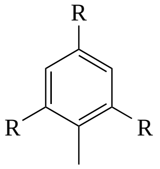
$$AsH_3 + HX(g) \longrightarrow [AsH_4]X \qquad X = Br, I \tag{5}$$

Diarsines are known but as AsH_3 they are also very unstable. Tetrahydrodiarsine, As_2H_4, has been prepared by the reaction between (Mg/Al) arsenide and cold 20% sulfuric acid. The gases are condensed in a liquid nitrogen trap and fractionally distilled. Small quantities of As_2H_4 are trapped at $-196\,°C$. As_2H_4 undergoes decomposition at $-100\,°C$ into AsH_3 and solid, polymeric, red $(As_2H)_n$. Dihydrodiarsine, As_2H_2 has been characterized as a brown solid. It has been prepared by the reaction between $AsCl_3$ and $SnCl_2$ in HCl solution (equation 6).

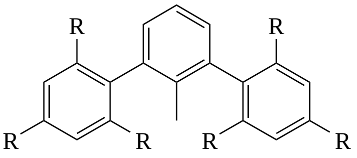
$$AsCl_3 + 4SnCl_2 + 2HCl \longrightarrow As_2H_2 + 4SnCl_4 \tag{6}$$

Tetraarsine dihydride, As_4H_2, prepared from AsH_3 and $SnCl_4$ has been characterized as a brown-red amorphous solid. It is stable when stored in a dry atmosphere free from oxidizing agents. In the absence of air it thermally decomposes into arsenic metal and AsH_3.

Stable monomeric arsenic hydride species of the type $RAsH_2$ and R_2AsH have been prepared using substituents R which have no β-hydrogen atoms and are sterically demanding like $(Me_3Si)_2N$-,[16] trisalkylphenyl ligands (**6**), 2,6-bis(trialkylphenyl)phenyl ligands (**7**)[17] and recently triptycene (Trip) (**8**).[18] Figure 2 shows the X-ray structures of two

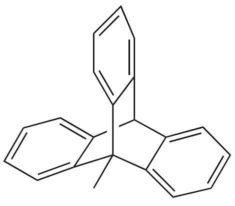


(**6**)



(**7**)

R = Me, *i*-Pr, *t*-Bu

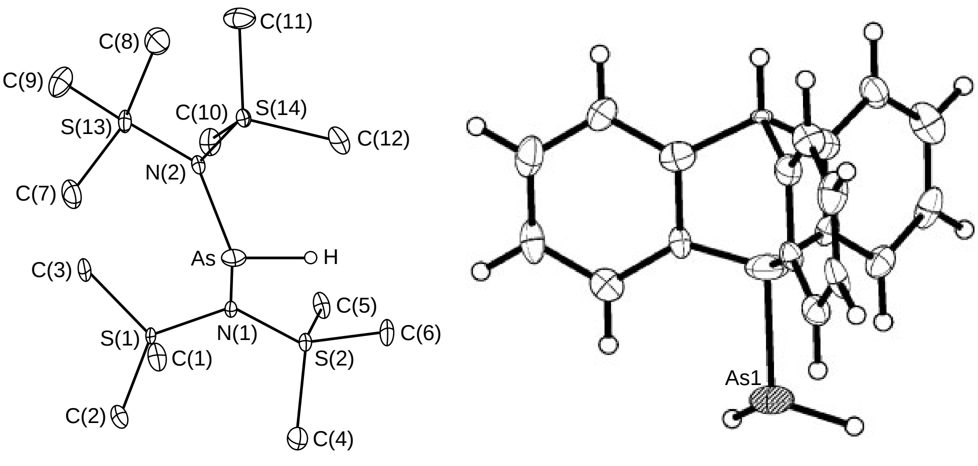


(**8**)

examples of these arsines: $[(Me_3Si)_2N]_2AsH$ (**9**)[16] and the air-stable $TripAsH_2$ (**10**).[18] Interestingly, compound (**9**) shows a monomeric pyramidal structure in the solid state contrary to the phosphine analog $\{[(Me_3Si)_2N]_2PH_2\}_2$ which is planar and features a planar P_2H_2 core.[16] The monomeric nature of (**9**) has been ascribed to the poor overlap of orbitals between As and the H atoms that prevents the formation of H-As-H bridges.

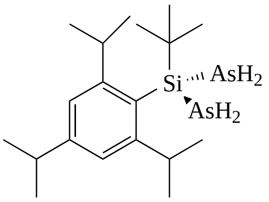
4.2 Arsine as a Ligand

Structurally characterized complexes with AsH_3 as a terminal ligand have yet to be reported.[13] This has been



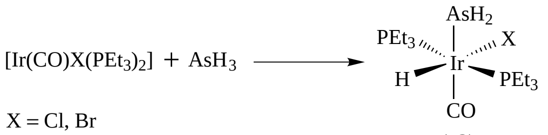
(**9**) (**10**)

Figure 2 X-ray structures of $[(Me_3Si)_2N]_2AsH$ (**9**)[16] and $TripAsH_2$ (**10**)[18]

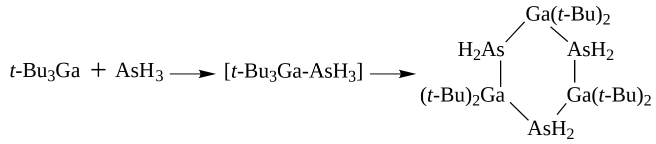


(**11**)

attributed to the weakness of the As–H bond which readily promotes elimination of H_2 to give As–As bonded compounds.[19] However complexes have been isolated that contain the AsH_2 moiety as in the silane $((i\text{-Pr})_3C_6H_2)(t\text{-Bu})Si(AsH_2)_2$ (**11**)[20] and the iridium^{III} complex *trans*-$[Ir(CO)XH(PEt_3)_2(AsH_2)]$ with X = Cl, Br (**12**) prepared by oxidative addition of AsH_3 to the Ir^I precursor (equation 7).[21] Reaction of AsH_3 with group 13 compounds afford oligomeric adduct complexes of the type $[R_3M\text{-}AsH_3]_n$ which on heating eliminate alkanes. This is exemplified by the reaction of $t\text{-}Bu_3Ga$ with AsH_3 which renders the trimer $[t\text{-}Bu_2GaAsH_2]_3$ (**13**) shown in equation (8).[22] Complex (**13**) was prepared in the context of the search of single-source precursors to GaAs by MOCVD (*see* ***Metallic Materials Deposition: Metal-organic Precursors***).



(**12**) (7)



(**13**)

(8)

5 ARSENIC HALIDES

5.1 Trihalides

All the arsenic trihalides are known compounds; this is also true for the rest of the group 15 cognates. Selected physical and molecular parameters for the arsenic halides are given in Table 2.[23]

The four arsenic halides are molecular compounds in the gas phase which have been shown by electron diffraction and microwave spectroscopy to have C_{3v} pyramidal structures.[23,24]

AsF_3 must be prepared in anhydrous conditions to prevent its hydrolysis from a CaF_2/concentrated H_2SO_4 mixture. The H_2O formed during the course of the reaction can be effectively sequestered by the sulfuric acid (equation 9).[23] In common with other pyramidal molecules AsF_3 undergoes inversion around the arsenic atom. Contrary to other pyramidal molecules that invert trough *vertex* inversion via a planar intermediate (D_{3h}), AsF_3 has been shown by theoretical calculations to invert trough *edge* inversion via a T-shaped intermediate (C_{2v}) (Figure 3).[25] Although AsF_3 is a weaker fluorinating agent than SbF_3, it is preferred for the preparation of high boiling point fluorides despite its obvious toxicity since $AsCl_3$ (b.p. 130 °C) can be distilled off, for example, equation (10).[1] AsF_3 with chlorine undergoes an interesting oxidation–reduction reaction to form $[AsCl_4]^+[AsF_6]^-$.

$$As_4O_6 + 12HF \longrightarrow 4AsF_3 + 6H_2O \qquad (9)$$

$$[PCl_4]^+[PCl_6]^- + 2AsF_3 \longrightarrow [PCl_4]^+[PF_6]^- + 2AsCl_3 \qquad (10)$$

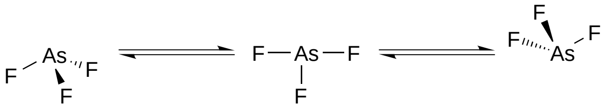


Figure 3 Inversion of AsF_3 trough *edge* inversion via a T-shaped intermediate

Table 2 Selected physical and molecular parameters for the arsenic halides[23]

	AsF_3	$AsCl_3$	$AsBr_3$	AsI_3

[a]X = F, Cl, Br, I respectively. [b]Determined by electron diffraction; gas phase. [c]Determined by X-ray crystallography.

The preparation of $AsCl_3$ at laboratory scale has been described in Section 2 (see equation 3). By comparison to the other elements of group 15, the arsenic–chlorine bond is more resistant to hydrolysis, therefore its preparation from aqueous solutions is possible, for example, using concentrated HCl (equation 11). Other methods for the synthesis of $AsCl_3$ include the direct reaction between the elements, the reaction between As_2O_3 and S_2Cl_2, and the treatment of AsF_3 with PCl_3, PCl_5, $PSCl_3$, $SiCl_4$, or $SOCl_2$. $AsBr_3$ has been prepared by the direct combination of arsenic metal powder with bromine. The direct reaction between As_2O_3, sulfur and bromine has also been described (equation 12). The synthesis of AsI_3 an orange-red crystalline solid can be accomplished in aqueous solution by the reaction between potassium iodide and arsenic trioxide in concentrated HCl (equation 13). The solid-state structure of $AsCl_3$ shows three short molecular As–Cl bonds (Table 2) and three longer intermolecular bonds from the nearest chloride atoms from other $AsCl_3$ molecule affording $AsCl_6$ with a distorted octahedral geometry. The same structure is found for $AsBr_3$ and AsI_3.[23] $AsCl_3$ is not as susceptible to nucleophilic attack as PCl_3 is. Therefore, the reactions of $AsCl_3$ proceed stepwise and it is much easier to stop at a lower level of substitution than with PCl_3. A few examples of reactions that illustrate the reactivity of $AsCl_3$ and the rest of arsenic trihalides are given in Scheme 1. Although the self ionization equilibrium of $AsCl_3$ to give $AsCl_2^+$ and $AsCl_4^-$ is very low (conductivity 1.4×10^{-6} $(\Omega\,cm)^{-1}$), $AsCl_3$ has been used as a nonaqueous solvent for chloride transfer reactions.

$$As_2O_3 + 6HCl \longrightarrow 2AsCl_3 + 3H_2O \quad (11)$$

$$2As_2O_3 + 3S + 6Br_2 \longrightarrow 4AsBr_3 + 3SO_2 \quad (12)$$

$$As_2O_3 + HCl \longrightarrow AsCl_3 + Kl \longrightarrow AsI_3 \quad (13)$$

5.2 Pentahalides

The only known arsenic pentahalides are AsF_5 and $AsCl_5$ of which the fluoride is the most stable species. The relative instability of the heavier arsenic halides can be ascribed to a tendency towards reduction to give the arsenic trihalides and elemental halogen (equation 14) owing to the shielding properties of the underlying full 3d orbitals of arsenic that reduce the availability of the electrons in the 4s orbital.[23]

$$AsX_5 \longrightarrow AsX_3 + X_2 \quad (14)$$
$$X = Cl, Br, I$$

A simple route to prepare AsF_5, which is a colorless gas, involves the reaction of fluorine with arsenic. In the laboratory it is conveniently prepared by the reaction between AsF_3, SbF_5, and bromine (equation 15). The electron diffraction structure in the gas phase of AsF_5 shows the expected trigonal bipyramidal arrangement around arsenic with axial bond lengths of 1.711 Å and equatorial bond lengths of 1.656 Å.

$$2SbF_5 + Br_2 + AsF_3 \longrightarrow AsF_5 + 2SbBrF_4 \quad (15)$$

Arsenic pentachloride was an elusive compound until it was finally obtained by the ultraviolet irradiation of an $AsCl_3/Cl_2$ mixture at −105 °C. Above −50 °C, a redox reaction occurs affording $AsCl_3$ and molecular chlorine (see equation 14 above). The identity of $AsCl_5$ was confirmed by elemental analysis and by comparison of its Raman spectrum with those of liquid PCl_5 and $SbCl_5$.[26]

Although not as convenient as PF_5 or SbF_5, AsF_5 has found some use as halide acceptor when a large anion is needed.

5.3 Mixed Arsenic Halides

The mixed arsenic trihalides $AsX_nX'_{3-n}$ and pentahalides $AsX_nX'_{5-3n}$ are essentially unstable compounds. But it has been observed that mixtures of $AsCl_3$ and AsI_3 favor the formation of $AsCl_2I$ according to equation (16). A mixture of AsF_3 and $AlCl_3$ has been shown to form small amounts of AsF_2Cl and $AsFCl_2$ by ^{19}F NMR. In a similar fashion, the combination of $AsCl_3$ and $AsBr_3$ forms $AsCl_2Br$ and $AsBr_2Cl$.

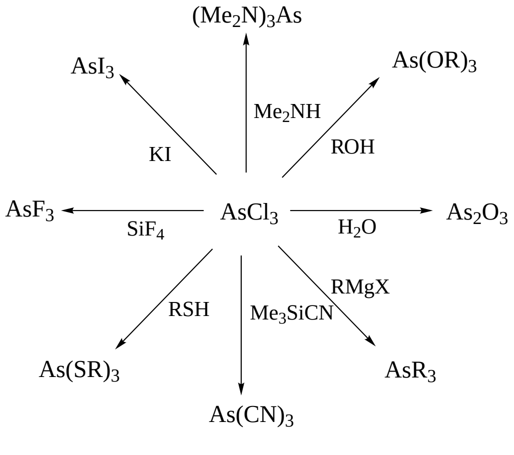
$$2AsCl_3 + AsI_3 \rightleftharpoons 3AsICl_2 \quad (16)$$

All the series of $AsF_{5-n}Cl_n$ ($n = 0-5$) compounds have all been observed, although some of them in an argon matrix. The structure of these halides is as it would be anticipated trigonal bipyramidal with the fluorine atoms in apical positions and the less electronegative chlorine atoms in equatorial sites.[23]

5.4 Haloarsenate Ions

The formation of the fluroarsenate anion $[As_2F_{11}]^-$ has served to stabilize the arsonium cation $[(CH_3)_3AsH]^+$ (equation 17), the colorless solid is stable for several months at −70 °C under a nitrogen atmosphere, decomposing at 5 °C.[27]

$$AsCH_3 + HF + 2AsF_3 \xrightarrow{HF/-78\,°C} [(CH_3)_3AsH]^+[As_2F_{11}]^- \quad (17)$$



Scheme 1

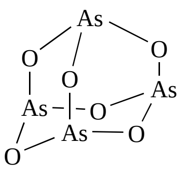
A number of chloroarsenate ions are known, and salts with the protonated cations of the bases dimethylamine, ethylamine, pyridine, guanidine, and quinoline with the following anions have been prepared: $[AsCl_4]^-$, $[AsCl_5]^{2-}$, $[AsCl_6]^-$, $[As_2Cl_9]^{3-}$, and $[As_3Cl_{11}]^{2-}$. Other identified haloarsenates are: $[As_3Br_{12}]^{3-}$, $[As_6Br_8]^{2-}$, $[As_6I_8]^{2-}$, and $[As_8I_{28}]^{4-}$.[28–30]

6 ARSENIC CHALCOGEN COMPOUNDS

6.1 Oxides of Arsenic

Arsenic^{III} oxide, As_4O_6, commonly referred to arsenic trioxide (As_2O_3) is the most important arsenic compound of commercial value since it is the raw material most widely used for the synthesis of arsenic compounds. As_4O_6 exists in both molecular and polymeric modifications. The cubic modification (arsenolite) contains discrete As_4O_6 (**14**) molecules with T_d symmetry in an adamantine-like structure in the vapor, liquid and solid phases. The structure is extremely stable and it is the main product obtained by burning arsenic in air. The second form of As_4O_6 has a monoclinic crystal system and it is commonly referred as claudetite which exists in two forms, claudetite I and II, each of which has a layered structure of arsenic atoms joined through oxygen atoms. This form of As_4O_6 is 8.7% more dense than the cubic form. Arsenic^{III} oxide is produced as a by-product of the nonferrous metals industry, primarily from the smelting of copper ores. Naturally occurring metal arsenides, realgar, and orpiment also convert to the trivalent oxide when roasted in air. The formation of the trioxide by the roasting of a sulfidic ore is illustrated in equation (18).[23,24]

$$2FeAsS + 5O_2 \longrightarrow Fe_2O_3 + As_2O_3 + 2SO_2 \quad (18)$$



(**14**)

Elemental arsenic undergoes reaction with oxygen to yield the trioxide (equation 19).

$$4As + 3O_2 \longrightarrow 2As_2O_3 \quad (19)$$

This direct reaction between the elements yields the trioxide almost exclusively. The reaction in air proceeds very slowly, but the rate increases rapidly with increasing temperature, decreasing particle size, and in the presence of moisture. It has also been noted that amorphous arsenic reacts with oxygen at a slower rate than the three recognized crystalline allotropes. Reacting As_4O_6 with water affords solutions of ''arsenious acid'', which is believed to be $As(OH)_3$. Arsenite ions are formed treating As_4O_6 with bases. These ions are formed by ionization of $As(OH)_3$, namely $[AsO(OH)_2]^-$, $[AsO_2OH]^{2-}$, and $[AsO_3]^{3-}$. The mixed-valence Arsenic^{III,V} oxide or more commonly known as arsenic dioxide, AsO_2 is formed by heating As_4O_6 in an autoclave for fourteen days at 260 °C under dioxygen pressure (5–50 MPa).[31] The structure consists of infinite layers of arsenic atoms coordinated to three or four oxygen atoms. The three coordinated arsenic atom is considered As^{III} and the four coordinated As^{V}. The complete range of possible oxides between $As_4^{III}O_6$ and $As_4^{V}O_{10}$ has been observed by means of matrix-isolation techniques. The structures proposed of these oxides are shown in Figure 4.

Arsenic^{V} oxide, As_4O_{10}, cannot be formed by the direct combination between the elements owing to the greater thermodynamic stability of As_4O_6, which promotes the back dissociation reaction illustrated in equation (20). The most useful preparative method involves the oxidation of elemental arsenic with concentrated nitric acid, followed by careful dehydration of H_3AsO_4 (equation 21).

$$As_4O_6 + 2O_2 \rightleftharpoons As_4O_{10} \quad (20)$$

$$4H_3AsO_4 \longrightarrow 6H_2O + As_4O_{10} \quad (21)$$

Hypochlorous, chloric, and perchloric acids also oxidize the metal or As_2O_3 to the pentavalent state. Interestingly, dilute HIO_3 oxidizes elemental arsenic to the pentavalent state more easily than the concentrated acid.

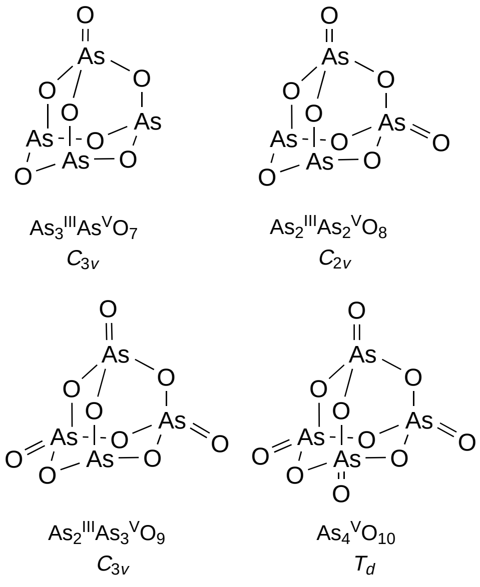


Figure 4 Mixed-valence arsenic oxides

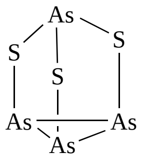
6.2 Sulfides of Arsenic

Yellow arsenic^{III} sulfide (orpiment), As_2S_3 is prepared by heating the elements in stoichiometric amounts or by heating As_4O_6 with sulfur. It is also formed by passing H_2S into acidified aqueous solutions containing As^{III} compounds. Electron diffraction in the gas phase reveals a cage structure As_4S_6 similar to As_4O_6. In the solid state, the structure is composed of trigonal pyramidal AsS_3 units,[32] which is quite similar to what it is observed for As_2O_3. One of the principal impurities which accompanies the formation of As_2S_3 is elemental sulfur. This has been removed by extraction with carbon disulfide.

As_2S_3 has found use in the manufacture of glass, especially infrared transmitting glass, in pyrotechnics and, because it is a semiconductor, in photoconducting devices.

Arsenic has a very well-developed mixed-valence chemistry with sulfur in part to the occurrence of several of these species as arsenic minerals. Tetraarsenic trisulfide, As_4S_3, is orange-yellow and occurs as the mineral dimorphite which is found in α and β forms. The solid-state structure of both the α and β forms exhibit C_{3v} symmetry (**15**), differences arise due to crystal packing effects.[23]



(**15**)

Tetraarsenic tetrasulfide, As_4S_4, occurs as the orange-red to orange-yellow mineral realgar. Heating dimorphite with a carbon disulfide solution of sulfur renders realgar as shown in equation (22). Mild oxidizing agents such as MgO, BiO, HgO, Pb_3O_4, MoO_3, and $CuSO_4$ have been reported to convert As_4S_6 to As_4S_4.

$$As_4S_3 + S \xrightarrow{CS_2} As_4S_4 \qquad (22)$$

On an industrial scale realgar has been prepared by the reaction between sulfur and an excess of elemental arsenic or As_2O_3. Other commercial procedure involves the sublimation of a mixture of pyrites (FeS_2), arsenopyrite (FeAsS), or the heating of arsenical pyrites, but these methods yield an impure product.

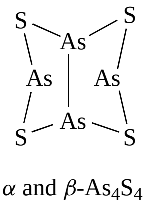
In the laboratory, realgar can be accessed by the fusion between stoichiometric quantities of arsenic metal with sulfur.

The reaction between As_4O_6 and sulfur is reported to follow the stoichiometry of equation (23).

$$2As_2O_3 + 7S \longrightarrow As_4S_4 + 3SO_2 \qquad (23)$$

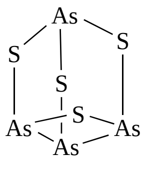
As_4S_4 is normally prepared as an impure material and must be purified by sublimation under an atmosphere of CO_2.

As a result of crystal packing, synthetic As_4S_4 exists as an α and a β forms (**16**). The As_4S_4 units in the solid and in the vapor phases are identical. The α form is stable at ambient temperature and is the same to the mineral realgar, whereas the β form is a high-temperature modification. In the third isomer of realgar γ-As_4S_4 (**17**) there is arsenic with a coordination sphere composed of three, two, and one sulfur neighbors.[33]



α and β-As_4S_4

(**16**)



γ-As_4S_4

(**17**)

Pentavalent arsenic sulfides are not well defined. The only accepted compound is As_2S_5 which is prepared from H_2S and a solution of an As^V compound (equation 24) or acidification of a thioarsenate salt (equation 25).[34]

$$2H_3AsO_4 + 5H_2S \xrightarrow{H^+} As_2S_5 + 8H_2O \qquad (24)$$

$$2Na_3AsS_4 + 6HCl \longrightarrow As_2S_5 + 6NaCl\ 3H_2S \qquad (25)$$

6.3 Selenides of Arsenic

Arsenic^{III} selenide, As_2Se_3, is isomorphous with As_2S_3. The reaction between As_2Se_3 and liquid ammonia gives a small yield of the unusual salt $[NH_4][AsSe(NH_2)_2]$. The latter loses NH_3 to give NH_2AsSe.

The pentavalent arsenic selenide species has not been yet structurally characterized and it is produced in similar manner to As_2S_5.

Mixed valent arsenic selenide compounds are known, and they are related to the arsenic sulfide species. For example, As_4Se_4 is isomorphous with realgar As_4S_4 and As_4Se_3 is isomorphous with As_4S_3. However, chemical reactivity is different due to the larger size of the selenium atom.[23]

6.4 Tellurides of Arsenic

By the direct fusion of the elements in the appropriate stoichiometric ratios, the following tellurides of arsenic have been prepared: As_2Te_3, As_2Te_2, and As_8Te_3. A weakly acidic solution of $AsCl_3$ deposits a precipitate of As_2Te_3 when saturated with H_2Te. Because hydrogen telluride decomposes at 0 °C, temperature control is important. These compounds have not been the subject of a great deal of investigation.

6.5 Oxoacids of Arsenic

Arsenic trioxide is the anhydride of arsenous acid, H_3AsO_3. The solubility of arsenic trioxide in water at 25 °C is 21.6 g L^{-1}. The rate of dissolution of the trioxide in water is painstakingly slow, sometimes requiring up to 50 h of continuous agitation. The free acid has never been isolated. The solubility of arsenic trioxide increases greatly and occurs much more rapidly in both acid and alkaline media.

Proton NMR studies of aqueous arsenious acid solutions show only a single proton resonance attributable to arsenious acid. This result together with Raman spectroscopy suggest the species having a pyramidal structure which can be formulated as $As(OH)_3$. This is to be contrasted with H_3PO_3, which is $HP(O)(OH)_2$ with four-coordinate phosphorus and which exhibits two distinct proton NMR resonances. Spectroscopic evidence supports the formation of the three anions $[H_2AsO_3]^-$, $[HAsO_3]^{2-}$, and $[AsO_3]^{3-}$ when solutions of $As(OH)_3$ are treated with hydroxide ion. This observation agrees with a three-step acid dissociation. The pK_a for the dissociation of the first proton is 9.2, which means that H_3AsO_3 is a very weak acid.

Dissolution of As_4O_{10} in water the anhydride of arsenic acid, H_3AsO_4, is very soluble in cold water and dissolves to form a solution of arsenic acid. The free acid can be obtained as a hydrate, $H_3AsO_4{\cdot}0.5H_2O$, by the evaporation of a cold aqueous solution. When crystallization is carried out above 100 °C, hydrates of arsenic pentoxide are formed, examples of which are $3As_2O_5{\cdot}5H_2O$ and $As_2O_5{\cdot}4H_2O$.

Industrially, solutions of arsenic acid are prepared by the oxidation of readily available As_2O_3 with nitric acid (equation 26).

$$As_2O_3 + 2NO_3{}^- + 2H_2O \longrightarrow 2H_2AsO4^- + 2NO + 0.5O_2 \quad (26)$$

Arsenic acid is about as strong an acid as H_3PO_4. The acid dissociation pK_a constants are: pK_{a1}, 2.25; pK_{a2}, 6.77; and pK_{a3}, 11.60. In arsenic acid the oxidation state of arsenic is formally +5.[23] It behaves as a moderately strong oxidizing agent ($E^0 = 0.559$ V) in a number of reactions. The following are some typical examples.[24]

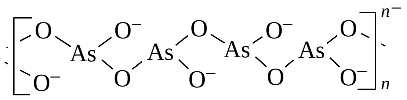
1. Reduction with Sn/HCl yields arsine. This reaction is catalyzed by divalent transition metal ions including Cu^{2+}, Fe^{2+}, and Hg^{2+}. Reduction by $[BH_4]^-$ also converts $AsO_4{}^{3-}$ to AsH_3.
2. In hydrochloric acid, together with a reducing agent such as Cu^+ or SO_2, $AsO_4{}^{3-}$ is converted to $AsCl_3$.
3. In a solution containing a nonoxidizing acid, for example, HCl, H_2S converts $AsO_4{}^{3-}$ to the trivalent sulfide As_2S_3, together with the precipitation of sulfur.
4. Sulfurous acid converts arsenic acid to arsenious acid (equation 27).

$$H_3AsO_4 + SO_2 + H_2O \longrightarrow H_2SO_4 + H_3AsO_3 \quad (27)$$

5. The following compounds are oxidized by H_3AsO_4: $TiCl_3$, $SnCl_2$, $CrCl_2$, $FeCl_2$, and Cu_2Cl_2. In each case the oxidation state of the metal is increased.
6. Hydrazine and hydroxylamine both reduce arsenic acid. Hydrazine is converted to nitrogen and water.

6.6 Oxoanions of Arsenic

Arsenites of the alkali metals are very soluble in water. Successive deprotonation of arsenous acid forms a series of salts: MH_2AsO_3, M_2HAsO_3, and M_3AsO_3. These salts may be stepwise dehydrated to two other series of salts, the pyroarsenites, $[As_2O_5]^{4-}$ and the meta-arsenites, $[AsO_2]^-$. Sodium meta-arsenite, $[NaAsO_2]_n$, consists of pyramidal AsO_3 units (**18**) which are linked together by shared oxygen atoms into linear chains.



(**18**)

Alkaline earth metal arsenites are less soluble than those of the alkali metals and heavy metal arsenites tend to be insoluble. Orthoarsenites are known, for example, Ag_3AsO_3. Once utilized as a green pigment was the copper arsenite $CuHAsO_3$, and as an insecticide, Paris green, $3Cu(AsO_2)_2{\cdot}Cu(C_2H_3O_2)_2$, which is an acetate arsenite. None of these is in use at the present time.

There are a number of heteropolyanions that contain arsenic and oxygen. An interesting example being the blue As^{III} heteropolyanion, $[H_6As^{III}_{10}Mo^{V}_{8}Mo^{VI}_{16}O_{90}]^{8-}$.[35] The anion is composed of two $As_4Mo_{12}O_{42}$ spherical moieties of C_{3v} symmetry with a central AsO_3 group.

Metal arsenates are easily prepared in solution by simple neutralization of arsenic acid with the appropriate base. For example, stepwise addition of sodium hydroxide to a solution of H_3AsO_4 affords $NaH_2AsO_4{\cdot}H_2O$ and $Na_2HAsO_4{\cdot}12H_2O$. On heating these arsenates easily lose water to ultimately give polyarsenate, $(NaAsO_3)_n$, which is an extended linear polyanion. Its structure parallels that of $(NaPO_3)_n$ (Maddrell's salt), a pair of AsO_4 tetrahedra share a corner oxygen and the resulting As_2O_7 units are joined by sharing two oxygen corners with the edge of a connecting AsO_4 tetrahedron.

A vast number of arsenates with metals of the rest of the *s*-block, and the *p*-, *d*- and *f*-blocks are known. The discussion of these anions is beyond the scope of this article, the interested reader may refer to the works of Godfrey *et al.*[23] and Thilo.[36]

6.7 Anions of Arsenic with Sulfur, Selenium, and Tellurium

Research involving chalcogenidoarsenic anions with heavier group 16 elements has been prompted by the technological potential of solid-state compounds having regularly spaced pores and cavities. The realization of these phases has been accomplished using mild solvothermal regimes (100–600 °C) with strongly polarizing media such as molten salts (T = 200–600 °C) or molecular solvents (100–400 °C). Under these conditions it is possible to assemble anion networks in which characteristic molecular building units such as chains or rings can be identified. The resulting channels or cavities are often found to reflect the geometry and size of structure-directing metal or alkylammonium cations. Thus, the rest of this section will be presented with an emphasis on the possible final structure of the materials and the building blocks that originated them rather than on the methods of synthesis. An exhaustive review of all the known phases will be avoided. For this matter the interested reader may refer to the excellent review of Sheldrick and Wachhold.[37]

Isolated pyramidal arsenic anions with sulfur and selenium of the type M_3AsE_3 (M = Na, K, Tl; E = S and M = Tl; E = Se) and pseudotetrahedral geometry Ba_2AsE_2 (E = S, Se) are known. The anions within these phases

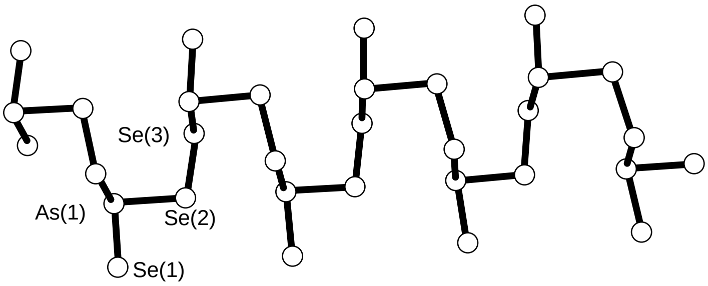
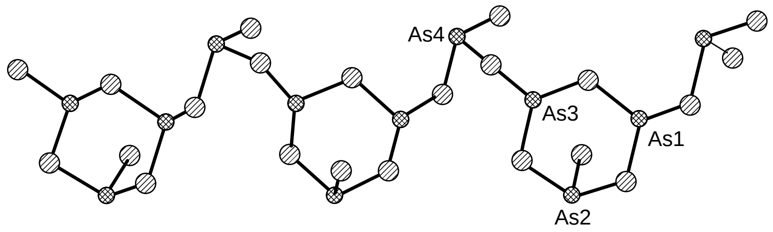
(**23**)



(**24**)



(**25**)

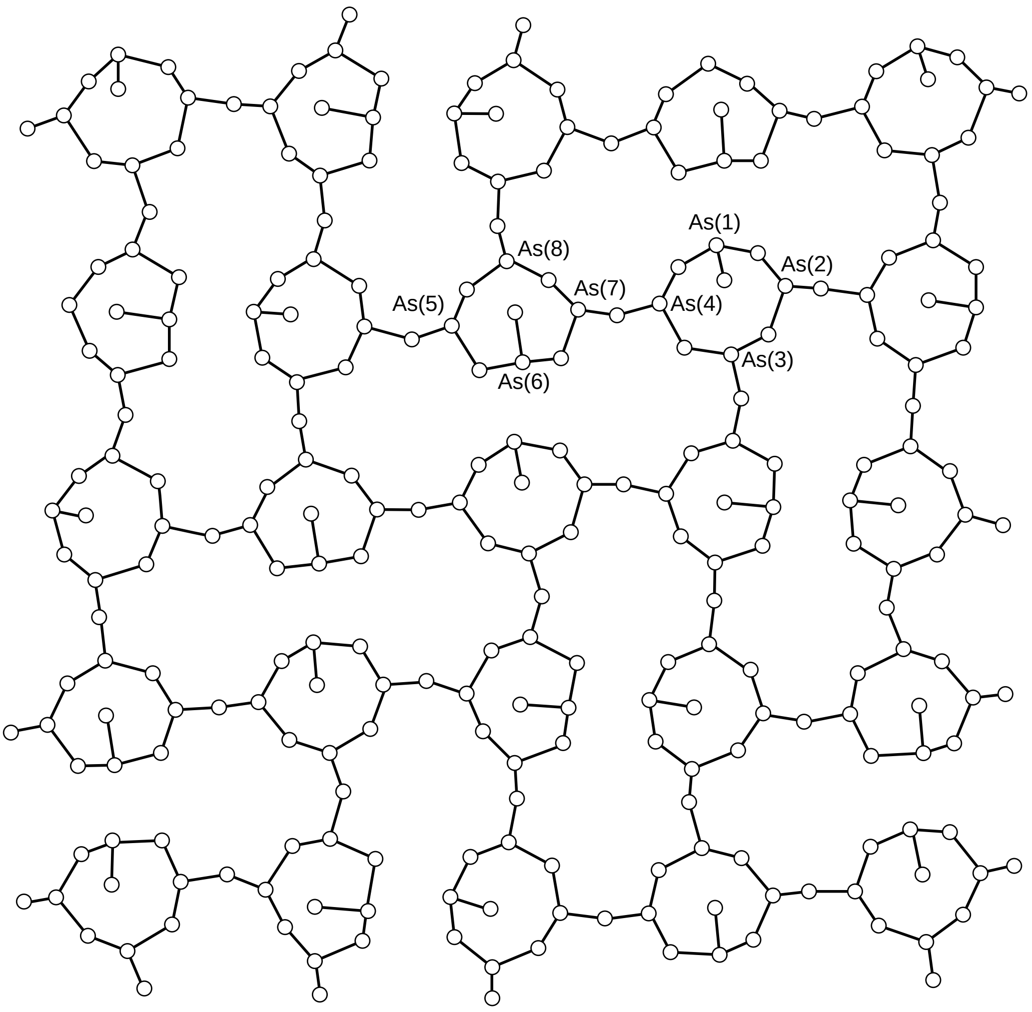
Figure 6 1-D chain-like polymers formed with mononuclear AsE_3 building units in $Na[AsSe_2]$ (**23**) and $K[AsSe_3]\cdot H_2O$ (**24**) or with cyclic molecular building units in $(Me_4N)_2As_4S_7$ (**25**)[37]

arrange in the crystal with discrete molecules. To this class of solid-state materials belong also those arsenic anions that show a cyclic molecular structure with one, two and three arsenic atoms in the ring. Examples are those anions found in $(Et_4N)[AsSe_8]$ (**19**), $Ba_2[As_2Se_5]$ (**20**) (anion with a trans configuration), $(Ph_4P)_2[As_2S_6]$ (**21**) and $[Sr(en)_4]_2[As_3Se_6]Cl$ (**22**) which are depicted in Figure 5. From (**19**–**22**) it is evident that stabilization of these species is accomplished with a large cation.

Polymer chain-like anions with 1-D dimensionality are formed either by assembling mononuclear AsE_3 building units like those in $Na[AsSe_2]$ (**23**) and $K[AsSe_3]\cdot H_2O$ (**24**) or with cyclic molecular building units in $(Me_4N)_2[As_4S_7]$ (**25**) (Figure 6).

A 2-D anionic structure has been achieved with the assembling of individual As_4S_4 rings that are connected to three further eight-membered rings trough As-S-As bridges in $Cs_2[As_8S_{13}]$ (**26**) (Figure 7). The Cs^+ cations function as templates for the construction of this material.

Selenium and tellurium arsenates in low oxidation states with direct As–As bonds can be generated either by controlled oxidation of elemental As or by reduction of a suitable binary As^{III} chalcogenide, for example, As_2Te_3. Rich tellurium phases $Na_4[As_2Te_4]$ and $K_4[As_2Te_4]$ are afforded by the first approach. The dinuclear anion $[As_2Te_4]^{4-}$ have a *gauche* (**27**) conformation in its Na^+ salt but a trans (**28**) conformation in its K^+ or Rb^+ salt (Figure 8). The trans conformation generates a larger cavity that can readily accommodate the voluminous cations K^+ or Rb^+. A derivative of the trans anion (**28**) is found in $Cs_4[As_2Te_6]$ (**29**), which is the product of the solvothermal reaction of Cs_2CO_3 and As_2Te_3 in methanol at 145 °C. The substitution of a terminal Te^{2-} by a $Te_2{}^{2-}$ dumbbell on each of the As atoms may be ascribed to the larger Cs^+ cation (Figure 8). The dinuclear anion $[As_2Se_5]^{4-}$ (**30**) present in the phase $K_5[Ag_2As_3Se_9]$ shows direct As–As bonding between a



(**26**)

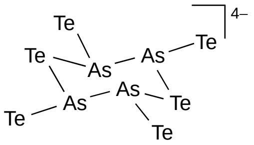
Figure 8 *gauche*-$[As_2Te_4]^{4-}$ (**27**) in $Na_4[As_2Te_4]$, *trans*-$[As_2Te_4]^{4-}$ (**28**) found in $K_4[As_2Te_4]$ or $Rb_4[As_2Te_4]$·en, *trans*-$[As_2Te_6]^{4-}$ with a dumbbell Te_2^{2-} on each As atom in $Cs_4[As_2Te_6]$ (**29**), $[As_2Se_5]^{4-}$ (**30**) in $K_5[Ag_2(AsSe_4)(As_2Se_5)]$ the ion fragment displays an As^{II} and As^{III} direct bond[37]

pyramidally coordinated As^{II} and a tetrahedrally coordinated As^{IV} center (Figure 8).

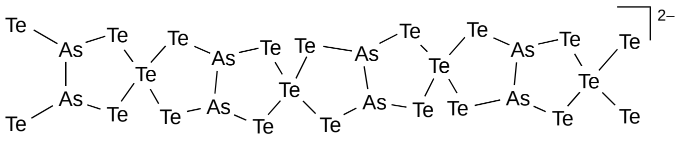
The basic $[As_2E_4]^{4-}$ building block can be related to other low oxidation state phases. In this regard, $[Ba(en)_4]_2[As_4Te_6]$, contains two $[As_2Te_4]^{4-}$ anions linked together in an 'head to head'/'tail to tail' fashion trough two common Te atoms to create a $[As_4Te_6]^{4-}$ six-memebered ring (**31**) (Figure 9). The same olygomeric anion is found in $(Me_4N)_4[As_4Te_6]$·2en. On the other hand, linear polymeric anion $[As_2Te_5]^{2-}$ (**32**) is contained in the telluridoarsenate $(Me_4N)_2[As_2Te_5]$ which can be thought to be the result of the condensation product of *trans*-$[As_2Te_4]^{4-}$ fragments and square-planar $[TeTe_4]^{6-}$ anions (Figure 9).

Interestingly, two different conformations of the eight-membered ring As_4Se_4 have been observed for the $[As_4Se_6]^{2-}$ anion (**33**) and (**34**) (Figure 10). When the counteranion is $[PPh_4]^+$, a boat–boat conformation (endo–endo with respect to the remaining selenium atoms) is observed.[38] Exchange of the counteranion for [K(2,2,2-cryptand)]$^+$ renders a boat–chair conformation (endo-exo).[39]

Arsenic chalcogen-poor anions of the type $[As_{10}E_3]^{2-}$ are likely to represent a rather stable cluster variety and are known for the chalcogenides S-Te. They have been prepared by reduction of As_4E_4 (E = S, Se) or As_2Te_3 with



(**31**)



(**32**)

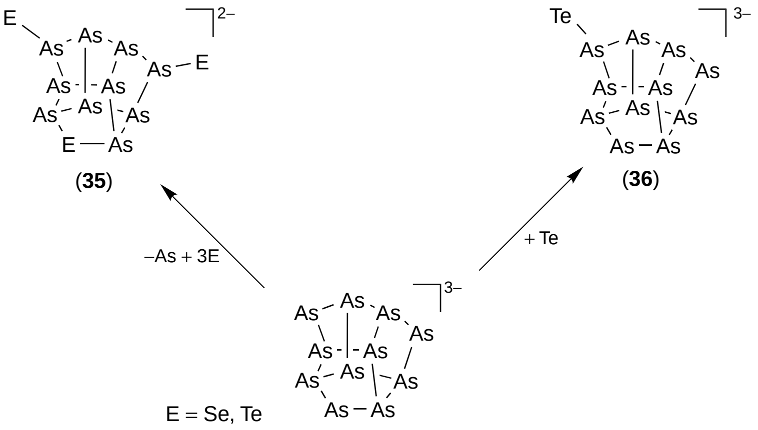

Figure 11 Arsenic-rich chalcogenide anions related to As_{11}^{3-}. $[As_{10}E_3]^{2-}$ ions (**35**) found in $[PPh_4]_2[As_{10}Se_3]$, $[PPh_4]_2[As_{10}Te_3]$, and $[K(2,2,2\text{-cryptand})]_2[As_{10}S_3]$; and the chalcogen-poorest arsenic anion $[As_{11}Te]^{3-}$ (**36**) in $[K(2,2,2\text{-cryptand})]_3[As_{11}Te]\cdot en$[37]

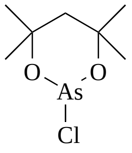
elemental K in NH_3 or ethylenediamine in the presence of $[PPh_4]^+$ or $[K(2,2,2\text{-cryptand})]^+$ as the counterion. The general structure of these anions which are closely related to that of As_{11}^{3-} (see also Figure 1) is represented by (**35**) in Figure 11. The arsenic chalcogen-poorest known anion, $[As_{11}Te]^{3-}$ (**36**) in $[K(2,2,2\text{-cryptand})]_3[As_{11}Te]\cdot en$ has been obtained by ethylenediamine extraction of a nominal alloy $K_8As_8Te_5$ in the presence of the sequestering agent 2,2,2-crypt. The As–As bond distances in the above mentioned As-rich clusters range from 2.388 to 2.479 Å and are significantly shorter than the distances found in elemental gray arsenic (2.517 Å).

6.8 Arsenic Complexes Based on Ligands with Chalcogen Donor Atoms

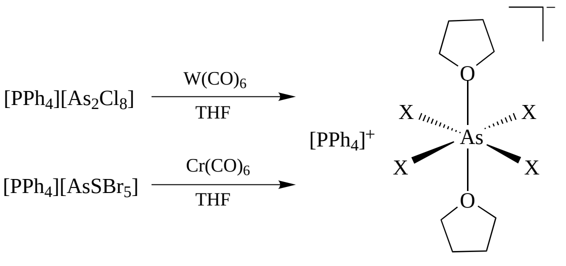
Inorganic arsenic complexes based on oxygen ligands is scarce. Simple esters of arsenic acid, $As(O)(OR)_3$ (R = Me, Et, *n*-Pr, *n*-Bu, C_6H_{13}) have tetragonal structures.[2] Reaction of the diol ligand 2,4-dimethyl-2,4-pentanediol with $AsCl_3$ affords an arsenic chloride complex in which the As atom is part of a six-membered ring (**37**).[40]

Reaction of $W(CO)_6$ and $[PPh_4]_2[As_2Cl_8]$ and of $Cr(CO)_6$ and $[PPh_4][As_2SBr_5]$ in THF yields the arsenic^V anionic complexes $[PPh_4][AsCl_4(thf)_2]$ (**38**) and $[PPh_4][AsBr_4(thf)_2]$ (**39**) both complexes display an octahedral coordination with a trans configuration (equation 28).[41] The anionic arsenic^V chatecholate complex $[H_7O_3][As(C_6H_4O_2)_3]\cdot$2,4-dioxane (**40**) prepared from $C_6H_4(OH)_2$ and $AsCl_3$ exhibits an octahedral



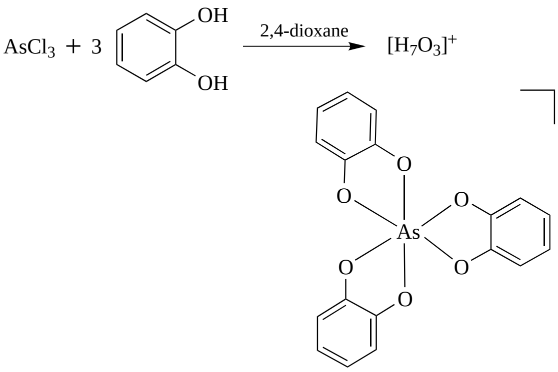
(**37**)

geometry with the anionic arsenic-containing fragment having D_3 symmetry (equation 29).[42]



(28)

X = Cl (**38**), Br (**39**)

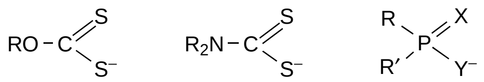


(29)

(**40**)

The chemistry of inorganic arsenic complexes with ligands that bear S donor atoms or S and O is more extensive. The chemistry of arsenic with xanthate (**41**), dithiocarbamate (**42**) and phosphorus based ligands (**43**) (Figure 12) has been reviewed.[43–46]

Homoleptic trisquelate arsenic complexes have been only structurally characterized with ligands (**41**) and (**42**). The complexes show mainly a distorted octahedral geometry, that is, $[As(S_2COMe)_3]$ (**44**), or antiprismatic, that is, $[As\{S_2CN(CH_2CH_2OH)\}_3]$ (**45**) (Figure 13). These



(**41**) (**42**) (**43**)

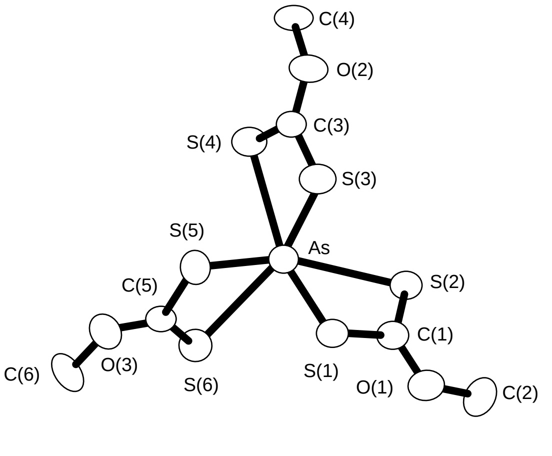
R′ = R or OR; R = alkyl or aryl; X, Y = O, S

Figure 12 General structures of xanthate (**41**), dithiocarbamate (**42**), and phosphorous-based ligands (**43**)

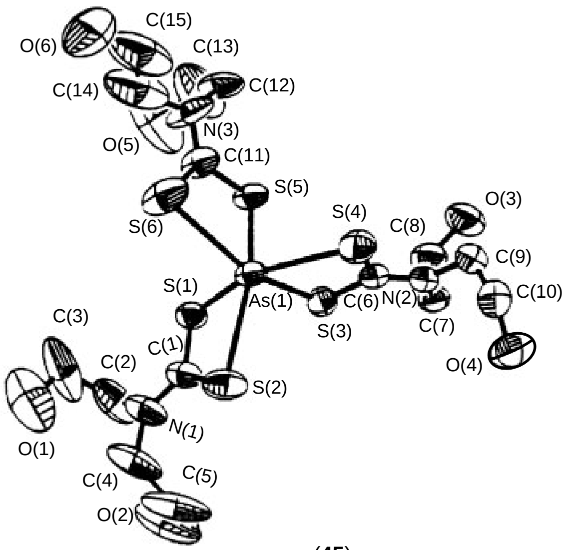
trisquelate complexes are generally synthesized by reaction between arsenic halides and sodium, ammonium, lead or silver. The free acids, particularly the dithiophosphorus, have been also employed.

Mixed ligand arsenic complexes have been reported. The chloro derivatives of general formula $[AsCl_{3-n}\{S_2P(OR)_2\}n]$ ($n = 1, 2$; R = Et, *n*-Pr, *i*-Pr, *i*-Bu) and $[AsBr(S_2CNEt_2)_2]$ have been synthesized. The homoleptic complexes $[As(S_2CNR_2)_3]$ react with bromine or iodine affording $[AsX(S_2CNR_2)_2]$ (X = Br, I). Complexes that incorporate dithiolates and ligands (**43**) are also known, for example, reaction of $[Y(CH_2CH_2O)_2AsCl]$ (Y = O, S) with $[NH_4][S_2PPh_2]$ in CH_2Cl_2 affords $[O(CH_2CH_2O)_2As(S_2PPh_2)]$ (**46**) and $[S(CH_2CH_2O)_2As(S_2PPh_2)]$ (**47**) respectively. The arsenic atom in (**46**) and (**47**) display a pseudobipyramidal geometry and Y···As transannular bonding. Additionally, one of the sulfur atoms of the phosphorus ligand binds the metal with a long S···As interaction (Figure 14).[47]

An interesting benzothiazarsolium arsenic cation (**49**) has been isolated from the reaction of the chlorobenzothiazarsole (**48**) with $AlCl_3$ in CH_2Cl_2 (equation 30).[48] The spectroscopic data and the X-ray structure confirm in (**49**) a dicoordinate cationic environment around arsenic. Part of the



(**44**)



(**45**)

Figure 13 Homoleptic trisquelate arsenic complexes $[As(S_2COMe)_3]$ (**44**) and $[As\{(S_2CN(CH_2CH_2OH)\}_3]$ (**45**)[46]

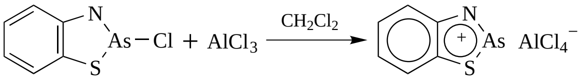
Figure 14 X-ray structures of $O(CH_2CH_2O)_2As(S_2PPh_2)$ (**46**) and $S(CH_2CH_2O)_2As(S_2PPh_2)$ (**47**)[47]

stabilization in (**49**) comes from the delocalized 10π-electron, naphtalenic framework, which necessitates the employment of As–S $4p\pi-3p\pi$ and As–N $4p\pi-2p\pi$ bonding. As a consequence of $p\pi$ bonding in this arsenic cation the As–S and As–N distances (2.1536(15) and 1.776(4) Å respectively) are amongst the shortest known for As^{III} species.

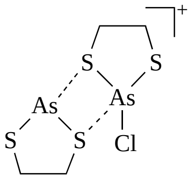


(30)

(**48**) (**49**)

Electron deficient coordinatively unsaturated thiaarsolidinium cations (**50**)[49] and (**51**)[50] have also been isolated. These *carbenic* arsenium cations have been prepared by the combination of the appropriate chlorodithiaarsolidine complex and a Lewis acid such as $AlCl_3$ or $GaCl_3$ that function as a halide abstractor. The reaction can be carried out in CH_2Cl_2 as the solvent (Scheme 2).

X-ray crystallography revealed that the arsolidinium cation (**50**) exists as a dimeric dication. The dimmer is formed via intermolecular As···S interactions (2.422(6) Å). Addition of another equivalent of $[(CH_2CH_2S_2)AsCl]$ to (**50**) affords a bicyclic monocation, which can be viewed as the Lewis complex (**52**) of the corresponding chloroarsolidine $[(CH_2CH_2S_2)AsCl]$, and the arsolidine cation (**50**).[49]



(**52**)

7 ARSENIC COMPOUNDS CONTAINING CARBON

A compound that can be formulated as the carbide As_2C_6 has been obtained in a most unexpected manner: by the reaction between arsenic trichloride and the Grignard reagent prepared by acetylene (equation 31).

$$2AsCl_3 + 3IMgC{\equiv}CMgI \longrightarrow As_2C_6 + 3MgI_2 + 3MgCl_2 \quad (31)$$

The reaction is carried out in ether, out of which it separates as a brown, amorphous solid. It is chemically resistant to both acids and bases. On heating, or by frictional action, the material decomposes violently into the elements. Based on this behavior it has been proposed that the compound is a derivative of acetylene, that is, essentially arsenic acetylide.

The action of CNI on metallic arsenic gives a mixture of AsI_3 and $As(CN)_3$, from which the iodide can be separated by extraction with CS_2. The arsenic tricyanide hydrolyzes to As_2O_3 and HCN on exposure to moisture.

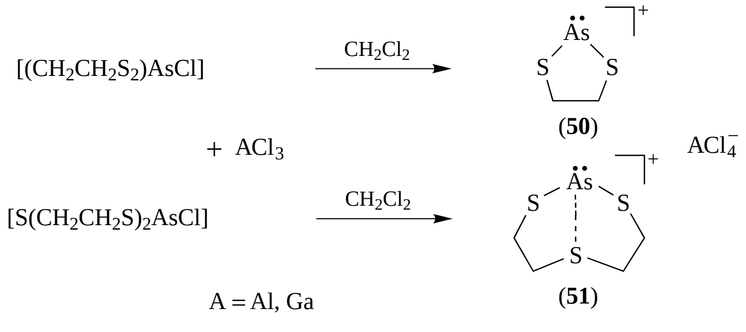
In a benzene solution the reaction between silver isocyanate and $AsCl_3$ forms a precipitate of $AgCl{\cdot}As(ONC)_3$ is obtained upon evaporation of the benzene in the form of a white, crystalline solid which melts at 97.1 °C. The cyanate $Ag(CNO)_3$ is obtained by heating the isocyanate to 230 °C under reflux. At this temperature it isomerizes to the cyanate. $Ag(CNO)_3$ decomposes rapidly in the presence of water or acid.

In a parallel manner, the reaction between $Pb(CNS)_3$ and arsenic trichloride in CS_2, followed by filtration to remove $PbCl_2$ and evaporation of the solvent, gives $As(CNS)_3$. The same product, a colorless, crystalline solid, can be prepared in benzene solution from AgCNS and $AsCl_3$.

8 ARSENIC PNICTOGEN COMPOUNDS AND COMPLEXES BASED ON LIGANDS WITH PNICTOGEN DONOR ATOMS

8.1 Nitrogen Compounds of Arsenic

A normal amide of trivalent arsenic, $As(NH_2)_3$, can be synthesized by the reaction between gaseous ammonia and an arsenic trihalide (except the fluoride) at low temperatures



Scheme 2

(−30 to −40 °C). The white, amorphous solid is washed with liquid ammonia in which it does not dissolve. This amide hydrolyzes readily to form arsenite.

The amide begins to decompose at 0 °C into the imide (equation 32). The decomposition is complete at 60 °C.

$$2As(NH_2)_3 \longrightarrow As_2(NH)_3 + 3NH_3 \qquad (32)$$

The imide is a clear yellow solid which is much more resistant to hydrolysis than the amide and which possesses greater thermal stability. At 250 °C it evolves ammonia and converts to the binary nitride (equation 33), which is a red-orange solid that decomposes violently on heating.

$$As_2(NH)_3 \xrightarrow{250\,°C} 2AsN + NH_3 \qquad (33)$$

The above mentioned nitride has also been synthesized by passing a gaseous mixture of 10% nitrogen and 90% argon through an electric arc between two arsenic electrodes.

Alquilaminoarsines can be prepared by stepwise addition of amines to arsenictrihalides in cooled ether solutions. The halogens are replaced successively by the alkylamino groups as shown in Scheme 3.

The As–N bond is labile compared to the As–C, As–O, or As–S bonds and this has been widely exploited in synthetic arsenic chemistry. For example, heating secondary amines with tris(dialkylamino)arsines effects transamination (equation 34).

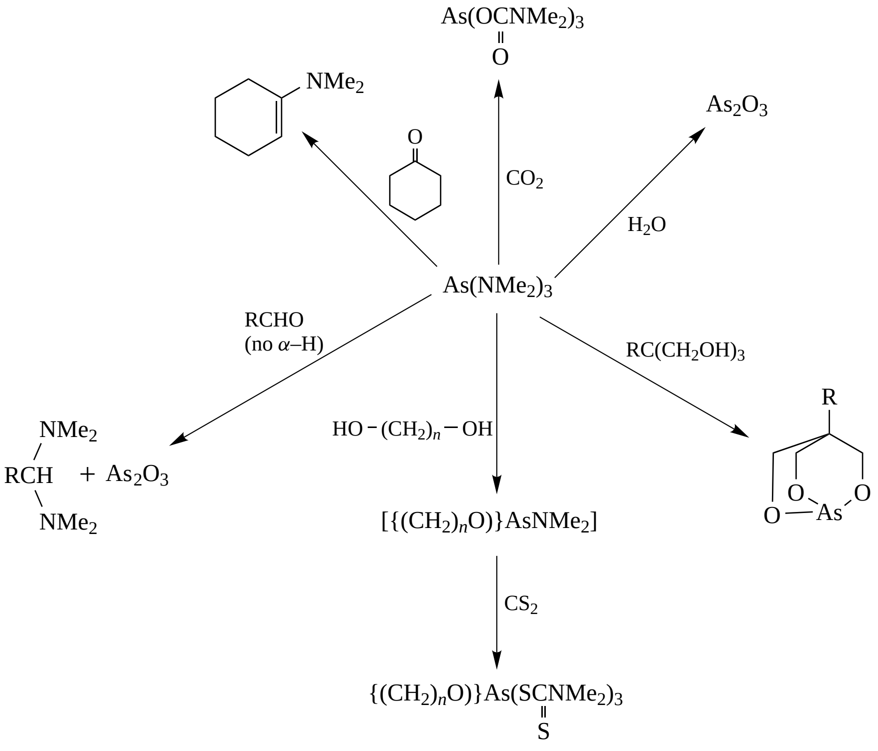
$$As(NMe_2)_3 + 3HNR_2 \xrightarrow[\text{reflux}]{C_6H_6} As(NR_2)_3 + 3HNMe_2 \qquad (34)$$

$$AsCl_3 + 2Me_2NH \xrightarrow[0\,°C]{Et_2O} [(Me_2N)AsCl_2] + [Me_2NH_2]Cl \quad (a)$$

$$[(Me_2N)AsCl_2] + 2Me_2NH \longrightarrow [(Me_2N)_2AsCl] + [Me_2NH_2]Cl \quad (b)$$

$$[(Me_2N)_2AsCl] + 2Me_2NH \longrightarrow [(Me_2N)_3As] + [Me_2NH_2]Cl \quad (c)$$

Scheme 3

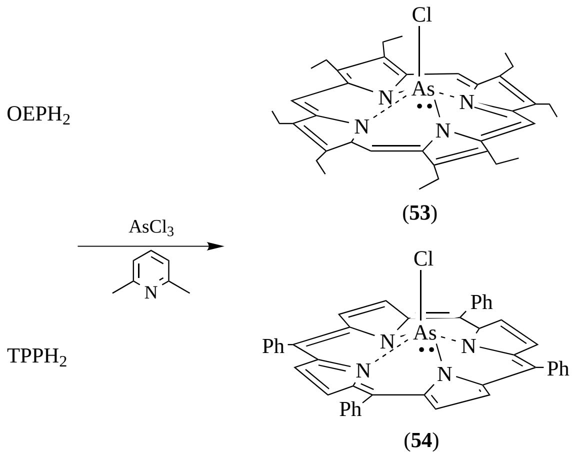


Scheme 4

These tris(dialkylamino)arsines give access to a wide variety of compounds, which is illustrated for $As(NMe_2)_3$ in Scheme 4.[2]

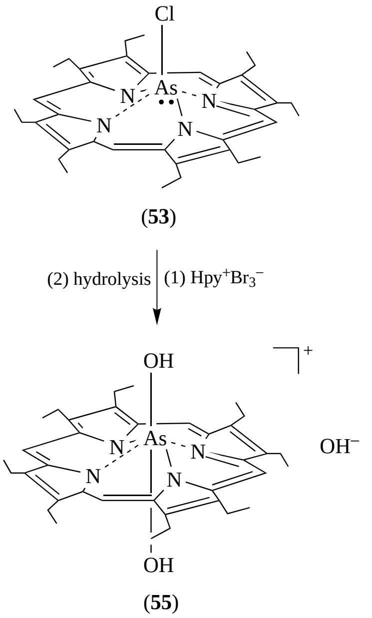
8.2 Arsenic Complexes Based on Ligands with Nitrogen Donor Atoms

In the context of the preparation of novel arsenic hypervalent species and the systematic study of ruffling in porphyrins by the influence of axially coordinated ligands to a central element, complexes with arsenic and porphyrins were isolated and fully characterized. The porphyrins used are octaethylporphyrin, (OEP) and tetraphenylporphirin (TPP). Reaction of $OEPH_2$ or $TPPH_2$ with $AsCl_3$ in the presence of lutidine give [(OEP)AsCl] (**53**) or [(TPP)AsCl] (**54**) according to equation (35).[51]



(35)

After bromination and subsequent hydrolysis of (**53**) the cationic arsenic complex (**55**) with arsenic in the 5+ oxidation state is obtained (equation 36).



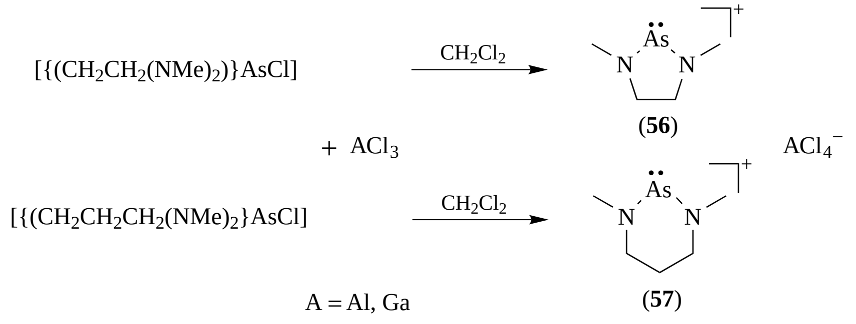
(36)

Interestingly, the X-ray structure of the arsenic^{V} fluoride porphyrin complex, $[(OEP)AsF_2]^+PF_6^-$ shows an almost planar conformation within the porphyrin core, which contrasts the S4 ruffled conformation found for $[(TPP)AsF_2]^+\ PF_6^-$.

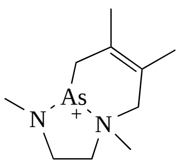
A limited number of dicoordinate arsenium cations with nitrogen based ligands have been isolated. Reaction of the chlorodiazaarsenanes, $[\{(CH_2CH_2)(NMe)_2\}AsCl]$ and $[\{(CH_2CH_2CH_2)(NMe)_2\}AsCl]$ with $AlCl_3$ or $GaCl_3$ in CH_2Cl_2 afford the corresponding arsenium cations (**56**)[48] and (**57**)[52] in good yield (Scheme 5).

X-ray crystallography revealed a dimeric structure for cation (**56**), whereas cation (**57**) is monomeric in the solid state. The dimer in (**56**) is made with intermolecular As···N interactions (2.103(4) Å).

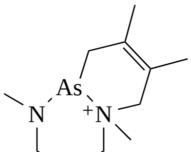
Cations (**56**) and (**57**) react rapidly with 2,3-dimethyl-1,3-butadiene in CH_2Cl_2 to give the bicyclic cationic products (**58**) and (**59**). The quantitive formation of (**58**) and (**59**) imply a concerted process, possibly a Diels–Alder type cycloaddition



Scheme 5



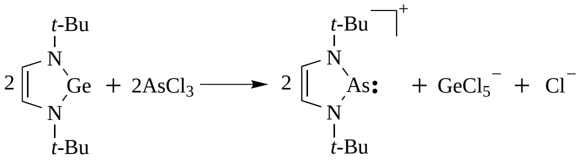
(**58**)



(**59**)

involving the As–N bond of either the monomer or dimmer as the dienophile.[50,52]

A monomeric arsenium cation with 6π electrons (**60**) has been isolated by a metal exchange reaction according to equation (37).[53]



(**60**) (37)

The reaction depicted in equation (37) proceeds with the oxidation of germanium from the 2+ to the 4+ state. The metrical parameters in (**60**) are in agreement with a localized electron distribution within the five-membered ring, which contrasts the view of aromatic 6π-stabilization that was invoked for the 10π electrons arsenium cation (**49**).

8.3 Phosphorus Compounds of Arsenic

Two binary As–P compounds have been reported. They are As_2P and AsP. Diarsenic phosphide has been prepared by heating a mixture of elemental phosphorus with As_2O_3, As_2O_5, or As in phosphoric acid. It is described as black and lustrous and turning brown on exposure to air. It has not been well characterized.

Arsenic monophosphide, AsP is described as a lustrous, red-brown powder. It has been synthesized by the direct fusion of the elements, by the reaction between AsH_3 and PCl_3, and by the reduction of a solution of As_2O_3 in HCl ($AsCl_3$) by PH_3.

A normal arsenic orthophosphate, $AsPO_4$, has been prepared by heating pyrophosphoric acid ($H_4P_2O_7$) with As_2O_3. The temperature is maintained between 230 and 245 °C and then finally taken to 280 °C. At a stoichiometric ratio of 2 moles of $AsPO_4$ to 3 moles of H_3PO_4, followed by heating to 320 °C, there is formed a compound whose stoichiometry corresponds to $4AsPO_4{\cdot}3H_3PO_4$.

A mixture of As_2S_3 and P_2S_5 yields, upon fusion, the tetrathiophosphate, $AsPS_4$.

9 ARSENIC IN THE ENVIRONMENT

Arsenic is widely distributed on earth in the atmosphere, in the aquatic environment, in soils and sediments, and in organisms. Just in the earth crust arsenic ranks 51st in abundance with a concentration of 1.8 g $tonne^{-1}$. It is frequently found to occur as a component of sulfidic ores, especially those of the nonferrous metals in which it occurs in the following forms: nickel diarsenide, cobalt diarsenide, nickel arsenide, cobalt arsenide sulfide, copper arsenide sulfide, and iron diarsenide. Arsenates of aluminum, barium, bismuth, calcium, cobalt, copper, iron, lead, magnesium, manganese, uranium, and zinc have also been found to occur naturally. Arsenic trioxide (arsenolite), As_2O_3, which is formed when arsenides are oxidized on exposure to the atmosphere, has also been found to occur naturally. Some naturally occurring arsenic minerals are realgar As_4S_4, orpiment As_2S_3, arsenolite As_2O_3, arsenopyrite FeAsS and Enargite Cu_3AsS_4.[1,54,55]

The element is very widely distributed in Nature. It is found in igneous rocks (1–3 ppm), in sedimentary rocks (1–25 ppm, but concentrations as high as 400 ppm have been reported), and in virtually all soils (0.1–40 ppm). In waters, it occurs in rivers, lakes, streams, groundwaters, and in the seas and oceans. Concentrations vary greatly, from 0.1 ppb in Lake Superior to as high as 276, 000 ppb in the Waiotapu Valley rivers of New Zealand.

Arsenic is distributed widely among plant and animal species. In plant tissues, its normal concentration varies from 0.01 to 5 ppm on a dry-weight basis. When plants are grown in soils which have been treated by arsenic compounds, these concentrations can reach 5 ppm on a dry-weight basis. Marine plants have been found to possess much higher arsenic concentrations. Seaweed growing along the British coast has been reported to possess arsenic concentrations as high as 94 ppm. Brown algae also concentrate arsenic in their tissues.

Arsenic is always present in all animals. Human body tissues generally average less than 0.3 ppm of the element. Marine organisms are noteworthy for their ability to concentrate arsenic. Cod, shrimp, oysters, and lobsters have been reported to contain up to 128 ppm of arsenic on a dry-weight basis. Values from 3 to 30 ppm are common among marine organisms. The typical human ingests between 29 and 169 mg of arsenic per day.[56]

The main introduction of arsenic into the biosphere is anthropogenic as result of industrial activity and the use of herbicides and biocides that contain the element. Arsenic is mainly released into the atmosphere as a consequence of its isolation, burning of fossil fuels and the smelting of ores (combustion). The oxides generated thermally are particulate in nature, which owing to their small size (in the nanometer scale) are held up in the exhaust gases and are easily vented into the local atmosphere and then distributed by the prevailing air currents. Models for the transport of arsenic predict that currently 285 tonnes are deposited annually on the Artic as a consequence of industrial activity in the northern hemisphere.

The ability of arsenic to incorporate to the food chain and become transformed into a variety of organic forms during its pass through the biological hierarchy is known.

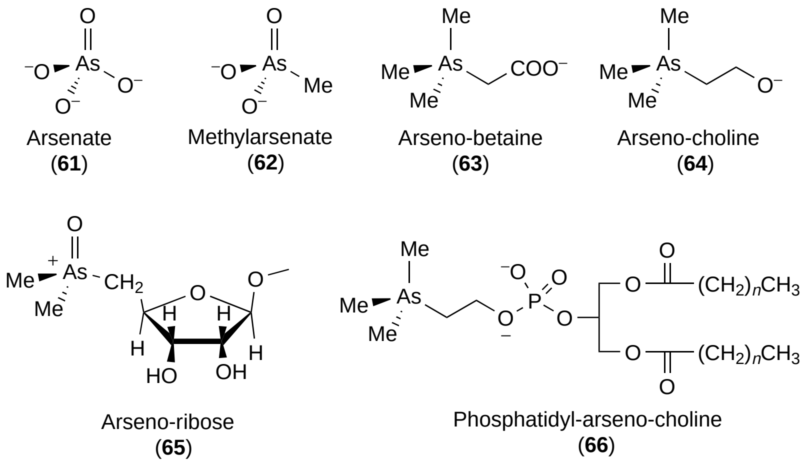


Figure 15 The structures of some common arsenic-containing natural products

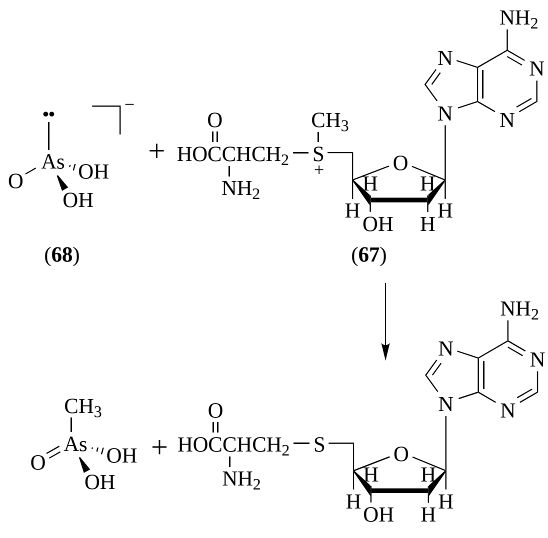
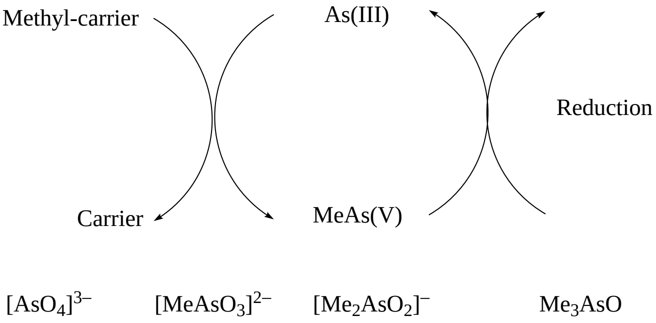
The simple oxides $[AsO_2]^-$ or $[AsO_4]^{3-}$ (**61**) are slowly organified to produce simple methylarsonic acids (**62**), more complex betaines (**63**), cholines (**64**), sugar derivatives (**65**), and lipids (**66**) (Figure 15).

Biological methylation of arsenic is effected via the transfer of a carbocation, a process known as oxidative methylation. The methyl transfer agent can vary from simple sulphonium salts, for example, *S*-adenosyl-*S*-methionine (**67**) (equation 38) to specific methyltransferase enzymes. The oxidation and methylation of the arsenite ion, $[AsO_3]^{3-}$, at physiological pH with (**67**) is illustrated in equation (38). In solution under these conditions the major species is $[H_2AsO_3]^-$ (**68**). The cycle is completed trough the re-reduction of new methylated arsenical^{V} by a range of nonspecific reductants (Scheme 6). The organoarsenicals produced during biomethylation can be reduced by bacteria with lipoic acid and by mammals with the ubiquitous thiolate glutathione, as has been reported in *in vitro* studies.[57]



(38)



Scheme 6

Studies of microbial systems have shown that the production of trimethylarsine from the various methylarsonates is more rapid than their respective thioarsinites, for example, Me_2AsSR, $MeAs(SR)_2$. However, there is a possible role for the thioarsinite in arsenic methylation. Studies on the binding of arsenic to the methyltransferase enzyme suggest that prior to the transfer of the methyl group the arsine oxide becomes bound to a thiolate at the active site. In this way it is possible to assist the binding of the softer arsenic^{III} substrate prior to methylation and facilitate the release of the harder arsenic^{V} species.[54,57]

In general the toxicity of arsenic is more pronounced with the lower oxidation states. The nature of the ligands around arsenic has also a profound effect on the overall toxicity of the element. For example, dimethylarsonate, $[Me_2AsO_2]$ has a $LD_{50} = 700\,mg\,kg^{-1}$ while a richer oxygen environment in arsenate, $[AsO_4]^{3-}$ (**61**) makes the element much more toxic with a $LD_{50} = 20\,mg\,kg^{-1}$. Small inorganic species are more toxic than are organoarsenicals. Libile ligands such as Cl^- or NH_2 and the presence of lone pairs would seem to increase toxicity, for example, $[Me_2AsCl]$ with a $LD_{50} = 5\,mg\,kg^{-1}$. Quaternary

arsonium salts effectively protect the arsenic center giving relatively nontoxic and almost inert compounds, for example, $[Me_3AsCH_2COO]$.

Compounds that contain arsenic^{V} in general are carcinogenic. This is probably the result of its reduction to arsenic^{III}. The thiophilicity of arsenic^{III} affect key enzymes, such as acetylcholine estereases, lipoic acid, and hemoglobin. Long-term contact with the organometallic forms cause hyperactivity, dizziness, speech, and psychological problems, possibly linked to methylation which in turn facilitates its transport across the blood-brain barrier.[54]

Diarsene: general formula $RAs{=}AsR'$, where R and R′ are bulky groups
Haloarsorane: general formula R_nAsX_{5-n}, where $n = 1-3$
Phosphaarsene: general formula $RP{=}AsR'$, where R and R′ are bulky groups

1 INTRODUCTION

The organometallic chemistry of arsenic has a long history that dates back to the synthesis and discovery in 1760 of the first organometallic compound, $Me_2AsAsMe_2$, by L. C. Cadet de Gassicourt. During the late-1800s, there was considerable interest in the synthesis of organoarsenic compounds that paralleled the heightened pursuit of synthetic organic chemistry. This led to the development of synthetic pathways to the organohalo, organoamino, and tertiary arsines. A significant upsurge in activity in synthetic organoarsenic chemistry occurred with the discovery by P. Ehrlich in 1910 that 3,3′-diamino-4,4′-dihydroxyarsenobenzene (Salvarsan base) was an effective cure for syphilis. The next 33 years witnessed the synthesis and biological testing of thousands of new organoarsenic compounds and the development of new synthesis strategies to heterocyclic compounds. With the advent of penicillin as a cure for syphilis in the 1940s, a lull occurred in the synthetic chemistry of organoarsenicals. The decreased activity and interest in main group chemistry that occurred from the late-1960s to the mid-1980s brought few developments to the organometallic chemistry of arsenic, but saw their use as ligands in transition-metal chemistry. Beginning with the mid-1980s and the renewed interest in main group synthetic chemistry as it relates to materials chemistry, there has been a resurgence in research activity in organometallic arsenic chemistry. Much of this has occurred in the quest to develop viable single-source precursors for group 13–15 thin-film technologies. Thus, the areas of arsenic–aluminum, arsenic–gallium, arsenic–indium, and multiple bonding in As/As and As/P systems have received significant attention and many new bonding and As– group 13 core systems have been explored. Synergistic, spectroscopic, structural, and materials studies have occurred.

This review surveys the chemistry and reactivity of several major classes of organometallic arsenic compounds that serve as the core of the field and represent those major areas of current research thrusts. General structural and recent spectroscopic data are discussed for each class of organometallic compound. Because of the great diversity of organoarsenic compounds and limited space, not all areas of organoarsenic chemistry can be covered nor can all the synthetic strategies and reactivity be discussed. For example, we have chosen not to cover transition-metal complexes that employ organometallic arsenic compounds as ligands, so we refer the reader to a book that provides a basic overview.[1] Also, the heterocyclic chemistry of arsenic is not presented and the reader is referred to a book that surveys that field.[2] For the same reason, we have not covered the biological and environmental aspects of organoarsenic chemistry. The latter has been reviewed.[3]

In each section, we have referenced several books,[4–14] monographs, and review articles that provide in-depth coverage of the chemistry that is presented and give references to the primary literature for developments in the field that have taken place subsequent to the latest applicable review article. We have focused on reviewing the primary synthetic routes and reactivity that appear in previously published books and monographs and providing the reader with more in-depth coverage of the latest developments.

The physical, structural, and spectroscopic properties of organoarsenic compounds have been summarized in a

series of excellent reviews and monographs (1966,[7] 1968,[8,9] 1970,[6] 1972,[10,15] 1975,[5] 1979,[11] and 1985[4]). In addition, annual reviews have provided key access to the literature (see cf. *Journal of Organometallic Chemistry*, *Coordination Chemistry Reviews*, and *Organometallic Chemistry*, Royal Society of Chemistry). The reader is referred to these sources for specific information on given organoarsenic compounds.

2 FULLY SUBSTITUTED ORGANOARSENIC COMPOUNDS

2.1 Tricoordinate Arsenic

Tertiary arsines comprise the most common class of tricoordinate, fully organosubstituted arsenic compounds. Although there are a variety of methods for synthesizing C–As bonds in tertiary arsines,[4–11,16] the most extensively utilized routes involve the reaction of *Grignard Reagents* with arsenic trihalides to give symmetric tertiary arsines (equation 1). The yields of trialkylarsines are generally low to moderate and those of triarylarsines high. This reaction has been used to prepare the trineopentylarsine, $As(CH_2CMe_3)_3$.[17]

$$AsX_3 + 3RMgX \longrightarrow AsR_3 + 3MgX_2 \qquad (1)$$

When the Grignard reagents react with primary and secondary haloarsines, As_2O_3, As_2S_3, trialkyl arsenites, and arsenic thioacid esters, the resulting tertiary arsines are often contaminated with other arsenicals. Lithium alkyls are frequently used when the Grignard is difficult to obtain, but side-products serve as contaminants. Although the reaction times are long and yields depend upon the alkyl group, aluminum alkyls also effectively alkylate As_2O_3 and arsenic trihalides. The Würtz–Fittig reaction is seldom used in synthesizing trialkylarsines, but has been utilized to prepare cyclic arsines (equation 2).

$$C_6H_4(CH_2Br)_2 + MeAsCl_2 + 4Na \longrightarrow C_6H_4(CH_2)_2AsMe + 2NaCl + 2NaBr \qquad (2)$$

Zinc and mercury dialkyls have found limited application in alkylating arsenic trihalides. The advantage with the zinc dialkyls is that they give very pure tertiary arsines even though the arsines are obtained in low yields. Numerous other methods that employ redistribution of alkylhaloarsines at elevated temperatures, reduction of arsonium salts, pyrolysis of arsonium salts and arsine oxides, reaction of arsenic halides with diazoalkanes, reaction of SnR_4 and alkyl radicals with elemental arsenic, alkylation of diarsines and aminoarsines with organolithium, or the action of *Penicillium brevicaule* on bread that contains sodium cacodylate have provided unique routes to specific, symmetric tertiary arsines. Probably the most exhaustive coverage with references to the primary literature for known synthetic routes to tertiary arsines is provided by Dub,[9,10] Cullen,[7] Doak and Freedman,[6] and Aylett.[11]

Two practical synthetic methods have been reported for the high-yield preparation of tertiary arsines. The reactions of chlorodioxarsolane, $\overline{OCH_2CH_2OAs}Cl$, with aluminum alkyls, Grignard reagents, organolithium, and dialkylzinc give high yields of the fully substituted organoarsines.[18] Grignard reagents and aluminum alkyls readily react with $As[NMe_2]_3$ to give tertiary arsines.[19] The latter method is an adaptation of the high-yield route to Me_3As[20] that does not require using a complexing agent for the Me_3As (equation 3).

$$2As(NMe_2)_3 + 3[Me_3Al]_2 \longrightarrow 2Me_3As + 3[Me_2AlNMe_2]_2 \qquad (3)$$

Unsymmetric arsines of the type R_2AsR' and $RR'R''As$ are well known.[3–11,16,21,22] The most common synthetic procedure involves alkylating the organomonohalo- or organodihaloarsine with the desired Grignard or organolithium reagent. Di-Grignard reagents have also been used to prepare cyclic arsolanes.[23] Good yields of heteroleptic tertiary arsines are obtained in the reaction of an organohalide with the appropriate metal arsenide. The reaction of an organohalide with a diarsine, R_2AsAsR_2, or a primary arsine, $RAsH_2$, is another route to unsymmetric arsines. The microbial activity of molds acting on arsenicals in anthropogenic and natural sources has also been exploited in producing unsymmetric arsines.[3,24,25] Et_4Pb and n-Bu_3Sb alkylate the haloorganoarsines to give ethyl and butyl derivatives. Bn_2Hg gives a quantitative yield of Me_2AsBn when Me_2AsI is used, but a lesser yield and by-product contamination result when Me_2AsH is alkylated.[26] By capitalizing on the reactivity of Me_2AsNMe_2 toward Grignard reagents and aluminum alkyls, a general protocol has also been developed to the Me_2AsR arsines (equation 4).[27]

$$2Me_2AsNMe_2 + 2Et_3Al \longrightarrow 2Me_2AsEt + [Me_2NAlEt_2]_2 \qquad (4)$$

Dinuclear arsines containing a bridging methylene unit, $R_2AsCH_2AsR_2$, have been prepared from the parent haloarsine using RLi.[28] With PhC≡CLi, cleavage of the $AsCH_2As$ backbone occurs and $As(C{\equiv}CPh)_3$ is isolated.

Tertiary arsines are readily oxidized with common oxidizing agents (H_2O_2, $KMnO_4$) to the arsine oxide. Oxidation of the alkyl derivatives with H_2O_2 or HgO gives the trialkylarsine oxide R_3AsO, but air oxidation produces the dialkylarsinic acids, $R_2As(O)OH$. With sulfur and selenium, the trialkylarsines are oxidized to the corresponding sulfide and selenide. They readily form adducts with diborane, aluminum alkyls, $AlCl_3$, and gallium alkyls.[29] Their reactions with NH_2Cl, MeNHCl, and Me_2NCl produce the respective aminoarsonium chlorides (equation 5).[30,31]

$$Et_3As + Me_2NCl \longrightarrow [Et_3AsNMe_2]Cl \qquad (5)$$

Et_3As reacts with $AsCl_3$ in *n*-pentane to give a quantitative yield of the sublimable dimer $[Et_3As{\cdot}AsCl_3]_2$,[32] which disproportionates above its melting point to a mixture of Et_2AsCl and $EtAsCl_2$. Tertiary arsines react with a stoichiometric amount of halogen to form the R_3AsX_2 species (equation 6). These disproportionate on heating to give the haloarsine and an alkyl halide (equation 7). This can serve as a convenient synthetic route to the dialkylhaloarsines. Although the tertiary arsines have been extensively used as ligands in transition-metal complexes,[1,9–11] this chemistry will not be treated here as part of the chemistry of organometallic arsenic compounds.

$$R_3As + X_2 \longrightarrow R_3AsX_2 \qquad (6)$$

$$R_3AsX_2 \longrightarrow R_2AsX + RX \qquad (7)$$

There is a very extensive heterocyclic chemistry of tricoordinate arsenic wherein arsenic is incorporated in four- to ten-membered ring systems.[2,9,10] Although the most prevalent synthetic route involves the reaction of a dihaloarsine with a di-Grignard or dilithium reagent, there are many custom syntheses to specific heterocycles. The synthesis and reactivity of the heterocyclic arsenic chemistry will not be reviewed here. Instead, the reader is referred to the comprehensive treatise by Mann and the primary literature that is cited therein.[2]

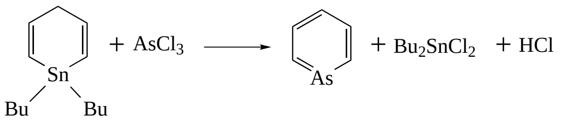
Gas-phase electron diffraction and solid-state *X-ray diffraction* studies on R_3As indicate pyramidal geometry about the arsenic.[4–7,11] In Me_3As, the As–C bond distance is 1.968 Å and the C–As–C angle has an average value of 96.1°. Correspondingly, for $(CF_3)_3As$, the As–C bond distance is increased to 2.053 Å and the C–As–C angle opened to 100.1°. X-ray diffraction studies on $As(CH_2CMe_3)_3$[17] give an average As–C distance of 1.998 Å and a C–As–C angle equal to 94.6°. For Ph_3As, there are four symmetrically independent molecules in the crystal structure, which are connected in pairs by the elements of symmetry.[33] The average As–C bond distance value is 1.957 Å and that of the C–As–C angle is 100.1°. Substitution in the p-position on the aromatic ring does not significantly affect these values, that is, tri-*p*-tolylarsine, 1.964 Å and 99.3°; tri-*p*-chlorophenylarsine, 1.958 Å and 99.8°; tri-*p*-methoxyphenylarsine, 1.963 Å and 98.3°. However, substitution of methyl groups in the 2 and 6 positions of the phenyl rings leads to an increase of the C–As–C angle by approximately 7°. For the perfluoro derivative, $(C_6F_5)_3As$, the average As–C bond distance is 1.959 Å and the average C–As–C angle is 100.5°.[34]

Early ^1H NMR data were obtained on trimethyl and dimethylphenyl derivatives of the group 15 elements, Me_3E and Me_2PhE (E = N, P, As, Sb, Bi). The methyl group chemical shift changes in each series were attributed to the electronegativity of the central atom.[6,7] Subsequently, similar studies were reported by ^{13}C NMR.[35,36] Detailed ^1H and ^{13}C NMR data have been reported for two series of tertiary arsines, R_3As[18] and Me_2AsR.[27]

Barriers to inversion of about 200 kJ mol^{-1} have been determined for tertiary arsines, both by experimental and semiempirical quantum mechanical calculations (*see Semi Empirical Theoretical Methods*).[5,11] The inversion barriers in arsines are considered to be the maximum for the group 15 elements, with values being about 60 kJ mol^{-1} higher than for corresponding phosphines.[11] For partially and fully substituted silylarsines,[11,37] the inversion barrier at arsenic decreases as more silicon atoms are directly attached.

2.2 Dicoordinate Arsenic

Several heterocyclic arsenines, which are derivatives of the unsubstituted arsenine $HC(CH)_4As$, are known and their chemistry has been reviewed.[38,39] Arsenine is prepared by the reaction of 1,4-dihydro-1,1-dibutylstannabenzene with $AsCl_3$ (equation 8).[40] The reader is referred to two reviews[38,39] and the references that are cited therein for information on the chemistry of the arsenines.



(8)

2.3 Tetracoordinate Arsenic

There are two classes of organoarsenic compounds in which the arsenic is tetracoordinated to only organo moieties, namely the tetraorganoarsonium salts[4,7,9–11] and the organoarsenic ylides.[4,5,9–11] Alkylation of the tertiary arsines with organohalides is the common mode of preparation of the arsonium salts. The alkyl iodides are more reactive than the alkyl bromides and chlorides. Alkyl halides can be reacted with elemental arsenic to yield the respective arsonium halides. The arylarsonium halides can be obtained from the reaction of the arylarsine oxide and the corresponding Grignard reagent (equation 9).

$$Ph_3AsO + PhMgX \longrightarrow [Ph_4As]X + MgO \qquad (9)$$

X-ray and spectroscopic studies indicate that the arsonium halides are ionic. Me_4AsBr consists of tetrahedral Me_4As^+ units and separate bromide ions.[11] X-ray structures have also been obtained on a series of tetraphenylarsonium salts.[4–7,11,41] A regular tetrahedral structure is found about the arsenic atom when the counterion is a halide or ion of similar size. However, as the size of the counterion increases, the crystals become more disordered.[41] In solution, tetraphenylarsonium salts are almost completely dissociated, but ion pairing can be significant and is dependent primarily on the dielectric constant of the solution.

^{13}C and ^1H NMR data have been reported for several tetraalkylarsonium salts[36,42] and the ^{13}C NMR chemical

shifts compared with the corresponding tertiary arsines. Similar multinuclear NMR data have been summarized for $Ph_4As^+X^-$.[41,42]

Deprotonation of arsonium salts $[R_3AsCHR_2]X$ with phenyllithium or -sodium in liquid ammonia yields the ylides $R_3As{=}CR_2$ (*see Ylide*). $Me_3As{=}CH_2$ can be synthesized from Me_3As by first quaternizing the arsine with Me_3SiCH_2Cl, then using BuLi to deprotonate the arsonium salt, and finally removing the Me_3Si by the reaction with Me_3SiOH. The first mixed P/As double ylide, $Ph_2(Me)P{=}C{=}As(Me)Ph_2$, was prepared from the reaction of the arsonium salt $[Ph_2(Me)P–CH_2–As(Me)Ph_2](SO_3F)_2$ with $NaNH_2$ in liquid ammonia.[43]

The ^1H NMR chemical shift for the CH_2 group in $Me_3As{=}CH_2$ is to high field, above TMS. This suggests the importance of the canonical form $Me_3As^+{-}^-CH_2$ in contributing to the structure.[4,5,11,15]

2.4 Pentacoordinate Arsenic

A limited number of pentaorganoarsoranes, AsR_5, are known.[4,5,44,45] Me_5As is prepared in high yield by the reaction of methyllithium with Me_3AsCl_2. On the other hand, Ph_5As is formed by reacting phenyllithium with either Ph_3AsO, $[Ph_4As]Br$, or the tosylimine $Ph_3As{=}NSO_2C_6H_4Me$. A redox reaction occurs when $(Me_3SiCH_2)_3As$ is mixed with $AsCl_3$ to give $(Me_3SiCH_2)_3AsCl_2$ and elemental arsenic.[46] A recent review article[45] provides references on the synthesis and reactivity of several other arsoranes.

A trigonal bipyramidal solution structure (*see Trigonal Bipyramidal*) has been proposed for Me_5As from vibrational and ^1H NMR studies.[11,44,45] ^1H NMR, vibrational, and crystal-structure data indicate that Ph_5As is trigonal bipyramidal in solution and the solid state.[4–7,11,44,45]

3 ORGANOARSINES CONTAINING As–H BONDS

3.1 Primary and Secondary Arsines

Organoarsines containing the As–H bond are limited to the primary and secondary organoarsines.[4,5,7,9–11,47] Both the alkyl and aryl derivatives are usually synthesized by the reduction of the arsinous acid $[R_2AsOH]$, arsonic acid $[RAsO(OH)_2]$, arsinic acid $[R_2As(O)OH]$, or organohaloarsines $[RAsX_2$ or $R_2AsX]$ with powdered zinc or zinc amalgam and hydrochloric acid (equations 10 and 11). Reduction of $(Me_3SiCH_2)_2AsCl$ with Zn/Cu amalgam in a hydrochloric acid/THF solution gives a high yield of the secondary arsine and avoids the formation of the diarsine.[48]

$$RAsO(OH)_2 + 3Zn + 6HCl \longrightarrow RAsH_2 + 3ZnCl_2 + 3H_2O \quad (10)$$

$$R_2AsCl + Zn + HCl \longrightarrow R_2AsH + ZnCl_2 \quad (11)$$

Reduction of the dialkylchloroarsines with $LiAlH_4$ affords an alternative route to the secondary arsines, but gives low yields of primary arsines in the reduction of alkyldichloroarsines. In the latter case, the formation of Al–As bonded species is thought to significantly lower the arsine yields, but with the bulky Me_3SiCH_2 and Me_3CCH_2 groups, both the primary and secondary arsine are readily obtainable through the reduction of the respective haloarsine with $LiAlH_4$.[46,49,50] Similarly, 2,6-$(Me_2NCH_2)_2C_6H_3AsCl_2$ is easily reduced to the primary arsine using $LiAlH_4$.[51] $LiBH_4$ is excellent for reducing $PhAsCl_2$. Although a complex mixture of alkylated arsines and AsH_3 is obtained when $LiAlH_4$ is used to reduce vinylchloroarsines, good yields (ca. 60%) of the respective primary and secondary vinyl arsines are obtained using butylstannane.[52] Benzene reacts with $AsCl_3$ in the presence of $AlCl_3$ to give a mixture of Ph_2AsH and $PhAsH_2$. The alkylarsines are also prepared by the reaction of an alkyl halide with $NaAsH_2$. When potassium diaryl- or arylalkylarsenide is reacted with water, a high yield of the secondary arsine results. MeAsHCl can be synthesized by reacting $MeAsCl_2$ with $EtSbH_2$ (equation 12).[53]

$$2MeAsCl_2 + EtSbH_2 \longrightarrow 2MeAsHCl + EtSbCl_2 \quad (12)$$

Although primary and secondary arsines do not react with water, they are easily oxidized by oxygen.[4–6,9–11,54] For this reason, oxygen must be rigorously excluded in their synthesis. In the presence of oxygen, primary arsines give the cyclopolyarsines (equation 13), but in a stoichiometric excess of oxygen yield the arsonic acids $RAs(O)(OH)_2$ (equation 14). The hydrogens are easily replaced by treatment with sodium, organolithium, or Grignard reagents to give organoarsenides of the type R_2AsM, $RAs(H)M$, and $RAsM_2$ (M = Li, Na, K, MgX), which are useful in the synthesis of tertiary, ditertiary, and tritertiary arsines.

$$10MeAsH_2 + 5O_2 \longrightarrow 2(MeAs)_5 + 10H_2O \quad (13)$$

$$2MeAsH_2 + 3O_2 \longrightarrow 2MeAs(O)(OH)_2 \quad (14)$$

Both the primary and secondary arsines are strong reducing agents and undergo facile oxidization with the halogens, aliphatic and aromatic aldehydes, haloarsines, chloramine and dimethylchloramine, SO_2Cl_2, and Me_3PbOMe to give the corresponding diarsines or cyclopolyarsines.[4–6,9–11,54] In the absence of triethylamine or with higher stoichiometric amounts of the halogen, halogenation of the primary and secondary arsines leads to substitution and formation of the dihalo- and haloarsine (equations 15–18).

$$6PhAsCl_2 + 12Ph_2AsH \longrightarrow (PhAs)_6 + 6(Ph_2As)_2 + 12HCl \quad (15)$$

$$5MeAsH_2 + 5H_2NCl \longrightarrow (MeAs)_5 + 5NH_4Cl \quad (16)$$

$$6PhAsH_2 + 6SO_2Cl_2 \longrightarrow (PhAs)_6 + 12HCl + 6SO_2 \quad (17)$$

$$2Me_2AsH + Cl_2 + 2Et_3N \longrightarrow Me_2AsAsMe_2 + 2Et_3NHCl \quad (18)$$

$MeAsH_2$ reacts with $Me_2AsAsMe_2$ to give $(MeAs)_5$ and Me_2AsH.[55] With Me_2AsNMe_2, the products are $(MeAs)_5$,

Me_2AsH, and Me_2NH.[56] Other primary arsines easily react with $(MeAs)_5$ to generate the respective cyclopolyarsine $(RAs)_n$, where $n = 5$ or 6, and $MeAsH_2$.[57,58] Me_2AsH reacts with Me_2AsNMe_2 (and its BH_3 adduct) to produce $Me_2AsAsMe_2$.[59] Secondary arsines also react with symmetric diarsines to give mixtures of unsymmetric and symmetric diarsines (equation 19).[60] The analogous reaction of Me_2AsH with Et_2PPEt_2 yields a mixture of Et_2PH, $Me_2AsAsMe_2$, and Me_2AsPEt_2.[60] Ph_2AsH will cleave the Sn–N bond in Me_2NSnMe_3 to give $Ph_2AsSn(Me_3)_3$.[61]

$$3R_2AsH + 2R'_2AsAsR'_2 \longrightarrow R_2AsAsR_2 + R_2AsAsR'_2 + 3R'_2AsH \quad (19)$$

The reaction of Me_2AsH with diborane produces $Me_2AsH\cdot BH_3$. When the reaction is carried out at 50 °C, $[Me_2AsBH_2]_3$ and $[Me_2AsBH_2]_4$ are formed. The reaction of Me_2AsH, $(t\text{-Bu})_2AsH$, or Ph_2AsH with aluminum alkyls proceeds through a 1,2-elimination reaction to yield arsinoalanes of the following type: $[Me_2AlAsMe_2]_3$,[62,63] $[Me_2AlAsPh_2]_3$,[64] $[Me_2AlAs(t\text{-Bu})_2]_2$,[65] and $[Et_2AlAs(t\text{-Bu})_2]_2$.[66] Other secondary arsines react in an analogous fashion with organogallanes and organoindanes to give $[Me_2GaAs(i\text{-Pr})_2]_3$,[67] $[Ph_2GaAs(CH_2SiMe_3)_2]_2$,[48] $[Me_2GaAs(CH_2CMe_3)_2]_2$,[50] $[(i\text{-Pr})_2GaAs(i\text{-Pr})_2]_2$,[68,69] $[Me_2InAsMe_2]_3$,[62] $[Me_2InAsPh_2]_2$,[70] and $[Me_2InAs(t\text{-Bu})_2]_2$.[65] With primary arsines, the reactions proceed to give uncharacterized oligomers, except when there are bulky substituents on arsenic or gallium. For example, the reaction of $Me_3CCH_2AsH_2$ with Me_3Ga gives $[Me_2GaAs(H)CH_2CMe_3]_n$[50] and that of $PhAsH_2$ with $[Me_3SiCH_2]_3Ga$ produces the unique gallium–arsenic cluster compound $(PhAsH)\{[Me_3SiCH_2]_2Ga\}(PhAs)_6[Me_3SiCH_2Ga]_4$ (see Section 5).[71]

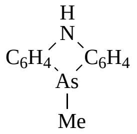
Vibrational and NMR spectroscopic techniques have been employed to investigate general conformational properties in primary and secondary organoarsines, as well as the determination of As–H bond strength and lability.[6,15,37,72] Molecular orbital calculations (*see* ***Molecular Orbital Theory***) have also been published on a series of $RAsH_2$.[73] There has been considerable interest in the characterization of organoarsines, including ^{13}C NMR data.[49,50,55,56,58,60,74,75] Most of this interest is due to the assessment of their possible use as replacements for AsH_3 in the production of gallium arsenide thin films and in the synthesis of precursors for group 13–15 semiconductors.[76]

4 ORGANOARSENIC COMPOUNDS CONTAINING As–HALOGEN BONDS

4.1 Mono- and Dihaloarsines

The haloarsines are most commonly prepared from the reduction of the arsonic or arsinic acids by sulfur dioxide in the presence of a hydrogen halide and a trace of KI.[4–7,9–11,77] Because haloarsines are in equilibrium with their respective arsonous or arsinous acids in aqueous solution, they can be prepared by the addition of excess hydrohalic acid to the respective acids (equation 20). Highly pure alkyldichloroarsines are obtained by heating the 10-alkyl-5,10-dihydrophenarsazines with hydrogen chloride (equation 21). Cleavage of the As–N bond in aminoarsines with hydrogen halides provides another route to the haloarsines (equation 22).

$$RAs(OH)_2 + 2HX \longrightarrow RAsX_2 + 2H_2O \quad (20)$$



$$+ 3HCl \longrightarrow MeAsCl_2 + [Ph_2NH_2]^+Cl^- \quad (21)$$

$$EtAs(NMe_2)_2 + 4HCl \longrightarrow EtAsCl_2 + 2[Me_2NH_2]^+Cl^- \quad (22)$$

Redistribution reactions that involve heating the appropriate stoichiometric mixtures of the tertiary arsines with $AsCl_3$ produce the mono- and dihaloarsines (equations 23 and 24). Disproportionation of a dihaloarsorane at high temperatures serves as a convenient synthetic route to the dialkylhaloarsines (equation 25).

$$2AsR_3 + AsCl_3 \longrightarrow 3R_2AsCl \quad (23)$$

$$AsR_3 + 2AsCl_3 \longrightarrow 3RAsCl_2 \quad (24)$$

$$2RAsX_2 \longrightarrow R_2AsX + AsX_3 \quad (25)$$

Alkylation of AsX_3 using organomercury and tetraalkyllead works well for those haloarsines that are difficult to prepare by the more drastic conditions of the disproportionation and redistribution reactions. Although incomplete alkylation of $AsCl_3$ with aluminum alkyls gives haloarsines, these usually are obtained as mixtures of the mono- and dihaloarsines with the tertiary arsines. Because complete alkylation of $AsCl_3$ does not generally occur with the Grignard reagents, this method is only used in a few special cases. The reaction of organohalides at moderate temperatures with elemental arsenic in the presence of copper yields mixtures of R_2AsX, $RAsX_2$, R_3As, AsX_3, and As_2X_4. The salt elimination reaction has been used in the recent synthesis of $(\eta\text{-}C_5Me_5)_2AsCl$ from $AsCl_3$ and LiC_5Me_5.[78] Vinylhaloarsines have been prepared in high yields by the reaction of $AsCl_3$ with 1:1 and 1:2 mol ratios of vinylstannane.[51] Numerous other methods are employed to prepare specific haloarsines and references to the primary literature for these can be found in reviews.[4–7,9–11,77] In general, the chloro- and bromoarsines are the most easily synthesized and are used in halogen exchange reactions to prepare the fluoro- and iodoarsines (equation 26).

$$Ph_2AsCl + AgF \longrightarrow Ph_2AsF + AgCl \quad (26)$$

The organohaloarsines are very reactive species and are commonly used to prepare heteroleptic tertiary arsines (see Section 2), primary and secondary arsines (see Section 3), and aminoarsines and catenated arsines (see Section 7.3). They easily hydrolyze to their respective arsonous and arsinous acids (equation 27) and are oxidized in air to the corresponding arsonic and arsinic acids (equation 28).

$$RAsX_2 + 2H_2O \longrightarrow RAs(OH)_2 + 2HX \quad (27)$$

$$2R_2AsX + O_2 + 2H_2O \longrightarrow 2R_2As(O)OH + 2HX \quad (28)$$

Both the monohalides, R_2AsX, and the dihalides, $RAsX_2$, are pyramidal molecules.[5–7,11,37] Electron diffraction studies on Me_2AsX show a regular variation in the As–X bond length, where As–F = 1.95 Å[79] and As–Cl = 2.18 Å, As–Br = 2.34 Å, and As–I = 2.52 Å.[5,11] The As–F bond length in $MeAsF_2$ is 1.74 Å[5,6] (microwave) while the As–I value in $MeAsI_2$ = 2.54 Å[5–7] (X ray). Ph_2AsX (X = Cl, Br, I) are isomorphous from X-ray data, where the As–X bond lengths[5–7] are Cl, 2.26 Å, Br, 2.40 Å, and I, 2.53 Å. The phenyl rings are rotated about 36° and 80° from their positions in an ideal model, which would allow maximum overlap of the π-orbitals of the aromatic groups with the arsenic lone pair electrons.[7] The structure of $PhAsBr_2$ has been studied by electron diffraction.[80]

4.2 Haloarsoranes

Haloarsoranes of the type $RAsX_4$, R_2AsX_3, and R_3AsX_2 are conveniently prepared by the direct reaction of the halogen with $RAsX_2$, R_2AsX, and R_3As respectively.[4–7,9–11,45,77] Other halogenating agents (SF_4, $TlCl_3$, $PbCl_4$, $HgCl_2$, PCl_5) have been used to halogenate the arsinous acid anhydrides, arsonic and arsinic acids, and tertiary arsines. Generally, the fluoro- and chloroarsoranes are pentacoordinate, while the bromo and iodo compounds of these compositions are ionic arsonium salts when the R substituent is not very sterically demanding. Hydrolysis of $RAsX_4$ and R_2AsX_3 yields the corresponding arsonic or arsinic acids and pyrolysis produces the organohalide and AsX_3 and $RAsX_2$, respectively. R_3AsX_2 hydrolyzes to R_3AsO and gives R_2AsX and RX when heated above the melting point.

A trigonal bipyramidal structure has been postulated for $PhAsCl_4$ where the phenyl group occupies an equatorial site.[45] Similarly, Me_2AsCl_3, Ph_2AsCl_3, and Ph_2AsF_3 are trigonal bipyramidal from spectroscopic data. However, Me_2AsF_3 is associated in solution.[45] The structures of R_3AsX_2 have been studied in much greater detail[4,5,7,11,37,45] and are generally thought to be either trigonal bipyramidal or ionic, $[R_3AsX^+]X^-$, in nature, although certain systems such as Ph_3AsI_2 are complex. The R_3AsX_2 species (R = Me, Et, Ph; X = F, Cl) have a trigonal bipyramidal structure. Me_3AsBr_2, Et_3AsBr_2, and Me_3AsI_2 are ionic with the expected tetrahedral geometry about the arsenic atom.[17] Interestingly, X-ray studies have established that the neopentyl derivative $As(CH_2CMe_3)Br_2$ is trigonal bipyramidal.[17]

5 ORGANOARSENIC COMPOUNDS CONTAINING As–GROUP 13 BONDS

5.1 As–B Bonded Compounds

Relatively few organoarsenic compounds that contain an As–B bond are known.[11,15,81–84] In most cases, these are synthesized by the straightforward reaction of the primary, secondary, and tertiary arsine with diborane or BH_3·THF (equation 29). As–B bonding also results when the BH_3 moiety reacts with Sn–As and As–P–As bonded compounds (equations 30 and 31).[81]

$$2Me_2AsH + B_2H_6 \longrightarrow 2Me_2AsH{\cdot}BH_3 \quad (29)$$

$$Me_3SnAsPh_2 + THF{\cdot}BH_3 \longrightarrow Me_3SnAs({\cdot}BH_3)Ph_2 + THF \quad (30)$$

$$(Me_2As)_2PCF_3 + B_2H_6 \longrightarrow (Me_2As)_2PCF_3{\cdot}2BH_3 \quad (31)$$

BH_3 coordinates at arsenic in Me_2NAsF_2.[85] At low temperatures, As–B bonded adducts are observed in the reaction of THF·BH_3 with Me_2AsNEt_2, $Me_2AsN(n\text{-}Pr)_2$, and $Me_2AsN(i\text{-}Pr)_2$.[82,84] The ethyl and n-propyl derivatives also exhibit N–B bonded adducts, with the As–B adduct being favored over the N–B adduct with increasing steric bulk of the alkyl substituent on the nitrogen. Arsine–borane adducts that contain As–H, As–As, and As–N bonds decompose at moderate temperatures to cycloarsinoborines, $[Me_2AsBH_2]_{3,4}$ (equation 32).

$$B_2H_6 + 2Me_2AsH \xrightarrow{50\,^{\circ}C} \frac{2}{n}[Me_2AsBH_2]_n + 2H_2 \quad (32)$$

Dehalosilylation in the reaction of Ph_2BCl with $Me_2AsSiMe_3$ gives $[Ph_2BAsMe_2]_3$ (equation 33).[86] The reaction of Me_2BBr with $Me_2AsSnMe_3$ produces the corresponding trimer and with $MeBBr_2$ gives $[Me(Br)\text{-}BAsMe_2]_3$.[87] Using the salt elimination procedure, $[PhAs\text{-}(BNMe_2)]_2$ has been synthesized from a 1:1 reaction of Li_2AsPh with $B_2(NMe_2)_2Br_2$.[88] This procedure has also been used to prepare $[PhB(Cl)As(t\text{-}Bu)_2]_2$, $PhB[As(t\text{-}Bu)_2]_2$, $Cp^*B(Cl)As(t\text{-}Bu)_2$, $(C_{20}H_{30})BAs(t\text{-}Bu)_2$, and $Mes_2BAs\text{-}(Ph)SiMe_3$.[89] The reaction of Mes_2BF with Li_2AsPh in THF gives the compound $Li(THF)_3PhAsBMes_2$, which contains a B–As double bond. By adding two equivalents of TMEDA to a solution of this compound in diethyl ether, another B–As double-bonded compound is formed, $[Li(TMEDA)_2][PhAsBMes_2]$.[90] On the other hand, Mes_2BF reacts with $LiAs(i\text{-}Pr)_2$ and $LiAs(t\text{-}Bu)_2$ to give the monomeric arsinoboranes, $Mes_2BAs(i\text{-}Pr)_2$ and $Mes_2BAs(t\text{-}Bu)_2$.[91] The cyclic $(i\text{-}Pr)_2NB(N\text{-}t\text{-}Bu)B(N\text{-}i\text{-}Pr_2)AsPh$[92] and monomeric arsenoborane[83] $Cp^*(Cl)BAs(t\text{-}Bu)_2$ have been

reported.

$$3Ph_2BCl + 3Me_3SiAsMe_2 \longrightarrow [Ph_2BAsMe_2]_3 + 3Me_3SiCl \quad (33)$$

The addition compounds formed by the interaction of BX_3 (X = F, Cl, Br, I) and B_2H_6 Lewis acids (*see Lewis Acids & Bases*) with arsines have been characterized by several spectroscopic methods.[82,84,93] Multinuclear NMR chemical shift data have been used extensively to explore the comparative donor properties of structurally similar amines, phosphines, and arsines toward boron-containing acceptors. Relative adduct stabilities have been determined for BX_3 and B_2H_6 with several homologous series of compounds containing group 15 elements. From these studies, Lewis acid and base strengths within given series have been proposed. For example, $Me_nAsH_{3-n}{\cdot}BH_3$ ($n = 1-3$) adduct stability decreases as n decreases[5,11] and $BH_3{\cdot}ER_3$ adduct stability follows the order E = P > N > As > Sb.[84]

Arsenoboranes like $[Ph_2BAsMe_2]_3$ and $[Me_2AsBH_2]_{3,4}$ have been assumed to be ring structures with head-to-tail As–B arrangements, σ-type bonding, and tetrahedral B and As geometries, although no structural data have been reported. Monomeric arsenoboranes, as discussed above, have been obtained by introduction of bulky groups on boron.[83,90] Strategies have also been developed to create planarity at the arsenic center and enhance As–B multiple bonding.[83] For example, As–B double bonding has been proposed in $Li(THF)_3PhAsBMes_2$ and $[Li(TMEDA)_2][PhAsBMes_2]$ from As–B bond distance and other structural and spectroscopic data.[90] X-ray data indicate multiple As–B bonding in $Li(THF)_3PhAsBMes_2$,[90] and $[Li(TMEDA)_2][PhAsBMes_2]$[90] with the As–B bond lengths being 1.926 and 1.936 Å respectively. As–B bond lengths of 2.063, (2.200 and 2.184), 2.064, 2.084, 2.031, and 2.085 Å are found in cyclic $(i\text{-}Pr)_2NB(N\text{-}t\text{-}Bu)B(N\text{-}i\text{-}Pr_2)AsPh$,[92] $[PhB(Cl)As(t\text{-}Bu)_2]_2$, $PhB[As(t\text{-}Bu)_2]_2$, $C_{20}H_{30}BAs(t\text{-}Bu)_2$, $Mes_2BAs(Ph)SiMe_3$, and $Cp^*(Cl)BAs(t\text{-}Bu)_2$[83] respectively. With $[PhAs(BNMe_2)_2]_2$, the six-membered As_2B_4 ring is in a chair configuration with four As–B bond lengths of 2.082, 2.063, 2.041, and 2.068 Å.[88] These distances are to be compared with As–B values in boron arsenide (2.069 Å) and in the Zintl compound (*see* ***Zintl Compounds***) K_3BAs_2 (1.868 Å),[94] where the boron is dicoordinate.

5.2 As–Al Bonded Compounds

The tertiary arsines easily form adducts with the aluminum alkyls.[29,95] The reaction of R_2AlCl (R = Me, *i*-Bu) with $As[SiMe_3]_3$ does not lead to a dehalosilylation reaction, but yields the adducts $R_2(Cl)Al{\cdot}As[SiMe_3]_3$.[96] The other known As–Al bonded compounds are base-stabilized monomeric arsinoalanes and the cycloarsinoalanes. Although a few secondary arsines react with aluminum alkyls to give the cycloarsinoalanes (equations 34 and 35),[65,66,70] this 1,2-elimination route to arsinoalanes becomes impractical as the steric bulk of the substituents increases.[97] AsH_3 reacts with $t\text{-}Bu_3Al$ to produce the trimeric $[(t\text{-}Bu)_2AlAsH_2]_3$.[98] The salt elimination method, which has been widely used in organometallic synthesis, has been used to synthesize As–Al ring compounds with bulky moieties on the arsenic and aluminum (equation 36).[96,99] Equilibration of an equal molar mixture of $[Et_2AlP(SiMe_3)_2]_2$ and $[Et_2AlAs(SiMe_3)_2]_2$ produced a four-membered ring compound, $Et_2AlP(SiMe_3)_2(Et_2Al)As(SiMe_3)_2$, with P and As atoms bridging the two aluminum centers.[100] The trimeric borazine analogue, $[Mes^*AlAsPh]_3{\cdot}Et_2O$ ($Mes^* = 2,4,6\text{-}(t\text{-}Bu)_3C_6H_2$), was synthesized by heating a mixture of Mes^*AlH_2 and H_2AsPh at 160°.[101] The first base-stabilized arsinoalane monomer was prepared using the salt elimination procedure (equation 37).[102] $Me_3N{\cdot}Al(H_2)As(SiMe_3)_2$ results from the dehydrosilylation reaction of $H_3Al{\cdot}NMe_3$ with $As(SiMe_3)_3$.[103] Recently, the base-stabilized monomeric species $dmap{\cdot}R_2AlAs(SiMe_3)_2$ (R = Me, Et) have been isolated and characterized from the reaction of dmap with $[Me_2AlAs(SiMe_3)_2]_3$ and $[Et_2AlAs(SiMe_3)_2]_2$.[104] Table 1 lists the known arsinoalanes and the preparative route to each.

$$2(t\text{-}Bu)_2AsH + 2AlEt_3 \xrightarrow{220\,^\circ C} [(t\text{-}Bu)_2AsAlEt_2]_2 + 2EtH \quad (34)$$

$$2(t\text{-}Bu)_2AsH + Al_2Me_6 \xrightarrow{220\,^\circ C} [(t\text{-}Bu)_2AsAlMe_2]_2 + 2MeH \quad (35)$$

$$2Et_2AlCl + 2LiAs(SiMe_3)_2 \longrightarrow [Et_2AlAs(SiMe_3)_2]_2 + 2LiCl \quad (36)$$

$$H_2AlCl{\cdot}NMe_3 + LiAsMes_2 \longrightarrow H_2AlAsMes_2{\cdot}NMe_3 + LiCl \quad (37)$$

Computational studies[95] of $R_3Al\text{–}ER'_3$ (E = P, As, Sb, Bi) Lewis acid–base adducts indicate that Al–E bond length does not directly correlate with adduct stability. Rather, Al–C(H)

Table 1 Known arsinoalanes

Arsinoalane	Preparative method
$Tmp_2AlAsPh_2$	Salt elimination[105]
$[Me_2AlAsMe_2]_3$	1,2-elimination;[62] H_2-elimination[63]
$[Me_2AlAsPh_2]_3{\cdot}(C_7H_8)_2$	1,2-elimination[64]
$[Me_2AlAs(t\text{-}Bu)_2]_2$	1,2-elimination[65]
$[Et_2AlAs(t\text{-}Bu)_2]_2$	1,2-elimination[66]
$[(t\text{-}Bu)_2AlAsH_2]_3$	1,2-elimination[98]
$[Me_2AlAs(SiMe_3)_2]_2$	Salt elimination;[96] Dehydrosilylation[104]
$[Et_2AlAs(SiMe_3)_2]_2$	Salt elimination;[99] Dehydrosilylation[104]
$[(i\text{-}Bu)_2AlAs(SiMe_3)_2]_2$	Salt elimination[96]
$[Me_2AlAs(CH_2SiMe_3)_2Ph]_3$	1,2-elimination[64]
$[2,6\text{-}Mes_2C_6H_3(H)AlAs(H)Ph]_2$	H_2-elimination[106]
$H_2AlAsMes_2{\cdot}NMe_3$	Salt elimination[102]
$Me_2AlAs(SiMe_3)_2{\cdot}dmap$	Ring cleavage[104]
$Et_2AlAs(SiMe_3)_2{\cdot}dmap$	Ring cleavage[104]
$H_2AlAs(SiMe_3)_2{\cdot}NMe_3$	Dehydrosilylation[103]
$[Mes^*AlAsPh]_3{\cdot}Et_2O$	H_2-elimination[101]

bond distances and C(H)–Al–C(H) bond angle parameters are useful in predicting adduct stability. Four cycloarsinoalane dimers have been characterized by single-crystal X-ray analysis. In each case, the $(Al–As)_2$ ring is planar with a distorted tetrahedral geometry about both the Al and As atoms and the endocyclic angle subtended at arsenic is larger than at aluminum. The Al–As bond distances and the Al–As–Al and the As–Al–As angles are as follows: $[Me_2AlAs(SiMe_3)_2]_2$[96] (triclinic: 2.536 Å, 91.71°, 88.29°); $[Et_2AlAs(SiMe_3)_2]_2$[99] (monoclinic: 2.535 Å, 91.01°, 88.99°); $[(i\text{-}Bu)_2AlAs(SiMe_3)_2]_2$[96] (monoclinic: 2.550 Å, 92.23°, 87.77°); $[Et_2AlAs(t\text{-}Bu)_2]_2$[66] (monoclinic: 2.567 Å, 94.54°, 85.46°). For the base-stabilized monomeric aminoalanes, the Al–As bond distances are as follows: $Me_2AlAs(SiMe_3)_2\cdot dmap$, 2.470 and 2.472 Å;[104] $Et_2AlAs(SiMe_3)_2\cdot dmap$, 2.473 Å;[104] and $(Me_3Si)_2AsAlH_2\cdot NMe_2$, 2.438 Å.[103] The borazine analogue, $[Mes^*AlAsPh]_3$, exhibits a nonplanar boat conformation with little or no arsenic lone pair delocalization and bond lengths consistent with Al–As single bonds.[101]

5.3 As–Ga Bonded Compounds

Prior to 1986, there were very few known and characterized As–Ga compounds.[29,107,108] Since that time, there has been a significant increase in the number of synthesized and fully characterized As–Ga species. Table 2 contains a listing of the organometallic As–Ga bonded compounds that have been synthesized from 1986 to 2003 and indicates their method of synthesis.

These compounds can be classified according to the As–Ga bonding nucleus as simple As–Ga adducts, twist-boat conformation $(As–Ga)_3$ rings, planar or nonplanar $(As–Ga)_2$ rings, nonplanar Ga–As–Ga–X rings (X = halogen), pyramidal Ga_3As gallanoarsines, and planar As_3Ga arsinogallanes. Much of the synthesis activity is a consequence of the search for volatile, single-source, gallium arsenide precursors that will not incorporate As–C bonds into thin films grown from OMCVD processes.[141] There has been a judicious variation of substituents and the application of three general synthesis methodologies, other than direct adduct formation, to give compounds that contain these As–Ga linkages: 1,2-elimination (equation 38), salt elimination (equation 39), and dehalosilylation (equation 40).

$$2(Me_3SiCH_2)_2AsH + 2GaPh_3 \longrightarrow [(Me_3SiCH_2)_2AsGaPh_2]_2 + 2PhH \quad (38)$$

$$2(Me_3Si)_2AsLi + 2ClGa(CH_2SiMe_3)_2 \longrightarrow [(Me_3Si)_2AsGa(CH_2SiMe_3)_2]_2 + 2LiCl \quad (39)$$

$$(Me_3SiCH_2)_2AsSiMe_3 + 2GaBr_3 \longrightarrow [(Me_3SiCH_2)_2AsGaBr]_2 + 2Me_3SiBr \quad (40)$$

Dehydrosilylation occurs in the reaction of $H_3Ga\cdot NMe_3$ with $As(SiMe_3)_3$ to provide an efficient route to $[(Me_3Si)_2AsGaH_2]_3$.[123]

Table 2 As–Ga bonded compounds synthesized after 1985

As–Ga bonded compounds	Method of preparation
$Et_3As\cdot GaMe_n(C_6F_5)_{3-n}$	Direct[109]
$[ClMe_2Ga\cdot AsEt_2]_2CH_2$	Direct[110]
$(t\text{-}Bu)_2(H)As\cdot Ga(i\text{-}Pr)_3$	Direct[69]
$(Me_3Si)_3As\cdot GaPh_3$	Direct[111]
$(Me_3Si)_3As\cdot Ga(Cl)(CH_2CMe_3)_2$	Direct[112]
$Ph_3As\cdot GaI_3$	Direct[113]
$(p\text{-}MeOC_6H_4)_3As\cdot GaI_3$	–[114]
$(Et_3As)_2\cdot Ga_2I_4$	–[114]
$[(THF)Br_2Ga]_3As$	Dehalosilylation[115]
$\{[2,4,6\text{-}(i\text{-}Pr)_2C_6H_2]_2Ga\}_2AsPh$	Salt elimination[116]
$(Ph_3Si)[(Me_3Si)_2CH]AsGa(t\text{-}Bu)_2$	Salt elimination[117]
$[(Mes)_2As]_3Ga$	Salt elimination[97,118]

$Ga_2\{As(Si(i\text{-}Pr)_3)\}_4$	Salt elimination[140]

The first example of an arsinogallane that contains the H_2As moiety, $[(t\text{-Bu})_2GaAsH_2]_3$, has been prepared in quantitative yield from the reaction of $t\text{-Bu}_3Ga$ with AsH_3.[134] Although the 1,2-elimination route was first used to prepare $[Me_2AsGaMe_2]_3$[62] and $[Me_2AsGaPh_2]_2$,[70] as the steric bulk of the substituents increases the utility of this approach becomes impractical to prepare arsinogallanes. For example, the reaction of $(t\text{-Bu})_2AsH$ with $Ga(i\text{-Pr})_3$ gives only the simple adduct $(t\text{-Bu})_2AsH{\cdot}Ga(i\text{-Pr})_3$[69] and the reaction of $PhAsH_2$ with $Ga(CH_2SiMe_3)_3$ yields the As–Ga cluster compound $(PhAsH)\{[Me_3SiCH_2]_2Ga\}(PhAs)_6[Me_3SiCH_2Ga]_4$.[71] Salt elimination and dehalosilylation have now become the preferred synthetic routes to the nonadduct systems (see Table 2).[122]

Arsenic–halogen mixed-bridge compounds, $\overline{R_2GaAs(SiMe_3)_2Ga(R)_2X}$, have been prepared by dehalosilylation that involves $As(SiMe_3)_3$ and R_2GaX (R = Ph, X = Cl, Br; R = Me_3SiCH_2, Me_3CCH_2, X = Cl) (equation 41).[112,122,124,126,127] The dimeric arsinogallanes also react with halogallanes to yield the mixed-bridge species (equation 42), which can be reconverted to the respective dimer by reaction with the $LiAs(SiMe_3)_2$.[112] Reaction of the mixed-bridge $\overline{Ph_2GaAs(SiMe_3)_2Ga(Ph)Cl}$ with $LiP(SiMe_3)_2$ leads to substituent transfer at both Ga and As to yield the adduct $Ph_3Ga{\cdot}As(SiMe_3)_3$, which can also form from the direct reaction of Ph_3Ga and $As(SiMe_3)_3$.[111] An As_2Ga_2 ring that is intramolecularly base-stabilized, $[(t\text{-Bu})GaAsC_6H_3(CH_2NMe_2)(CH_2NMe_2)]_2$, has been prepared by treating $t\text{-BuGaCl}_2$ with $Li_2AsC_6H_3(CH_2NMe_2)_2$.[137]

$$(Me_3Si)_3As + 2Ph_2GaCl \longrightarrow Ph_2GaAs(SiMe_3)_2GaPh_2Cl + Me_3SiCl \quad (41)$$

$$[(Me_3Si)_2AsGa(CH_2CMe_3)_2]_2 + 2(Me_3CCH_2)_2GaCl \longrightarrow 2(Me_3CCH_2)_2GaAs(SiMe_3)_2Ga(CH_2CMe_3)_2Cl \quad (42)$$

The salt elimination reaction has been employed to prepare two volatile monomeric arsinogallanes with bulky substituents on both As and Ga (equations 43 and 44).[129,133] Three sterically hindered trisarsinogallanes, $(Mes_2As)_3Ga$,[118] $\{[(Me_3SiCH_2)_2As]_3Ga\}_2$,[121] and $(t\text{-Bu}_2As)_3Ga$,[65,119] have been synthesized by salt elimination in the reaction of the lithium arsenide and the respective chlorogallane. Dehalosilylation is an alternative route to the mesityl compound.[97] $[(Me_3Si)_2As]_3Ga$ has been isolated as one of the products from the reaction of $LiAs(SiMe_3)_2$ and $[Cl_2GaP(SiMe_3)_2]_2$.[120]

$$(t\text{-Bu})_2AsLi + ClGa(t\text{-Bu})_2 \longrightarrow (t\text{-Bu})_2AsGa(t\text{-Bu})_2 + LiCl \quad (43)$$

$$(Me_3Si)_2AsLi + ClGaCp^*{}_2 \longrightarrow (Me_3Si)_2AsGaCp^*{}_2 + LiCl \quad (44)$$

The first arsinogallate $[(C_4Me_4As)_4Ga]Li(THF)_4$ has been reported.[139] It is synthesized from the lithium salt of the $[C_4Me_4As]^-$ anion, which is a permethylated arsole derivative, and $GaCl_3$. $Li(THF)_2Ga_2\{As[Si(i\text{-Pr})_3]_3\}_4$ is synthesized by an analogous route.[140]

A few studies have been carried out on the arsinogallanes as potential single-source GaAs precursors. Pyrolysis of $(t\text{-Bu})_2GaAs(t\text{-Bu})_2$,[133] $[(t\text{-Bu})_2GaAsH_2]_2$,[134] $[Me_2GaAs(t\text{-Bu})_2]_2$,[130] and $[Et_2GaAs(t\text{-Bu})_2]_2$[130] gives polycrystalline GaAs. GaAs films have been obtained from $[Me_2GaAs(t\text{-Bu})_2]_2$[142,143] and $[Et_2GaAs(t\text{-Bu})_2]_2$[130,143] using these as single sources in a chemical beam epitaxy reactor. $[(t\text{-Bu})_2As]_3Ga$ also produces thin films, which are n-type.[143] The pyrolysis mechanism of $Et_3As{\cdot}GaMe_n(C_6F_5)_{3-n}$[109] and $[ClR_2GaAsEt_2]_2CH_2$[110] (R = Me, Et) has been studied using mass spectrometry in GaAs vapor-phase epitaxy.

Mono(arsino)gallanes can occur as monomers, dimers, or trimers (see Table 2). More sterically demanding substituents enhance monomer or dimer formation. In three instances,[122,135] dimer/trimer equilibrium has been detected by NMR spectroscopic techniques. $(Me_3Si)_2AsGa(C_5Me_5)_2$[129] and $(t\text{-Bu})_2AsGa(t\text{-Bu})_2$[133] are monomeric. The following $R_2AsGaR'_2$ arsinogallanes are dimeric: R = Me_3CCH_2, R′ = Me;[50] R = Me_3SiCH_2, R′ = Ph;[48] R = Me_3Si, R′ = CH_2CMe_3,[112] CH_2SiMe_3,[124] Me,[128] t-Bu,[125] or Ph;[126,127] R = t-Bu, R′ = Me,[65,119] Et,[130] or n-Bu.[119] In each case, available X-ray data indicate planar $(Ga–As)_2$ rings. Trimers have been reported for $Me_3SiCH_2(H)AsGaPh_2$,[49] $(t\text{-Bu})(H)AsGa(t\text{-Bu})_2$,[98] $H_2AsGa(t\text{-Bu})_2$,[134] $(i\text{-Pr})_2AsGaMe_2$,[67] and $(Me_3SiCH_2)_2AsGaX_2$ (X = Cl,[97] Br[135,136]). X-ray studies[67,136] have indicated that the $(Ga–As)_3$ ring exists in a distorted or twisted-boat conformation. Trimers of $H_2GaAs(SiMe_3)_2$ exist as flattened $(Ga–As)_3$ rings.[123]

The bis(arsino)gallanes $[(Me_3SiCH_2)_2As]_2GaX$ (X = Cl,[97] Br[135]) are dimers with a planar $(Ga–As)_2$ ring and crystallize[135] in the trans configuration. The tris(arsino)gallane $(Mes_2As)_3Ga$ is nearly trigonal planar[97,118] and $[(Me_3Si)_2As]_3Ga$ is trigonal planar,[120] while $(t\text{-Bu}_2As)_3Ga$ has distorted pyramidal geometry.[65,119] However, $[(Me_3SiCH_2)_2As]_3Ga$ is dimeric[121] with a nonplanar $(Ga–As)_2$ ring.

The tris(gallyl)arsines $As[GaBr_2(THF)]_3$ and $Ph_3Si\text{-}[(Me_3Si)_2CH]AsGa(t\text{-Bu})_2$ have a pyramidal Ga_3As skeleton.[115] From X-ray data, the halogen mixed-bridge species contain a Ga–As–Ga–X ring that may be planar[112,125] or nonplanar,[124,126,127] depending on the steric requirements of the substituents.[122] $Ga_2\{As[Si(i\text{-Pr})_3]_4\}$ has a structure suggesting gallium–arsenic double bonds involving the exocyclic As moieties bound to the Ga atoms in the planar Ga_2As_2 ring.[140] The reader is referred to two excellent reviews on the characterization of these and other gallium–arsenic compounds.[122,141]

5.4 As–In Bonded Compounds

Prior to 1994, very few As–In bonded compounds were known. In the intervening 10 years, salt elimination, 1,2-elimination, and dehalosilylation preparative routes have been extended to As–In chemistry. Table 3 contains a listing of the

Table 3 Known As–In bonded compounds

As–In bonded compounds	Method of preparation
$[Me_2AsInMe_2]_3$	1,2-elimination[62]
$[Ph_2AsInMe_2]_2$	1,2-elimination[70]
$[(t\text{-Bu})_2AsInMe_2]_2$	1,2-elimination[65]
$[(Me_3Si)_2AsInEt_2]_2$	1,2-elimination[146]
$[EtInAsSi(i\text{-Pr})_3]_4$	1,2-elimination[147]
$[Ph_2InAs(SiMe_3)_2]_2$	Dehalosilylation[145]
$[(Me_3Si)_2AsIn(CH_2SiMe_3)_2]_2$	Dehalosilylation[144]
$(Me_3SiCH_2)_2InAs(SiMe_3)_2In(CH_2SiMe_3)_2Cl$	Dehalosilylation[144]
$[(Me_3Si)_2AsInMe_2]_2$	Dehalosilylation[148]
$(Me_3Si)_3AsIn(Me_3SiCH_2)_3$	Salt elimination;[111] direct[111]
$(MesInCl)_4(InCl)_2[As(t\text{-Bu})]_4$	Salt elimination[149]
$[Li(THF)_4]_2(MesInCl)_6(InCl)_2[(AsBu)t\text{-Bu}]_6$	Salt elimination[149]
$(Me_3Si)_3AsIn(CH_2CMe_3)_3$	Direct[150]
$(Me_3SiCH_2)_2InAs(SiMe_3)_2In(CH_2SiMe_3)_2P(SiMe_3)_2$	Equilibration[151]

organometallic As–In bonded compounds and indicates their method of synthesis. $[Me_2AsInMe_2]_3$,[62] $[Ph_2AsInMe_2]_2$,[70] and $[(t\text{-Bu})_2AsInMe_2]_2$[65] were prepared by reacting the respective secondary arsine with Me_3In. Four-membered arsinoindanes with arsenic and mixed As–Cl bridging have been synthesized by the salt elimination and dehalosilylation methods.[65,128,144,145] Dehalosilylation results in the formation of $[Ph_2InAs(SiMe_3)_2]_2$ from the room-temperature reaction of Ph_2InCl and $As(SiMe_3)_3$ (equation 45).[145]

$$2Ph_2InCl + 2As(SiMe_3)_3 \longrightarrow [Ph_2InAs(SiMe_3)_2]_2 + 2Me_3SiCl \quad (45)$$

When $(Me_3SiCH_3)_2InCl$ and $(Me_3Si)_3As$ are reacted in a 1:1 mol ratio, $[(Me_3Si)_2AsIn(CH_2SiMe_3)_2]_2$ results. With a 2:1 mol ratio, the mixed-bridge species, $(Me_3SiCH_2)_2In\text{-}As(SiMe_3)_2In(CH_2SiMe_3)_2Cl$, forms.[144] This mixed-bridge species can also be obtained from the reaction in equation (46), which is preferable to dehalosilylation as a preparative method and gives the mixed-bridge compound in greater yield.

$$2(Me_3SiCH_2)_2InCl + [(Me_3SiCH_2)_2InAs(SiMe_3)_2]_2 \longrightarrow 2(Me_3SiCH_2)_2InAs(SiMe_3)_2In(CH_2SiMe_3)_2Cl \quad (46)$$

Reaction of the mixed-bridge $(Me_3SiCH_2)_2InP(SiMe_3)_2\text{-}In(CH_2SiMe_3)_2Cl$ species with $LiAs(SiMe_3)_2$ gives the adduct $(Me_3SiCH_2)_3In{\cdot}As(SiMe_3)_3$.[111] This adduct can also be prepared from the direct reaction of $(Me_3Si)_3As$ and $In(CH_2SiMe_3)_3$.[111] Similarly, $(Me_3CCH_2)_3In{\cdot}As(SiMe_3)_3$ forms from the 1:1 mol ratio reaction of $(Me_3Si)_3As$ and $In(CH_2CMe_3)_3$.[150] When Me_3SiAsH_2 reacts with $Et_3In{\cdot}PR_2$ (R = Et, *i*-Pr), $[Et_2InAs(SiMe_3)_2]_2$ results.[146] $(t\text{-}Bu_2As)_3In$ has been synthesized from the reaction of $(t\text{-Bu})_2AsLi$ with $InCl_3$ at −78 °C.[65] Equilibration of $[(Me_3SiCH_2)_2InP(SiMe_3)_2]_2$ with $[(Me_3SiCH_2)_2InAs(SiMe_3)_2]_2$ in a 1:1 mol ratio yields $(Me_3SiCH_2)InAs(SiMe_3)_2In(CH_2SiMe_3)_2P(SiMe_{32})_2$, which has a four-membered planar (InAsInP) ring.[151] Et_3In reacts with $H_2AsSi(i\text{-Pr})_3$ to yield the $[EtInAsSi(i\text{-Pr})_3]_4$, which exhibits a heterocubane structure.[147] Other In–As cage type compounds have resulted by reacting $MesInCl_2$ and $InCl_3$ with the dilithium arsenide, $(BuAsLi)_2(t\text{-Bu})$, in a 4:2:4 mol ratio to produce $(MesInCl)_4(InCl)_2[As(t\text{-Bu})]_4$. Using Me_2InCl and MeInCl with $(BuAsLi)_2(t\text{-Bu})$ in a 6:2:6 ratio, $[Li(THF)_4]_2[(MesInCl)_6(InCl)_2[(AsBu)(t\text{-Bu})]_6]$ is isolated.[149]

An X-ray diffraction study indicates that $[Me_2AsInMe_2]_3$ contains two independent molecules per asymmetric unit in the solid state,[152] one with a planar $(AsIn)_3$ ring while the other is puckered. However, a dynamic ^1H NMR study indicates equivalence of the indium methyls and of the arsenic methyls in solution down to −80 °C. $[(t\text{-Bu})_2AsInMe_2]_2$[65,119] is dimeric by X-ray and mass spectral studies and the $(AsIn)_2$ core is planar.

The $(AsIn)_2$ ring is slightly puckered in $[(Me_3Si)_2AsInPh_2]_2$,[145] whereas the $(PIn)_2$ core in $[(Me_3Si)_2PInPh_2]_2$ is planar in the solid state. Both the $(AsIn)_2$ ring of $[(Me_3Si)_2AsIn(CH_2SiMe_3)_2]_2$ and the In–As–In–Cl ring of $(Me_3SiCH_2)_2InAs(SiMe_3)_2In(CH_2SiMe_3)_2Cl$ are planar by single-crystal X-ray diffraction studies.[144]

6 ORGANOARSENIC COMPOUNDS CONTAINING As–GROUP 14 BONDS

6.1 As–Si Bonded Compounds

Several references review the chemistry associated with organoarsines that contain the As–Si bond.[7,9–11,16,122,141,153,154] Silylation of the alkali metal organoarsenide leads to salt elimination and the formation of the silylarsines (equations 47–49).

$$Na_3As + 3Me_3SiCl \longrightarrow (Me_3Si)_3As + 3NaCl \quad (47)$$

$$Me_2SiCl_2 + 2Me_2AsLi \longrightarrow Me_2Si(AsMe_2)_2 + 2LiCl \quad (48)$$

$$Me_2SiCl_2 + 2(Me_3Si)_2AsLi{\bullet}2THF \longrightarrow [(Me_3Si)_2As]_2SiMe_2 + 2LiCl + 4THF \quad (49)$$

The reaction of LiAs(H)Me with Me_3SiCl at low temperature produces the unstable $Me_3SiAs(H)Me$, which decomposes with loss of $MeAsH_2$ to $(Me_3Si)_2AsH$. With Me_2SiCl_2, both $Me_2Si(AsHMe)_2$ and $(Me_2SiAsMe)_4$ form. When $ClSi(Me)_2SiMe_3$ and $ClSiMe(SiMe_3)_2$ react with Na_3As/K_3As in DME, the silicon-rich $As[Si(Me)_2SiMe_3]_3$ and $As[SiMe(SiMe_3)_2]_3$ are obtained respectively.[155]

The silylarsines readily undergo cleavage and insertion reactions and are quite useful in the synthesis of As–B, As–Al,

As–Ga, As–Ge, and As–Sn bonded compounds and transition-metal[156] complexes. The reaction of BF_3 with $Me_3SiAsMe_2$ at −50 °C gives a quantitative yield of $(Me_2As)_2BF$ and Me_3SiF. With MeI, cleavage of the Si–As bond occurs with a dehalosilylation reaction that gives alkylation on the arsenic (equation 50). Hydrolysis produces the arsine and silyl ether (equation 51), and $SiCl_4$ cleaves the As–Si bond to give a Cl_3Si derivative (equation 52). $Me_3SiAsMe_2$ has been used for fluorine substitution with an $AsMe_2$ group in polyfluoroarenes and C_5NF_5.[157]

$$Me_3SiAsMe_2 + MeI \longrightarrow Me_3As + Me_3SiI \quad (50)$$

$$2Me_3SiAsMe_2 + H_2O \longrightarrow 2Me_2AsH + (Me_3Si)_2O \quad (51)$$

$$Me_3SiAsMe_2 + SiCl_4 \longrightarrow Me_2AsSiCl_3 + Me_3SiCl \quad (52)$$

The importance of the silylarsines in the synthesis of arsinoalanes and arsinogallanes has been discussed in Section 5. Their use in synthesizing germyl- and stannylarsines is discussed below.

6.2 As–Ge Bonded Compounds

Relatively few germylarsines are known. They are usually prepared from the respective silylarsine by a salt elimination or dehalosilylation reaction (equations 53–55).[11,16,158] Cleavage of the Ge–N bond with a secondary arsine also leads to the formation of germylarsines (equation 56).[158] Oxidation of the germylarsines with oxygen leads to the respective metal arsinates, $R_3Ge–O–As(O)R'_2$.

$$Me_3GeCl + LiAsMe_2 \longrightarrow Me_3GeAsMe_2 + LiCl \quad (53)$$

$$Me_2As(CH_2)_2GeCl + Me_3SiAsMe_2 \longrightarrow Me_2As(CH_2)_2GeAsMe_2 + Me_3SiCl \quad (54)$$

$$Me_3GeCl + (t\text{-Bu})_2AsSiMe_3 \longrightarrow Me_3GeAs(t\text{-Bu})_2 + Me_3SiCl \quad (55)$$

$$Me_2NGe(CH{=}CH_2)Me_2 + Me_2AsH \longrightarrow Me_2AsGe(CH{=}CH_2)Me_2 + Me_2NH \quad (56)$$

6.3 As–Sn Bonded Compounds

The substantial number of known stannylarsines has been generally synthesized by the salt elimination or amine elimination reactions (equations 57–59).[11,16,61,159,160,161] Dehydrohalogenation in the presence of triethylamine is a convenient route to the stannylarsines (equation 60), and dehalosilylation has also been used to synthesize $(Me_3Sn)_3As$ (equation 61).

$$Et_2SnCl_2 + 2NaAsPh_2 \longrightarrow Et_2Sn(AsPh_2)_2 + 2NaCl \quad (57)$$

$$Ph_3SnLi + ClAsPh_2 \longrightarrow Ph_3SnAsPh_2 + LiCl \quad (58)$$

$$Me_3SnNMe_2 + Ph_2AsH \longrightarrow Me_3SnAsPh_2 + Me_2NH \quad (59)$$

$$Me_3SnCl + Me_2AsH + Et_3N \longrightarrow Me_3SnAsMe_2 + [Et_3NH]^+Cl^- \quad (60)$$

$$(Me_3Si)_3As + 3Me_3SnCl \longrightarrow (Me_3Sn)_3As + 3Me_3SiCl \quad (61)$$

Pyramidal geometry at arsenic has been inferred in $(Me_3Sn)_3As$ from vibrational data, in comparison with planar geometry at N in $(Me_3Sn)_3N$.[5,11] Because the stannylarsines are not sensitive toward hydrolysis, they can be prepared in aqueous oxygen-free solution. In the presence of oxygen, they are oxidized to the stannylarsinates, $R_3Sn–O–As(O)R'_2$. Methyl iodide cleaves the Sn–As bond and gives the respective tin iodide and arsonium iodide. Phenyl azide reacts with the mono- and bisstannylarsines to give the respective tin-substituted aminoiminoarsines (equation 62).

$$Ph_3SnAsPh_2 + 2PhN_3 \longrightarrow Ph_3Sn(NPh)As({=}NPh)Ph_2 + 2N_2 \quad (62)$$

6.4 As–Pb Bonded Compounds

The few known plumbylarsines have been prepared by the reaction of the organolead halide with the sodium arsenide in liquid ammonia (equation 63).[61]

$$Ph_3PbCl + NaAsPh_2 \longrightarrow Ph_3PbAsPh_2 + NaCl \quad (63)$$

7 ORGANOARSENIC COMPOUNDS CONTAINING As–GROUP 15 BONDS

7.1 As–N Bonded Compounds

7.1.1 Tricoordinate Arsenic

There have been several reviews that provide a comprehensive coverage of the synthesis and reactivity of organoarsenic compounds that contain tricoordinate arsenic with an As–N bond.[4,7,9–14,31,162–164] The acyclic aminoarsines, $R_nAs(NR'_2)_{3-n}$, are routinely synthesized by the aminolysis of a haloarsine or transamination of another aminoarsine (equations 64–68).

$$AsCl_3 + 6HNMe_2 \longrightarrow As(NMe_2)_3 + 3[Me_2NH_2]^+Cl^- \quad (64)$$

$$MeAsI_2 + 4HNPr_2 \longrightarrow MeAs(NPr_2)_2 + 2[Pr_2NH_2]^+I^- \quad (65)$$

$$AsCl_3 + 2HNEt_2 \longrightarrow Et_2NAsCl_2 + [Et_2NH_2]^+Cl^- \quad (66)$$

$$Me_2AsNMe_2 + HNPr_2 \longrightarrow Me_2AsNPr_2 + Me_2NH \quad (67)$$

$$PhAs(NMe_2)_2 + 2HNEt_2 \longrightarrow PhAs(NEt_2)_2 + 2Me_2NH \quad (68)$$

The association of the amine hydrochloride with the aminoarsine complicates the purification of the aminoarsine. When aminolysis of the arsenic trihalide is followed by alkylation of the mono- or bisaminohaloarsine with a Grignard reagent to synthesize the aminoalkyl(or aryl)arsine, the stoichiometry of the reaction must be carefully controlled to avoid cleavage of the As–N bond and formation of the tertiary arsine (see Section 2.1).[27] A recent study has shown that the highest yields are obtained from the transamination

reaction when the reactant aminoarsine is mixed neat with the desired secondary amine in the exact mole ratio for complete substitution.[165] Transamination becomes less effective as the steric bulkiness of the amine increases.

Although both aminolysis and salt elimination reactions can be used to give cyclic aminoarsines, aminolysis with a diamine is the best route (equation 69). Transamination of $As(NMe_2)_3$ with a symmetrical hydrazine provides a synthetic route to a caged species (equation 70). Cleavage of the heterocyclic N–P–N bond with $AsCl_3$ yields the cage compound $As[MeNCH_2CH_2NMe]_3As$ (equation 71).

$$2HN(Me)CH_2CH_2N(Me)H + AsCl_3 \longrightarrow (H_2C\text{–}NMe)_2AsCl + [H_2N(Me)CH_2]_2Cl_2 \quad (69)$$

$$3HN(Me)N(Me)H + 2As(NMe_2)_3 \longrightarrow As[N(Me)N(Me)]_3As + 6Me_2NH \quad (70)$$

$$3MeNCH_2CH_2N(Me)PMe + 2AsCl_3 \longrightarrow As(MeNCH_2CH_2NMe)_3As + 3MePCl_2 \quad (71)$$

Although salt elimination is another synthetic route to aminoarsines,[166] it has not found wide use. It has been used to synthesize silicon-substituted aminoarsines (equation 72). Dehalosilylation has been used to prepare a few aminoarsines, including bis- and tris-arsinoamines (equations 73 and 74). AsF_3 reacts with Me_3SnNMe_2 to cleave the Sn–N bond and produce $As(NMe_2)_3$ (equation 75). Perfluoromethyl-substituted aminoarsines have been prepared by the reaction of $(CF_3)_2NX$ (X = Cl, Br) and $(CF_3)_2NON(CF_3)_2$ with $(CF_3)_3As$ (equation 76).

$$O(SiMe_2NMeLi)_2 + AsCl_3 \longrightarrow O(SiMe_2NMe)_2AsCl + 2LiCl \quad (72)$$

$$Et_2NSiMe_3 + AsCl_3 \longrightarrow Et_2NAsCl_2 + Me_3SiCl \quad (73)$$

$$(Me_3Si)_2NH + 3Me_2AsCl \longrightarrow (Me_2As)_3N + 2Me_3SiCl + HCl \quad (74)$$

$$3Me_3SnNMe_2 + AsF_3 \longrightarrow As(NMe_2)_3 + 3Me_3SnF \quad (75)$$

$$(CF_3)_3As + (CF_3)_2NX \longrightarrow (CF_3)_2AsN(CF_3)_2 + CF_3X \quad (76)$$

Sodium amide cleaves the As–O bond in the arsoxane $Me_2AsOAsMe_2$ to give the trisarsinoamine $(Me_2As)_3N$. The analogous ethyl derivative can be synthesized by the ammonolysis of Et_2AsCl. As the steric bulk of the alkyl group increases, ammonolysis does not lead directly to the trisarsinoamine (equations 77 and 78). Generally, the bisarsinoamines can be prepared by the aminolysis of the dialkylhaloarsine with a primary amine (equation 79).

$$Bu_2AsCl + 2NH_3 \longrightarrow Bu_2AsNH_2 + NH_4Cl \quad (77)$$

$$2Bu_2AsNH_2 \xrightarrow{\Delta} (Bu_2As)_2NH + NH_3 \quad (78)$$

$$2Me_2AsCl + 3EtNH_2 \longrightarrow (Me_2As)_2NEt + 2[EtNH_3]^+Cl^- \quad (79)$$

Both aminolysis and transamination reactions that involve primary amines and AsX_3 (X = halogen) or dihaloarsines lead to the formation of cyclic or cage compounds that contain an As–N bonded core. The bulkiness of the amine substituent and reaction stoichiometry determine the nature of the cyclic or cage As–N core. For example, reaction of $PhNH_2$ with AsI_3 in a 4:1 mol ratio yields $As(HNPh)_2I$, which decomposes with cyclization to an As–N tetrameric core, $[IAs\text{–}NPh]_4$ (equations 80 and 81).

$$4PhNH_2 + AsI_3 \longrightarrow As(HNPh)_2I + 2[PhNH_3]^+I^- \quad (80)$$

$$4As(HNPh)_2I \longrightarrow [IAs\text{–}NPh]_4 + 4PhNH_2 \quad (81)$$

When the reaction is carried out in an excess of the amine, the fully aminated adamantane-type compound, $As_4(NPh)_6$, forms. This compound and its alkyl-substituted homologs are easily formed by transaminating $As(NMe_2)_3$ or $As_4(NPh)_6$ with an excess of the respective primary amine (equations 82 and 83).

$$6BuNH_2 + 4As(NMe_2)_3 \longrightarrow As_4(NBu)_6 + 12Me_2NH \quad (82)$$

$$6BuNH_2 + As_4(NMe)_6 \longrightarrow As_4(NBu)_6 + 6MeNH_2 \quad (83)$$

When the transamination with $As(NMe_2)_3$ is carried out in a 1:1 mol ratio, the cyclic compound $[Me_2NAs\text{–}NBu]_2$ forms. This compound disproportionates upon heating to give $As_4(NBu)_6$ and $As(NMe_2)_3$. As the bulkiness of the amine substituent increases, the cyclic As–N ring is favored over the adamantane cage structure. For example, with *t*-$BuNH_2$, aminolysis yields the dimer [*t*-BuN(H)As–N-*t*-Bu$]_2$. The reaction of AsF_3 with $(Me_3Si)_2NLi$ in a 1:2 mol ratio gives $[(Me_3Si)_2N]_2AsF$, which upon heating undergoes dehalosilylation and yields the dimeric $[(Me_3Si)_2As\text{–}NSiMe_3]_2$.

Ammonolysis of methyldichloroarsine provides a route to a cyclic As–N compound that contains a N–H bond (equation 84). On the other hand, ammonolysis of $PhAsCl_2$ yields the bicyclic species $(PhAs)_6N_3(NH)_3$. This involves a trigonal prismatic arrangement of arsenic atoms and a trigonal bipyramidal arrangement of nitrogen atoms.[14] Dehalosilylation has also been used to prepare the cyclic As–N species (equation 85). The reaction of $AsCl_3$ with Me_3SiN(*t*-Bu)Cl produces the dimeric [ClAs–N-*t*-Bu$]_2$. Arsenic-containing disulfonylamine derivatives have been prepared using $MeAsCl_2$, $PhAsCl_2$, and Me_2AsCl in a salt elimination reaction with $AgN(SO_2Me)_2$.[167]

$$18NH_3 + 6MeAsCl_2 \longrightarrow [MeAs\text{–}NH]_6 + 12NH_4Cl \quad (84)$$

$$3AsCl_3 + 3EtNHSiMe_3 \longrightarrow [ClAs\text{–}NEt]_3 + 3Me_3SiCl + 3HCl \quad (85)$$

The As–N bond is very reactive toward moisture and air and is easily cleaved by protonic acids, alcohols, thiols, water, ketones, aldehydes, and carboxylic acids (equations 86–89).[13,162,163] The reader is referred to these reviews for details and references to the original literature. Thus, aminoarsines are used as multipurpose precursors to

numerous other organoarsenic compounds that are otherwise difficult to prepare (see Section 2).[162,163]

$$MeAs(NMe_2)_2 + 4HCl \longrightarrow MeAsCl_2 + 2[Me_2NH_2]^+Cl^- \quad (86)$$

$$2Et_2AsNMe_2 + H_2O \longrightarrow (Et_2As)_2O + 2Me_2NH \quad (87)$$

$$Me_2AsNEt_2 + EtOH \longrightarrow Me_2AsOEt + Et_2NH \quad (88)$$

$$2As(NMe_2)_3 + 3EtCH_2CHO \longrightarrow As_2O_3 + 3Me_2NH + 3Me_2NCH{=}CHEt \quad (89)$$

Several studies have been conducted on the reactivity of diborane, $BH_3{\cdot}THF$, μ-$Me_2NB_2H_5$, and aluminum alkyls toward aminoarsines.[19,20,63,82,84,168,169] These reactions have been followed using multinuclear NMR to establish bonding site in the adducts and deduce the reaction pathway to the thermodynamic stable products. With the series Me_2AsNR_2 (R = Me, Et, Pr, *i*-Pr), the BH_3 binding site is dependent upon the bulkiness of the R group. Increasing bulkiness favors binding on the arsenic atom. Whereas, at low temperature, exclusive N–B binding occurs when R = Me, both As–B and N–B binding is observed with Et and Pr derivatives, and only As–B binding arises when R = *i*-Pr (equation 90).

$$2Me_2AsNEt_2 + 2BH_3{\bullet}THF \longrightarrow Me_2As({\bullet}BH_3)NEt_2 + Me_2AsN({\bullet}BH_3)Et_2 + 2THF \quad (90)$$

With increasing temperature the As–B adducts convert to the N–B adduct, except for the *i*-Pr compound, which is stable at room temperature, and decomposition leads to the formation of $Me_2AsAsMe_2$, Me_2AsH, $[R_2NBH_2]_2$, and $R_2NH{\cdot}BH_3$. The results from the aluminum alkyl reactions have been used to develop new syntheses to tertiary arsines (see Section 2).

$Me_{3-n}As(NMe_2)_n$ reacts with R_2PPR_2 (R = Me, Et, Ph) to give the respective aminophosphine and Me_2AsPR_2, which further reacts to give $Me_2AsAsMe_2$.[170] With $(MeP)_5$ the reaction yields $MeP(NMe_2)_2$, $Me_2AsAsMe_2$, $(MeAs)_5$, and elemental arsenic. Aminoarsines also react with diarsines to generate unsymmetric diarsines, which undergo symmetrization.[171] The unsymmetric diarsines are also formed from the reaction of aminoarsines with secondary arsines, R_2AsH,[172] while cyclopolyarsines form in the reactions with primary arsines, $RAsH_2$.[56]

7.1.2 Tetracoordinate Arsenic

Typical tetracoordinate arsenic compounds that contain an As–N bond are the aminoarsonium salts, the arsazenes, and the arsinimines.[4,7,11,12,31,162] The aminoarsonium chlorides are synthesized by the reaction of tertiary arsines with the following chloramines: NH_2Cl, $MeN(H)Cl$, and Me_2NCl (equations 91 and 92).[30,31]

$$Et_3As + NH_2Cl \longrightarrow [Et_3AsNH_2]Cl \quad (91)$$

$$Pr_3As + Me_2NCl \longrightarrow [Pr_3AsNMe_2]Cl \quad (92)$$

Heating Ph_2AsN_3, which is synthesized from the reaction of Ph_2AsCl with lithium azide, leads to the tetrameric arsazene $[Ph_2AsN]_4$ (equation 93). Pyrolysis of the dialkylarsine azides does not yield an As–N bonded product. The tetrameric $[Ph_2AsN]_4$ can also be obtained by the reaction of Ph_2AsCl_3 with NH_4Cl in liquid ammonia (equation 94) or from the conversion of the trimeric $[Ph_2AsN]_3$ that occurs in hot acetonitrile (equation 95). This trimer forms from the high-pressure, room-temperature ammonolysis of Ph_2AsCl_3 (equation 96), or the chloramination of Ph_2AsCl in the presence of NH_3 (equation 97). Treating $As(OMe)_5$ with ammonia in methanol gives $NH_4[As(OMe)_6]$, which loses methanol in vacuo to give material that is primarily $[AsN(OMe)_2]_3$, but also contains the tetramer, pentamer, and hexamer.

$$4Ph_2AsN_3 \longrightarrow [Ph_2AsN]_4 + 4N_2 \quad (93)$$

$$4Ph_2AsCl_3 + 4NH_4Cl \longrightarrow [Ph_2AsN]_4 + 16HCl \quad (94)$$

$$4[Ph_2AsN]_3 \longrightarrow 3[Ph_2AsN]_4 \quad (95)$$

$$3Ph_2AsCl + 6NH_3 \longrightarrow [Ph_2AsN]_3 + 3NH_4Cl + 3H_2 \quad (96)$$

$$3Ph_2AsCl + 6NH_3 + 3NH_2Cl \longrightarrow [Ph_2As(NH_2){=}N{-}As(NH_2)Ph_2]Cl \xrightarrow{\Delta} [Ph_2AsN]_3 + 6NH_4Cl \quad (97)$$

Dehydrochlorination of the aminoarsonium chloride $[Ph_3AsNH_2]Cl$ with sodium amide in liquid ammonia produces the triphenylarsinimine $Ph_3As{=}NH$. $(p\text{-}MeC_6H_4)_3As$ reacts with S_4N_4 at 50 °C to produce $(p\text{-}MeC_6H_4)_3As{=}NS_3N_3$.[173] Treating Ph_3As with the azide $C_6F_5N_3$ gives, upon heating, the arsinimine $Ph_3As{=}NC_6F_5$. $Ph_3As{=}NSO_2R$ species have been prepared from the reaction of Ph_3As with $PhI{=}NSO_2R$.[174] Also, triphenylarsine oxide reacts with isocyanates to produce triphenylarsinimines.[175] $(o\text{-tolyl})_3B{=}NCOCCl_3$ transfers the nitrenoid group to Ph_3As to yield $Ph_3As{=}NOCCl_3$.[176] The arsinimines hydrolyze with addition of water across the As=N bond to give $R_3As(OH)N(H)R'$. Methylation of the nitrogen atom occurs in the reaction with MeI to yield an arsonium salt (equation 98). The reaction between Ph_3AsCl_2 and $(Me_3Si)_3N$ produces $[Ph_3AsNAsPh_3]^+Cl^-$ (equation 99),[177] which can also be prepared by heating $[Ph_3AsNH_2]Cl$. A P–N–As bonded analog, $[Me_3PNAsMe_3]^+I^-$, is synthesized by methylating the product of the reaction between Me_3PNLi and Me_2AsCl (equations 100 and 101).

$$R_3As{=}NSiMe_3 + MeI \longrightarrow [R_3AsN(Me)SiMe_3]I \quad (98)$$

$$2Ph_3AsCl_2 + (Me_3Si)_3N \longrightarrow [Ph_3AsNAsPh_3]^+Cl^- + 3Me_3SiCl \quad (99)$$

$$Me_3PNLi + Me_2AsCl \longrightarrow Me_3P{=}NAsMe_2 + LiCl \quad (100)$$

$$Me_3P{=}NAsMe_2 + MeI \longrightarrow [Me_3PNAsMe_3]^+I^- \quad (101)$$

An X-ray study of $(Ph_2AsN)_3$ has shown that the six-membered ring is slightly puckered with all As–N distances equal. The ring in the phosphorus analog $(Ph_2PN)_3$ is more

nearly planar.[11] The corresponding tetramer, $(Ph_2AsN)_4$, has a nonplanar ring and is isostructural with $(Ph_2PN)_4$.[14] The As–N distances, in the trimer (1.758 Å) and the tetramer (1.73 Å), are shorter than the single bond value (1.87 Å). This suggests some degree of π-bonding in the oligomers. Other As–N ring systems have been reviewed.[14] The As–N bond distance in $[Ph_3AsNAsPh_3]^+Cl^-$ has been reported as 1.749 Å.[177]

Variable-temperature NMR has been employed to study barriers of rotation in As–N bonded compounds.[12,37] Both ^{13}C and ^{1}H NMR spectral data have been published for a homologous series of tertiary arsines, aminoarsines, and arsonium and aminoarsonium salts.[42] In addition, individual ^{1}H and ^{13}C NMR spectral data are available for individual aminoarsines.[20,30,84,165,169,171]

7.1.3 *Pentacoordinate Arsenic*

The general synthesis route to pentacoordinate arsenic compounds that contain an As–N bond is the aminolysis of a pentacoordinate oxyarsorane with a primary amine (equation 102).[13,31,45] With $PhNH_2$ in excess, polymeric pentacoordinate arsenic species are obtained. The chlorination of $(CF_3)_2AsN(SiMe_3)_2$ in a 1:1 mol ratio gives $(CF_3)_2As(Cl)_2N(SiMe_3)_2$, while an excess of Cl_2 produces $[(CF_3)_2As(Cl)NSiMe_3]_2$ via a dehalosilylation reaction. Several other pentacoordinate arsenic species have been prepared by specialized routes, which have been reviewed.[31,45]

$$2(MeO)_5As + 4H_2NPr \longrightarrow [(MeO)_2(PrNH)AsNPr]_2 + 6MeOH \quad (102)$$

7.2 As–P Bonded Compounds

Both As–P and As=P bonded compounds have been prepared.[12,31,178–187] The earliest demonstrated routes to arsinophosphines were the exchange reactions involving $(CF_3P)_4$ and $Me_2AsAsMe_2$ to give $Me_2AsP(CF_3)AsMe_2$ and Me_2AsH and $(CF_3)_2PP(CF_3)_2$ to yield $(CF_3)_2PAsMe_2$. A quantitative yield of $(CF_3)_2PAsMe_2$ also results from the reaction of $(CF_3)_2PP(CF_3)_2$ with $Me_2AsAsMe_2$.[188] An analogous exchange reaction that includes $(CF_3)_2PP(CF_3)_2$ and $(CF_3)_2AsAs(CF_3)_2$ gives an equilibrium statistical distribution of reactants and $(CF_3)_2PAs(CF_3)_2$. An equilibrium distribution of reactants and products, with $K_{eq} = 0.37$ in benzene at 30 °C, occurs when Ph_2PPPh_2 and $Ph_2AsAsPh_2$ are mixed (equation 103).

$$Ph_2PPPh_2 + Ph_2AsAsPh_2 \rightleftharpoons 2Ph_2PAsPh_2 \quad (103)$$

The reaction of Me_2AsNMe_2 with R_2PPR_2 (R = Me, Et, Ph) gives R_2PNMe_2 and R_2PAsMe_2, and the latter reacts further with Me_2AsNMe_2 to produce $Me_2AsAsMe_2$ and R_2PNMe_2.[170] Silane elimination occurs in the reaction of $Me_3SiAsMe_2$ with $(CF_3)_2PH$ to give $(CF_3)_2PAsMe_2$. Dehalosilylation also provides a pathway to arsinophosphines (equation 104).

$$2H_3SiPH_2 + F_3CAsI_2 \longrightarrow 2H_3SiI + F_3CAs(PH_2)_2 \quad (104)$$

The direct reaction between a tertiary phosphine and a haloarsine yields an arsinophosphonium salt (equation 105).

$$Me_2AsCl + Et_3P \longrightarrow [Me_2AsPEt_3]Cl \quad (105)$$

The introduction of sterically demanding substituents on P and As coupled with particular synthetic strategies has blocked oligomerization and permitted the preparation of P=As bond containing species, that is arsaphosphenes.[185] For example, base-promoted (DBU) condensation has provided a synthetic pathway to (2,4,6-t-$Bu_3C_6H_2$)P=AsCH$(SiMe_3)_2$ from (2,4,6-t-$Bu_3C_6H_2$)PH_2 and $(Me_3Si)_2C(H)AsCl_2$.[186] Similarly the analogous (2,4,6-t-$Bu_3C_6H_2$)As=PCH$(SiMe_3)_2$ has been synthesized, in addition to MesP=AsCH$(SiMe_3)_2$, MesAs=PCH$(SiMe_3)_2$, and MesAs=PCp*. MesP=AsC_6H_3-2,6-$Trip_2$ (Trip = 2,4,6-i-Pr_3) forms in the direct reaction of $MesPLi_2$ and 2,6-$Trip_2H_3C_6AsCl_2$.[187] A t-BuLi reductive coupling reaction between $(Me_3Si)_3CAsCl_2$ and $(Me_3Si)_3CPCl_2$ gives $(Me_3Si)_3CAs{=}PC(SiMe_3)_3$. Two pathways have been developed to (2,4,6-t-$Bu_3C_6H_2$)P=AsCp* that use either dehydrochlorination or dehalosilylation (equations 106 and 107).[179]

$$Cp^*AsCl_2 + (2,4,6\text{-}t\text{-}Bu_3C_6H_2)PHLi + DBU \longrightarrow (2,4,6\text{-}t\text{-}Bu_3C_6H_2)P{=}AsCp^* + LiCl + DBU{\cdot}HCl \quad (106)$$

$$Cp^*AsCl_2 + (2,4,6\text{-}t\text{-}Bu_3C_6H_2)P(SiMe_3)Li \longrightarrow (2,4,6\text{-}t\text{-}Bu_3C_6H_2)P{=}AsCp^* + LiCl + Me_3SiCl \quad (107)$$

All the P–As and P=As bonded compounds are sensitive to hydrolysis and to oxidation by air. The reaction of Cp*As=PMes with diazomethane adds a CH_2 group across the double bond and yields the three-membered heterocyclic phosphaarsirane Cp*AsCH_2PMes.[184] Sulfur and selenium add across the double bond to form three-membered heterocycles.[186] Dimerization of Cp*As=PCp* produces two isomeric diphosphadiarsetanes, one containing the P–P–As–As and the other the P–As–P–As core. Photolysis of Cp*As=PMes, Cp*P=AsMes, and (2,4,6-t-$Bu_3C_6H_2$)P=AsCp* yields the diarsadiphosphacyclobutanes.[183,186] Metal complexes of several of the P=As compounds have been prepared and characterized.[189]

^{31}P NMR chemical shift data have been used extensively to confirm double bond formation in phosphaarsenes and diphosphenes.[178,186] The ^{31}P chemical shift range for these compounds is typically from +500 to +700 ppm (85% H_3PO_4). The shifts are among the lowest known in ^{31}P NMR. ^{31}P NMR chemical shifts for phosphinoarsines are similar to those for diphosphines and aminophosphines.[170,179,188]

From X-ray crystallographic studies, the observed distances for P=P, P=As, and As=As (see Section 7.3) bonds are 2.0, 2.1, and 2.2 Å respectively.[178,181,186] In general, the compounds adopt a trans configuration and the R–E=E′–R′ skeleton is planar. Normal P–As and As–As single bond distances are assumed to be 2.34 and 2.44 Å respectively. However, the P–As and As–As distances are 2.35 and 2.38 Å in [2,4,6-t-$Bu_3C_6H_2PAs]_2$.[183]

7.3 As–As Bonded Compounds

The As–As bonded diarsines and cyclopolyarsines have been extensively reviewed.[4–7,9–12,14,54] The first synthesized organometallic compound was $Me_2AsAsMe_2$, which was prepared by heating As_2O_3 with $KC_2H_3O_2$. This compound and other symmetric or unsymmetric diarsines can be readily obtained by the reduction of the corresponding arsinic acid, RR′As(O)OH, or diarsoxane, RR′AsOAsRR′, with hypophosphorous acid in HCl or HI solution. Reaction of the diarsoxane or a monohaloarsine with a secondary arsine gives the diarsines (equations 108 and 109). When the substituents on the haloarsine and the secondary arsine are dissimilar, two different symmetric diarsines are formed (equation 110). This is a consequence of the exchange reactions that readily occur in mixtures of As–As bonded species.

$$(Ph_2As)_2O + 2Ph_2AsH \longrightarrow 2Ph_2AsAsPh_2 + H_2O \quad (108)$$

$$Me_2AsCl + Me_2AsH \longrightarrow Me_2AsAsMe_2 + HCl \quad (109)$$

$$2Ph(CF_3)AsCl + 2(CF_3)_2AsH \longrightarrow Ph(CF_3)AsAs(CF_3)Ph + (CF_3)_2AsAs(CF_2)_2 + 2HCl \quad (110)$$

The salt elimination reaction has also been used as a route to diarsines. Reductive coupling of a monohaloarsine with Hg or Zn gives diarsines. Oxidation of Me_2AsH and Ph_2AsH with Cl_2, NH_2Cl, or Me_2NCl gives good yields of $Me_2AsAsMe_2$ and $Ph_2AsAsPh_2$ respectively (equation 111). $Ph_2AsAsPh_2$ can also be prepared from the oxidation of $Ph_2AsMgBr$ with I_2, $HgCl_2$, Ph_2CCl_2, and Ph_2CHBr (equation 112). Reductive coupling occurs in the reaction of Ph_2AsCl with Bu_3P (equation 113).

$$2Me_2AsH + NH_2Cl \longrightarrow Me_2AsAsMe_2 + NH_4Cl \quad (111)$$

$$2Ph_2AsMgBr + HgCl_2 \longrightarrow Ph_2AsAsPh_2 + 2MgClBr + Hg \quad (112)$$

$$2Ph_2AsCl + Bu_3P \longrightarrow Ph_2AsAsPh_2 + Bu_3PCl_2 \quad (113)$$

$Mes_2AsAsMes_2$ has been prepared from the reaction of $Fe[N(SiMe_3)_2]_2$ with $HAsMes_2$.[190] $Me_2AsAsMe_2$ can also be obtained from the reaction of Me_2AsH with Me_2AsNMe_2 or $Me_2AsNMe_2{\cdot}BH_3$ (equation 114).[59] The polyarsines $(Ph_2As)_3As$ and $(Ph_2As)_2AsPh$ are obtained by reacting Ph_2AsI with the respective stannylarsine (equation 115).[54]

$$Me_2AsH + Me_2AsNMe_2 \longrightarrow Me_2AsAsMe_2 + Me_2NH \quad (114)$$

$$(Ph_3Sn)_2AsPh + 2Ph_2AsI \longrightarrow (Ph_2As)_2AsPh + 2Ph_3SnI \quad (115)$$

Very few asymmetric substituted diarsines are known. $Cp^*(CH_3)AsAs(CH_3)Cp^*$ has been prepared in high yield by reacting MeLi with $Cp^*(Cl)AsAs(Cl)Cp^*$. The latter is obtained in high yield from the reductive coupling of Cp^*AsCl_2 with cobaltocene in hexane.[191]

Most of the synthetic pathways to the cyclopolyarsines $(RAs)_n$, where $n = 3-6$, are analogous to those to the diarsines. For example, the reduction of arsonic acids, arsonous acids, and organodihaloarsines with hypophosphorous acids has been widely used. Primary arsines can also be oxidized by aromatic or aliphatic aldehydes, I_2, Cl_2, SO_2Cl_2, NH_2Cl, and Me_2NCl. The salt elimination reaction has been used in the low-temperature (−78 °C) synthesis of $(t\text{-BuAs})_3$, which converts to $(t\text{-BuAs})_4$ at room temperature (equations 116 and 117). The methyl and ethyl pentamer derivatives have been prepared in good yields by the reaction of the primary arsines with dibenzylmercury.

$$t\text{-BuAs(K)As(K)-}t\text{-Bu} + t\text{-BuAsCl}_2 \longrightarrow (t\text{-BuAs})_3 + 2KCl \quad (116)$$

$$4(t\text{-BuAs})_3 \longrightarrow 3(t\text{-BuAs})_4 \quad (117)$$

Reductive coupling of dihaloarsines with Na and Hg provides another pathway to several cyclopolyarsines. $(Me_3SiCH_2As)_5$ has been prepared from the reduction of $Me_3SiCH_2AsCl_2$ with Mg turnings.[49] Using Mg, Ca, Zn, Li, or $CoCp_2$ in THF as the reducing agents toward t-$BuAsI_2$ promotes reductive coupling and gives high yields of $(t\text{-BuAs})_4$. With $CoCp_2$ in a 1:1 mol ratio in n-pentane, the reduced species is $(t\text{-BuAsI})_2$.[192]

When primary arsines are reacted with $(MeAs)_5$, the respective cyclopolyarsine $(RAs)_n$ is prepared in high yield (equation 118).[57,58] Also the reaction of primary arsines with aminoarsines[56] and diarsines[55] generates cyclopolyarsines.

$$n\,RAsH_2 + \frac{n}{5}(MeAs)_5 \longrightarrow n\,MeAsH_2 + (RAs)_n \quad (118)$$

$(MeAs)_5$ is the yellow form of polymethylarsine, $(MeAs)_n$. An involatile red form and a sublimable purple-black form also exist. The interconversion of these forms on heating is catalyzed by impurities.

The As–As bond in the di- and cyclopolyarsines is easily cleaved using $RAsH_2$, R_2AsH, Me_2AsNR_2, halogens, methyl iodide, alkali metals, oxygen, and unsaturated organic compounds. In some cases, these reactions provide pathways to arsenic-containing heterocycles. Reaction of the diarsines with moist air results in oxidation to the corresponding arsinic acid (equation 119) and with polyarsines to the arsonic acid (equation 120).

$$2Me_2AsAsMe_2 + 3O_2 + 2H_2O \longrightarrow 4Me_2As(O)OH \quad (119)$$

$$(MeAs)_5 + 5O_2 + 5H_2O \longrightarrow 5MeAs(O)(OH)_2 \quad (120)$$

With the halogens, As–As bonds are cleaved in the diarsine to produce the monohaloarsine and in the cyclopolyarsine

to give the dihaloarsine. Sulfur and selenium react via an insertion reaction (equation 121). The reactions of primary and secondary arsines toward di- and cyclopolyarsines have been discussed in Section 3. Aminoarsines cleave the As–As bond in diarsines to yield unsymmetric diarsines, which undergo symmetrization (equations 122 and 123).[171]

$$15Se_8 + 24(MeAs)_5 \longrightarrow 40(MeAsSe)_3 \quad (121)$$

$$Me_2AsNMe_2 + Et_2AsAsEt_2 \longrightarrow Me_2AsAsEt_2 + Et_2AsNMe_2 \quad (122)$$

$$2Me_2AsAsEt_2 \longrightarrow Me_2AsAsMe_2 + Et_2AsAsEt_2 \quad (123)$$

By analogy with the phosphaarsenes, the bulky $(Me_3Si)_3C$ and Mes moities on arsenic facilitate the isolation of As=As species.[185,193] During the reductive coupling of $(Me_3Si)_3CPCl_2$ and $(Me_3Si)_3CAsCl_2$ with t-BuLi, the diarsene $(Me_3Si)_3CAs{=}AsC(SiMe_3)_3$ is formed.[186] This diarsene is also produced by the reductive coupling of $(Me_3Si)_3CAsCl_2$ with t-BuLi and in the reaction of $(Me_3Si)_3CAsCl_2$ with $Na_2Cr_2(CO)_{10}$. The bulky Mes substituent also prevents oligomerization and permits isolation of MesAs=AsMes (equation 124). The latter is also formed from the reaction of $Cp^*(CO)_2FeP(SiMe_3)_2$ and $MesAsCl_2$. The base-catalyzed condensation reaction yields an unsymmetric diarsene (equation 125).

$$2MesAsCl_2 + 2Mg \longrightarrow MesAs{=}AsMes + 2MgCl_2 \quad (124)$$

$$(Me_3Si)_2CH{-}AsCl_2 + H_2AsMes + 2DBU \longrightarrow (Me_2Si)_2CHAs{=}AsMes + 2HCl{\cdot}DBU \quad (125)$$

2,6-$(Mes)_2H_3C_6As{=}AsC_6H_3$2,6-$(Mes)_2$ and 2,4,6-$(i\text{-}Pr)_3H_2C_6As{=}AsC_6H_2$-2,4,6-$(i\text{-}Pr)_3$ were synthesized by reductive coupling with Mg of the corresponding dihaloarsines.[194] A salt elimination reaction involving 2,4,6-$(t\text{-}Bu)_3C_6H_2AsF_2$ and $LiAsC_6H_2$-2,4,6-$(t\text{-}Bu)_3$ gives excellent yields of 2,4,6-$(t\text{-}Bu)_3C_6H_2As{=}AsC_6H_2$-2,4,6-$(t\text{-}Bu)_3$.[195] Sulfur adds across the diarsene double bond to produce the three-membered heterocyclic thiadiarsiranes MesAs(S)AsMes and $(Me_3Si)_3C{-}As(S)AsC(SiMe_3)_3$. Diazomethane reacts with MesAs=AsMes to give the three-membered heterocyclic diarsirane $MesAs(CH_2)AsMes$.

The transition-metal chemistry and nature of the complexes formed with As–As bonded compounds has been reviewed.[196] The reader is referred to this comprehensive review for an overview of the nature of complexes that contain chains of coordinated R–As units, heterocyclic As–chalcogen rings, and unsubstituted arsenic atoms and for references to the primary literature. The limited transition-metal chemistry of the phosphaarsenes and diarsenes is also reviewed.[186]

Few diarsines have been structurally characterized. From X-ray data, crystalline tetramethyldiarsine exists in the trans form. However, Raman spectra of the liquid and electron diffraction and photoelectron spectroscopy data of the vapor indicate both gauche and trans forms present.[79] In the solid state, $Ph_2AsAsPh_2$ has an As–As bond length of 2.458 Å with the phenyl groups in a staggered conformation. $Mes_2AsAsMes_2$ possesses C_2 symmetry with the As–As distance being 2.472 Å.[190] $(C_6F_5)_4As_2$ is rotated 16.5° from a perfect trans conformation, while $(Me_3Si)_4As_2$ deviates significantly (54.3°) from a trans arrangement. In these two diarsines, the As–As bond distances are 2.479 and 2.458 Å, respectively.[34] Dynamic NMR spectroscopy has been used to study inversion processes of diarsines.[15]

Several X-ray diffraction studies of cyclopolyarsines, $(MeAs)_5$,[7,11,15] $(CF_3As)_4$, $(t\text{-}BuAs)_4$, $(Me_3SiCH_2As)_5$,[49] and $(PhAs)_6$, have been reported.[14] $(MeAs)_5$ has a puckered five-membered ring of arsenic atoms with a mean As–As distance of 2.428 Å. In contrast, the purple-black form of $(MeAs)_n$ has an unusual ladder-like structure in which the horizontal As–As distances are typical of single As–As bonds (2.4 Å), but the vertical distances are very long (2.9 Å).[11,197] In $(CF_3As)_4$, the four-membered ring is nonplanar with an As–As bond distance of 2.454 Å. $(Me_3SiCH_2As)_5$ has a solid-state conformation similar to $(MeAs)_5$.[49] In the hexamer $(PhAs)_6$, the ring is puckered (chair) and the average As–As distance is 2.459 Å. The ^1H NMR spectrum of $(MeAs)_5$ consists of three single resonances with relative intensities of 2:2:1.[11] However, in the solid state, all methyl groups are nonequivalent.[15] Variable-temperature NMR studies on this and other cyclopolyarsines have been performed.[14]

From these studies, two motional processes have been postulated, a low-energy pseudorotational motion and a higher-energy arsenic atom inversion process. Detailed equilibrium studies have been conducted involving ring, chain, and oligomeric forms of these species.[11,15,197]

8 ORGANOARSENIC COMPOUNDS CONTAINING As–O BONDS

The synthesis and reactivity of organoarsenic compounds that contain As–O bonds has been extensively reviewed.[4–7,9–11] Because of space limitations, the extensive chemistry associated with As–O bonded systems cannot be covered. Instead, the highlights of the chemistry will be presented here and the reader is referred to the reviews for the vast quantity of more detailed information. These highlights have been grouped according to the more common classes of As–O bonded compounds that serve as precursors to many of the compounds discussed in earlier sections of this review.

8.1 Arsonous Acids, Anhydrides, and Esters

These As–O bonded species are related by the fact that they contain arsenic in the +3 oxidation state and have one organo substituent bonded to the arsenic. The general formulas are as follows: arsonous acids, $RAs(OH)_2$; arsonous acid anhydrides, RAsO; arsonous acid esters, $RAs(OR')_2$.

The arsonous acids or acid anhydrides are obtained in the hydrolysis of dihalo-, dialkoxy-dicyano-, and bisaminoarsines. The nature of R usually determines whether the acid or the anhydride is formed. When R is aliphatic or aromatic, with an unsubstituted ring, the anhydride is the primary product (equation 126).

$$MeAs(NMe_2)_2 + H_2O \longrightarrow \frac{1}{n}(MeAsO)_n + 2Me_2NH \quad (126)$$

If R is aromatic with electron-withdrawing substituents, the acid is the major product. Because the anhydride is thought to be in equilibrium with the acid in solution, the separation conditions can determine whether the acid or anhydride is obtained. Because many dihaloarsines dissolve in water without appreciable hydrolysis, the addition of base is required to form the acid salt. Reduction of an arsonic acid, $RAsO(OH)_2$, in hydrochloric acid with SO_2 and I^- as a catalyst gives the anhydride (equation 127). The anhydride is also produced during the oxidation of cyclopolyarsines and primary arsines in the absence of water (equation 128).

$$MeAsO(OH)_2 + SO_2 \longrightarrow \frac{1}{n}(MeAsO)_n + H_2SO_4 \quad (127)$$

$$\frac{n}{5}(MeAs)_5 + \frac{n}{2}O_2 \longrightarrow (MeAsO)_n \quad (128)$$

The arsonous esters are easily synthesized by the reaction of the dihaloarsines with alcohols or alkoxides. With alcohols, $CaCl_2$ must be present because the esters are very sensitive toward hydrolysis, which leads to the reformation of the anhydride (equation 129). The reaction of an alcohol with a bisaminoarsine leads to an arsonous ester (equation 130), as does the alcoholysis of the anhydride. Reaction of diols with bis(dimethylamino)alkylarsines leads to esters of macrocyclic arsinous acid.[198,199]

$$EtAsCl_2 + 2NaOMe \longrightarrow EtAs(OMe)_2 + 2NaCl \quad (129)$$

$$MeAs(NMe_2)_2 + 2PhOH \longrightarrow MeAs(OPh)_2 + 2Me_2NH \quad (130)$$

8.2 Arsinous Acids, Anhydrides, and Esters

These As–O bonded species are related by the fact that they contain arsenic in the +3 oxidation state and have two organo substituents bonded to the arsenic. The general formulas are as follows: arsinous acids, R_2AsOH; arsinous acid anhydrides or diarsoxanes, $(R_2As)_2O$; arsinous acid esters, R_2AsOR'. The arsinous acids and diarsoxanes can be prepared by the hydrolysis of the monohalo-, amino-, or alkoxyarsines or the base hydrolysis of diarsoxanes (equation 131).

$$(Ph_2As)_2O + H_2O \longrightarrow 2Ph_2AsOH \quad (131)$$

The diarsoxanes are formed in the base hydrolysis of aminoarsines and monohaloarsines (equation 132) and in the reaction of aluminum trialkyls or Grignard reagents with As_2O_3 (equation 133). $(Me_2As)_2O$ is also obtained, in addition to other products, upon heating a mixture of As_2O_3 and potassium acetate.

$$2Me_2AsNMe_2 + H_2O \longrightarrow (Me_2As)_2O + 2Me_2NH \quad (132)$$

$$(Me_3Al)_2 + As_2O_3 \longrightarrow (Me_2As)_2O + 2MeAlO \quad (133)$$

By analogy with the arsonous acid esters, the arsinous acid esters form in the reaction of monohaloarsines with sodium alkoxides (equation 134). The alcoholysis of the diarsoxanes in the presence of copper sulfate also produces arsonous acid esters.

$$Et_2AsCl + NaOPh \longrightarrow Et_2AsOPh + NaCl \quad (134)$$

8.3 Arsonic and Arsinic Acids

These As–O bonded species are related by the fact that they contain arsenic in the +5 oxidation state. The arsonic acids, $RAsO(OH)_2$, have one organo substituent bonded to the arsenic, while the arsinic acids, $R_2As(O)OH$, have two. The most common preparative methods involve isolating the sodium or potassium salt.

Historically, the Meyer reaction, which consists of alkylating metal arsenites with alkyl halides, is the most widely used preparative method for alkylarsonic acid salts (equation 135). Subsequent alkylation of the alkylarsonic acid salt gives the alkylarsinic acid salt (equation 136). Excellent yields of alkylarylarsinic acid salts are obtained upon alkylating an arylarsonic acid salt. Aryl halides do not give satisfactory yields of the arylarsonic acid salts.

$$EtI + Na_3AsO_3 \longrightarrow EtAs(O)(ONa)_2 + NaI \quad (135)$$

$$EtI + EtAs(O)(ONa)_2 \longrightarrow Et_2As(O)(ONa) + NaI \quad (136)$$

The Bart reaction, which consists of reacting Na_3AsO_3 (sodium arsenite) with aromatic diazonium salts in buffered alkaline solution (pH = 8.8–9.2), provides an established route to the arylarsonic acids (equation 137). A useful variation consists of reacting the diazonium fluoroborates with $AsCl_3$ in a nonaqueous solvent and then hydrolyzing the products to produce a mixture of arylarsonic and diarylarsinic acids. Anhydrous conditions favor the arsonic acid, while the presence of water favors the arsinic acid.

$$RN_2^+X^- + Na_3AsO_3 \longrightarrow RAsO(ONa)_2 + N_2 + NaX \quad (137)$$

H_3AsO_4 arsonates phenyl ethers, phenols, and aromatic amines. The yields are usually low and arsonation occurs in the *para* position (equation 138).

$$C_6H_5OH + H_3AsO_4 \longrightarrow p\text{-}HOC_6H_4AsO(OH)_2 + H_2O \quad (138)$$

A useful route to dialkylarsinic acids involves the acid hydrolysis of aminoarsines (equation 139), followed by oxidization with H_2O_2 to give moderate to high yields of the acids (equation 140).

$$Et_2AsNEt_2 + H_2O + HCl \longrightarrow Et_2AsOH + [Et_2NH_2]^+ Cl^- \quad (139)$$

$$Et_2AsOH + H_2O_2 \longrightarrow Et_2As(O)OH + H_2O \quad (140)$$

8.4 Tertiary Arsine Oxides

Tertiary arsine oxides, R_3AsO, are known with alkyl and aryl substituents. The trialkylarsine oxides are prepared by the oxidation of the trialkylarsine using HgO or H_2O_2. For the triarylarsines, $KMnO_4$ and SeO_2 can also be used as oxidizing agents in synthesizing R_3AsO. These oxidizing agents cannot be used for the alkyl derivatives, because As–C bond cleavage occurs.

1 INTRODUCTION

The field of asymmetric catalysis has moved to the forefront of organic chemistry, culminating with the award of the 2001 Nobel Prize in Chemistry to Knowles, Noyori, and Sharpless. The goal of this tremendous effort continues to be the efficient generation of enantioenriched organic compounds. It is not surprising, therefore, that the practitioners of this popular field are overwhelmingly organic chemists, despite the fact that asymmetric catalysis is a discipline that is dependent on the synthesis and evaluation of inorganic catalysts. The chemical community has stressed the importance of generating functionalized chiral products of high enantiomeric excess (ee) and less emphasis has been placed on understanding the structure and the function of the catalyst. To some degree this is understandable, because mechanistic investigations are inherently more difficult than catalyst screening. Furthermore, it is often found that reaction mechanisms are more complicated than initially anticipated. Nonetheless, detailed mechanistic studies are of great value and have increased our understanding of catalytic asymmetric reactions. They can also position researchers to develop improved catalysts, and even new reactions.

The past several years have witnessed enormous advances in the number and variety of reactions that can be catalyzed with excellent enantioselectivities (*see Enantioselectivity*). The area has recently been comprehensively reviewed with volumes edited by the team of Jacobsen, Pfaltz, and Yamamoto[1] as well as Ojima.[2] These important treatises are quite detailed and cannot be summarized here. The goal of this section is to present some of the most important new approaches to asymmetric catalysis. The basic concepts necessary to understanding catalytic asymmetric reactions have been succinctly described by Bosnich[3] in the first edition of *Encyclopedia of Inorganic Chemistry* and will not be duplicated here.

While impressive progress has been made in asymmetric catalysis, it must be emphasized that most catalysts do not meet the criteria of exhibiting high turnover (*see Turnover*) frequency (TOF) and turnover number (TON), and being high yielding, highly enantioselective, easy to prepare, and stable to trace impurities such as air and moisture.[4] Given the limitations of most catalysts, there remains significant room for improvement and innovation in this field.

This summary is designed to introduce chemists with a background in inorganic chemistry to the field of asymmetric catalysis. The skills regularly employed by solution phase inorganic chemists are of great value in this area. The ability to synthesize, isolate, and characterize highly air or moisture sensitive compounds are important tools to probe catalyst structure. Experience in performing detailed kinetic and mechanistic studies are essential to understanding reaction mechanisms in asymmetric catalysis. Based on the insight gained through these studies, the likelihood of developing an improved catalyst is greatly increased. It must be borne in mind that although the development of new catalysts is clearly important, it does not always have the lasting impact and value as mechanistic studies. Catalysts like the titanium tartrate-based system for the asymmetric epoxidation of prochiral allylic alcohols developed by Sharpless and Katsuki,[5,6] which has been the catalyst of choice for this transformation for almost 25 years, are extremely rare. Catalysts with greater efficiency, enantioselectivity, substrate scope, and functional group compatibility are constantly being introduced. As a result, today's best catalyst is tomorrow's dog and may soon to be forgotten. In contrast, mechanistic studies serve as guiding principles on which future catalysts will be developed. Despite the large number of catalysts that have been reported, relatively few are understood. Thus, mechanistic investigations of known reactions represent an excellent entry into the field of asymmetric catalysis.

2 THE TRADITIONAL METHOD TO SCREENING ASYMMETRIC CATALYSTS

The traditional approach to asymmetric catalysis employing metal-based complexes is an iterative process, centered around the synthesis of highly enantioenriched organic ligands.[1,2,7] This task is often the rate limiting step, particularly when racemic ligand components must be resolved. After the enantioenriched ligands have been synthesized they are coordinated to the metal to provide the catalysts or catalyst precursors. Generation of these species can also be accomplished in situ, and this is often the method of choice among researchers working in this area. In situ catalyst generation, however, frequently introduces another level of uncertainty into the analysis of the mechanism. Unless the reaction is monitored spectroscopically, it must be assumed that the assembly of the ligands and metal precursors has taken place to afford catalyst or precatalyst with the expected structure.

After the generation of the catalyst or catalyst precursors, they are examined in the reaction of interest to evaluate their enantioselectivities and activities. The findings of these studies are assessed and the next generation of ligands is designed, beginning the second iteration of the catalyst development.

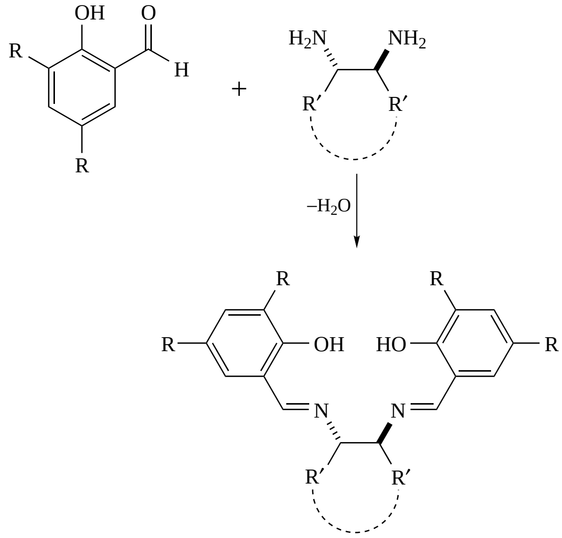
In the process of catalyst development, the key to efficient reaction optimization is frequently rapid access to catalysts with diverse chiral environments. Therefore, it is important to design ligands that can be generated from common intermediates in a few steps. While it is often useful to synthesize elaborate ligands to probe asymmetric induction and reaction mechanisms, few researchers are willing to perform multistep ligand syntheses in the application of catalysts.

An ideal ligand and catalyst system is outlined below to illustrate the utility of the traditional approach to asymmetric catalysis.

2.1 Application of Salen-based Catalysts to Asymmetric Catalysis

One of the most significant discoveries in asymmetric catalysis in the last 15 years was the importance of chiral metal salen catalysts. Chiral salen complexes exhibit high enantioselectivities in several mechanistically distinct reactions. As a result, they have been classified as 'privileged structures'.[8]

An important benefit of salen ligands and their metal complexes is that they are easily synthesized. Their straightforward synthesis involves mixing a resolved diamine with two equivalents of a salicyl aldehyde derivative, many of which are commercially available (equation 1). This design allows many derivatives to be prepared, allowing great structural diversity and facilitating catalyst optimization.



(1)

Initial successes with these ligands came independently from the groups of Jacobsen[9] and Katsuki[10] in the asymmetric epoxidation of unfunctionalized olefins.[9,10] Since these seminal works in 1990, metal salen complexes have become workhorse in asymmetric catalysis, finding applications in a wide variety of reactions. In Figure 1 is illustrated a variety of metal salen complexes. Scheme 1 lists some of the transformations in which they have been used, demonstrating the broad utility of these complexes.

To illustrate the utility of the metal salen complexes, several reactions are outlined in Scheme 1. They include the asymmetric epoxidation of unfunctionalized *cis*-disubstituted and trisubstituted olefins, which are promoted by (salen)Mn complexes.[11,12] In the case of *trans*-disubstituted olefins, the simple (salen)Mn complexes do not exhibit the same levels of enantioselectivity as they do with the *cis*- and trisubstituted derivatives. Promising alternatives include more elaborate (salen)Mn complexes based on the binaphthyl unit,[13] (salen)Cr complexes,[14] and (salen)Ru-based catalysts.[15] Catalysts based on (salen)Co moiety have exhibited amazing levels of selectivity in the hydrolytic kinetic resolution (HKR)[16] of terminal epoxides.[17,18] The HKR allows access to terminal epoxides and diols with very high enantioselectivities.

Terminal epoxides of high enantiopurity are among the most important chiral building blocks in enantioselective synthesis, because they are easily opened through nucleophilic substitution reactions. Furthermore, this procedure can be scaled to industrial levels with low catalyst loading.[19] Chiral metal salen complexes have also been successfully applied to the asymmetric hydroxylation[20,21] of C–H bonds, asymmetric oxidation of sulfides,[22,23] asymmetric aziridination of alkenes,[24] and the asymmetric alkylation of keto esters[25] to name a few.

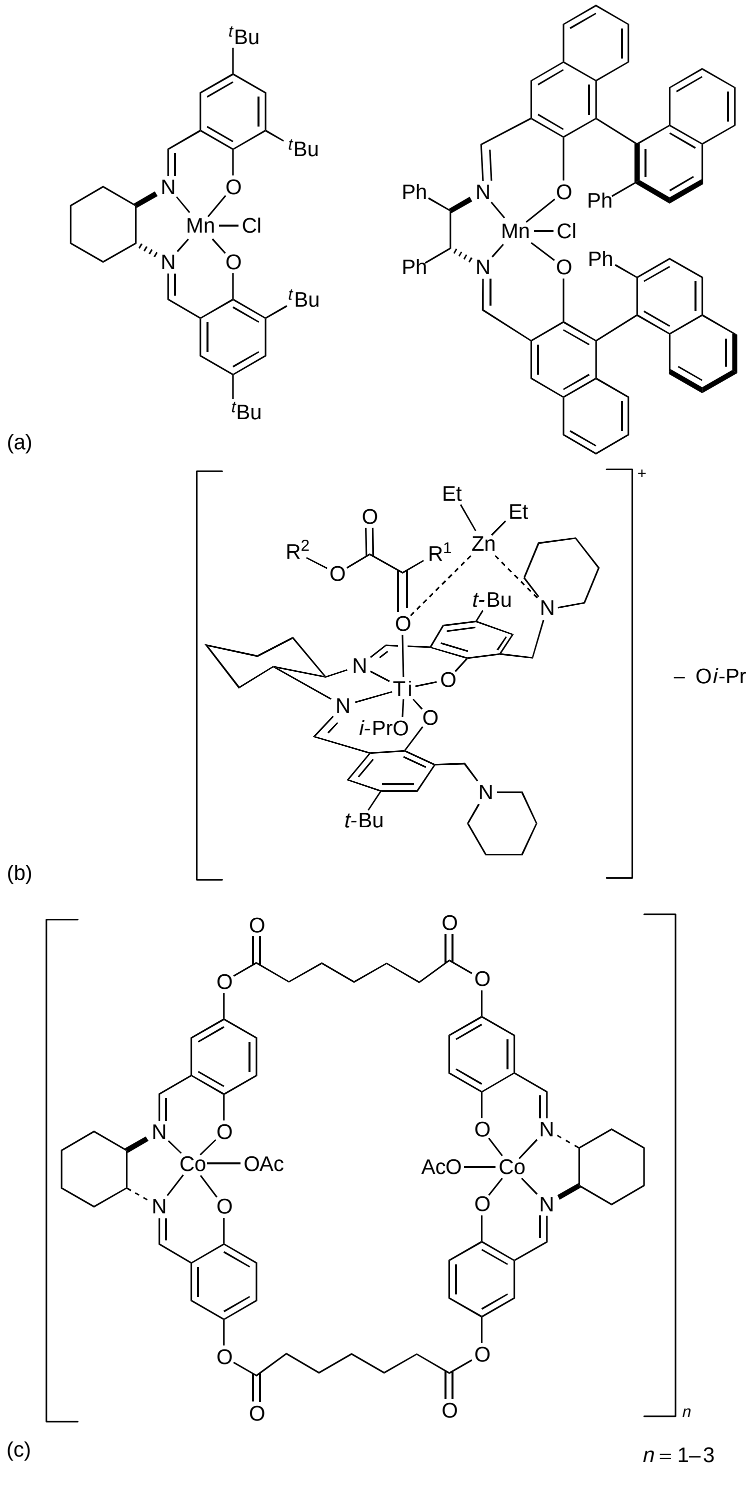


Figure 1 Structures of some metal salen complexes: (a) epoxidation catalysts, (b) proposed structure in the asymmetric addition of alkyl groups to alpha ketoesters with a bifunctional catalyst, and (c) oligomeric bifunctional salen catalyst for the hydrolytic catalytic resolution

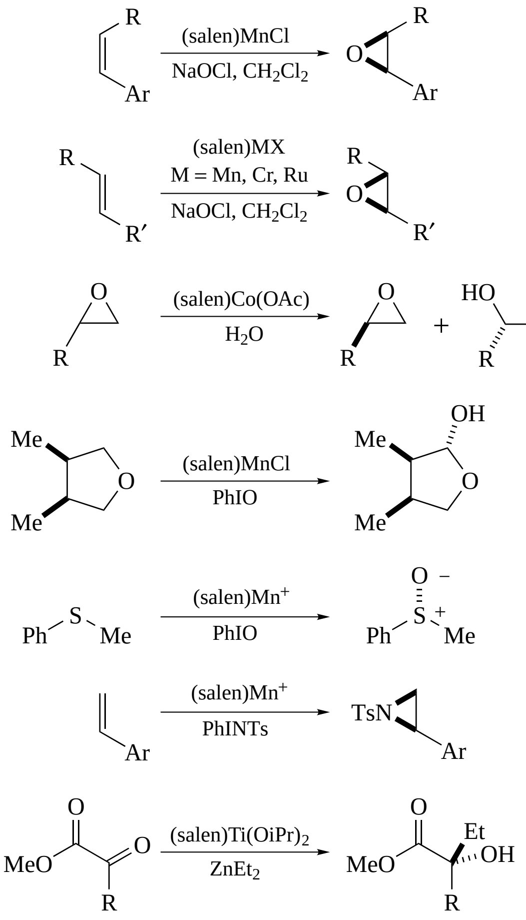
These transformations provide an indication of how different salen and metal combinations have been developed to optimize enantioselectivities and efficiency diverse reactions. The modular nature of the salen ligand allows the generation of structurally diverse ligands and complexes. In this regard, there are no ligands systems that are better suited to the traditional approach to asymmetric catalysis.



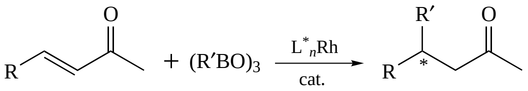
Scheme 1 Selected reactions of chiral salen-based catalysts

3 NONTRADITIONAL APPROACHES TO ASYMMETRIC CATALYSIS

The utility of the traditional approach to asymmetric catalysis, involving synthesis and screening of chiral ligands and complexes in catalytic reactions is a powerful method for the development and optimization of catalytic asymmetric processes. Such an approach, however, can be cumbersome if the ligands are difficult to synthesize and modify. In these cases, alternative strategies to the generation of asymmetric catalysts provide access to a large number of catalysts with minimal effort. The remainder of this section will focus on these methods.

3.1 Screening Mixtures of Chiral Monodentate Ligands

Reactions that result in the formation of C–C bonds are of central importance in the construction of organic molecules. One such reaction is the conjugate addition of organometallic reagents to α,β-unsaturated carbonyl compounds. The asymmetric addition of boronic acids to enones is promoted by rhodium catalysts bearing a bidentate[26] or two monodentate phosphorus-based ligands (equation 2).[27,28]



(2)

In the catalyst optimization process, a series of chiral bidentate ligands or chiral monodentate ligands could be screened. An alternative approach that provides access to a greater number of catalysts involves examination of mixtures of two monodentate ligands (L1* and L2*). If these ligands are part of a larger set of monodentate ligands (L1*, L2*, L3*,... Lx*, Ly*), many catalysts with combinations of ligands can be generated. As shown in Figure 2, combining two chiral ligands gives rise to formation of three catalysts, two homochiral complexes, $(\mathrm{L}x^*)_2\mathrm{Rh}$ and $(\mathrm{L}y^*)_2\mathrm{Rh}$, and a heterochiral complex $(\mathrm{L}x^*)(\mathrm{L}y^*)\mathrm{Rh}$.

These catalysts are likely to have different stabilities and be formed in unequal amounts. Both the homochiral complexes $(\mathrm{L}x^*)_2\mathrm{Rh}$ and $(\mathrm{L}y^*)_2\mathrm{Rh}$ are accessible by combining a chiral ligand with the rhodium precursor. The heterochiral complex, however, is new. If the heterochiral complex exhibits greater activity and enantioselectivity than the homochiral complexes, not only will the resulting combination lead to improved

$$\mathrm{L}x^* + \mathrm{L}y^* + [\mathrm{Rh}] \longrightarrow (\mathrm{L}x^*)_2\mathrm{Rh} + (\mathrm{L}y^*)_2\mathrm{Rh} + (\mathrm{L}x^*)(\mathrm{L}y^*)\mathrm{Rh}$$

Figure 2 Combination of two chiral ligands can result in generation of three catalysts, $(\mathrm{L}x^*)_2\mathrm{Rh}$, $(\mathrm{L}y^*)_2\mathrm{Rh}$, and $(\mathrm{L}x^*)(\mathrm{L}y^*)\mathrm{Rh}$

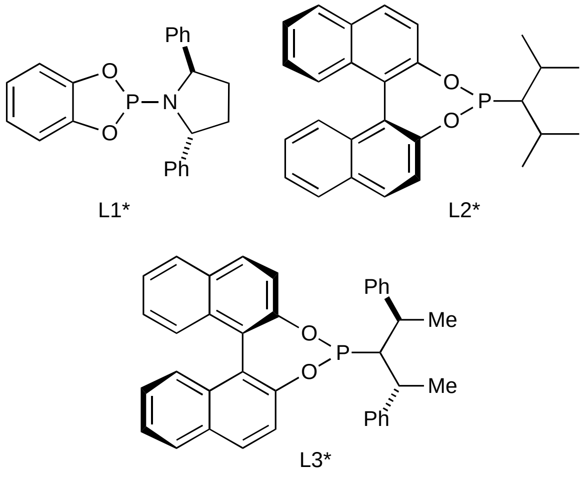


Figure 3 Ligands examined in the asymmetric conjugate addition reaction

Table 1 Ratios of homo- and heterochiral complexes determined by ^{31}P NMR

	$(L1^*)_2Rh$	$(L1^*)(L2^*)$ Rh	$(L2^*)_2Rh$
L1*/L2*	17	78	5
L1*/L3*	5	91	4
L2*/L3*	27	54	19

catalysts, it will indicate that a combinatorial approach to catalyst optimization is possible.

A small collection of ligands was examined to evaluate the potential of this approach (Figure 3).

Initially two equivalents of each ligand were combined with $Rh(acac)(CH_2{=}CH_2)_2$ to determine the ^{31}P NMR chemical shifts of the homochiral complexes. Next, 1:1 mixtures of chiral ligands were combined with an equivalent of the Rh(acac) $(CH_2{=}CH_2)_2$ and the ratio of the resultant complexes determined. As outlined in Table 1, the results of these experiments suggest that when L1*, with the smallest cone angle (*see Cone Angle*), is combined with the sterically bulkier ligands L2* or L3*, the equilibrium lies toward the heterochiral complex. When the sterically demanding ligands L2* and L3* are combined, however, the product ratio is closer to statistical.

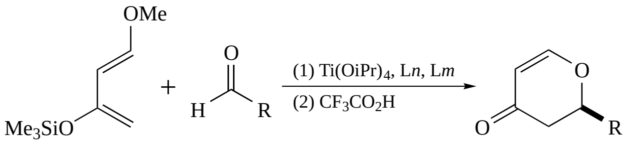
These ligand combinations were then applied to the asymmetric addition of aryl boronic acid derivatives to 2-cyclohexenone. The results of this study are illustrated in Figure 4. From this data it can be seen that the heterochiral ligand combination L1*/L2* exhibited the highest conversion during the 3 h evaluation period. Furthermore, the heterochiral complexes L1*/L2* and L1*/L3* are significantly more enantioselectivity than the homochiral combinations.

Despite the small ligand library employed, this study clearly indicates the benefit of combining chiral monodentate ligands in the optimization of catalyst enantioselectivity and efficiency. As illustrated below, larger libraries of bidentate ligands (*see Bidentate Ligand*) can likewise be employed.

3.2 Screening of Heterochiral (L)(L′)Ti Complexes in the Asymmetric Hetero-Diels-Alder Reactions

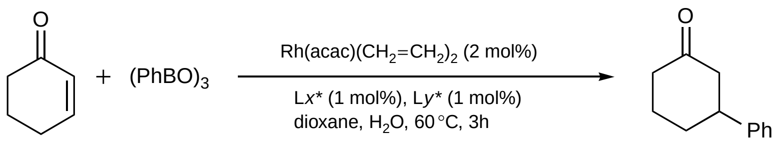
In a study aimed at the development of a highly enantioselective catalyst for the asymmetric hetero-Diels–Alder reaction, a series of diols and BINOL derivatives was employed (Figure 5, L1–L13). Titanium tetraisopropoxide was chosen as the metal precursor, because it readily undergoes alkoxide exchange reactions with alcohols and phenols. Furthermore, it has been successfully used in many Lewis acid (*see Lewis Acids & Bases*) catalyzed reactions. A beneficial feature of titanium tetraisopropoxide is that chelating alkoxide and aryloxide-based ligands and/or ligands with acidic hydroxyl groups will favor formation of the chiral titanium complex and liberation of isopropanol. By combining all possible combinations of L1–L13, a library of 104 combinations can be generated. Each of the ligand combinations above will likely result in a mixture of compounds that is under thermodynamic control. It is anticipated that the titanium centers will be coordinated to either two of the same ligands giving $(Lm)_2Ti$ and $(Ln)_2Ti$ or two different ligands as in $(Lm)(Ln)Ti$.

Combination of 1 mol% of each ligand and titanium tetraisopropoxide generated the catalyst mixtures that were screened in the asymmetric hetero-Diels–Alder reaction (equation 3). All reactions were conducted in diethyl ether at rt for 24 h and worked up with trifluoroacetic acid. Preliminary screening indicated that combination of ligands with substituents at the 3,3′-positions of the BINOL ligands gave either low yields or enantioselectivities. Combinations involving L4–L7 exhibited high enantioselectivities (77–95%) and good yields (63–100%).



(3)

Further screening identified L5/L5/Ti and L5/L6/Ti combinations as the most enantioselective combinations. Optimization of L5/L5/Ti and L5/L6/Ti combinations allowed



Lx*/Ly*	% conv.	% ee	Lx*/Ly*	% conv.	% ee
L1*/L1*	26	33	L1*/L2*	93	**75**
L2*/L2*	22	–27	L1*/L3*	40	**77**
L3*/L3*	18	–16	L2*/L3*	16	–60

Figure 4 The asymmetric conjugate addition of aryl boronic acids to 2-cyclohexenone with ligand combinations L1*–L3*

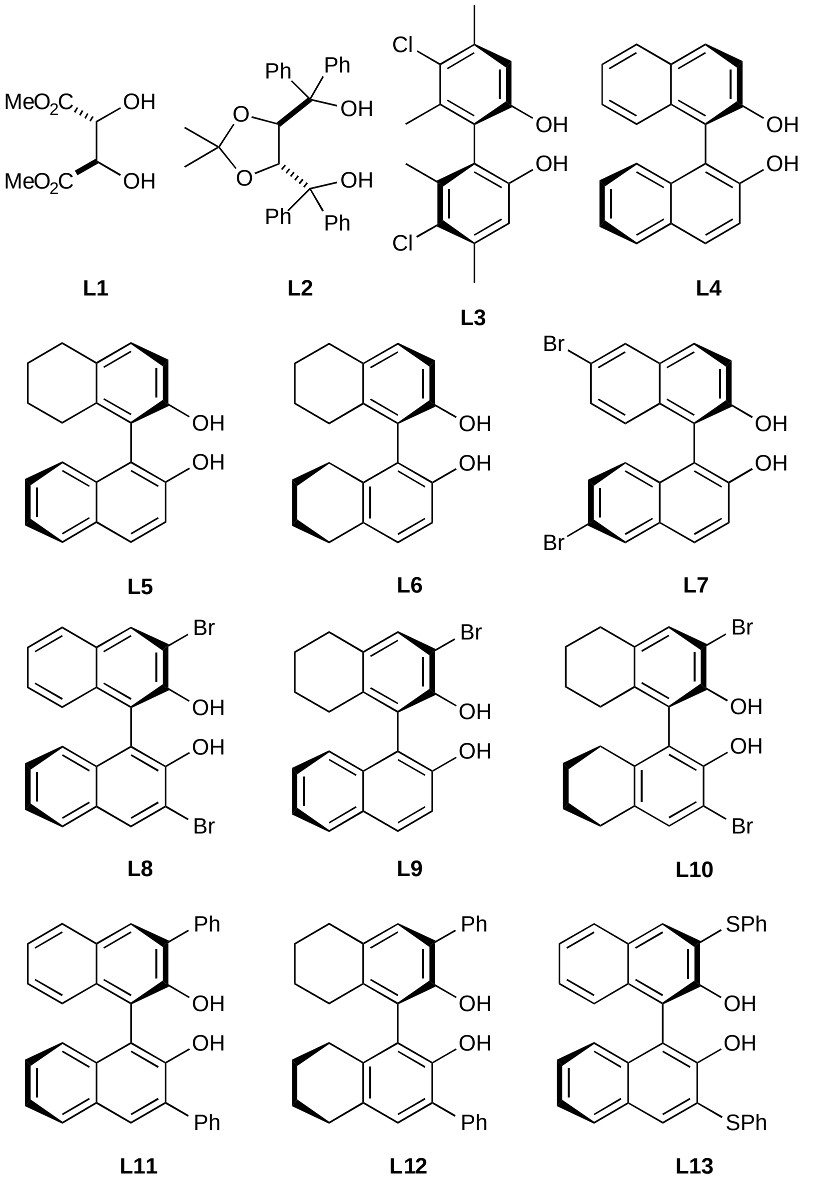


Figure 5 Ligands L1–L13 for the titanium catalyzed hetero-Diels–Alder reaction

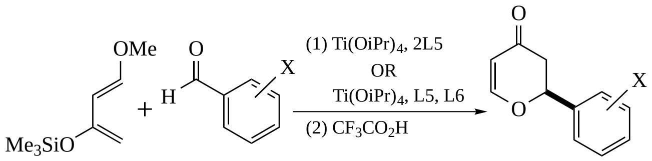
the loading of titanium and the ligands to be dropped to 0.05 mol% under solvent free conditions. In some cases, loadings could be reduced to 0.005 mol%, which is one of the lowest loadings for Lewis acid catalysts known that gave >95% ee.

Selected results employing 0.05 mol% loading of each ligand and titanium tetraisopropoxide are illustrated in Table 2. It is noteworthy that the enantioselectivities obtained with the L5/L6/Ti combination are 0.1–20% higher than the L5/L5/Ti combination. These results indicate that the most enantioselective catalyst contains both ligands.

This series of experiments clearly demonstrates the advantage of screening combinations of ligands. The

Table 2 Comparison of enantioselectivities with L5/L5/Ti and L5/L6/Ti combinations



Substrate	ee (%) 2L5/Ti	ee (%) L5/L6/Ti	Δee
X = H	99.3	99.4	0.1
X = 4-OMe	90.8	98.0	7.2

X = 2-OMe	75.1	95.1	20.0

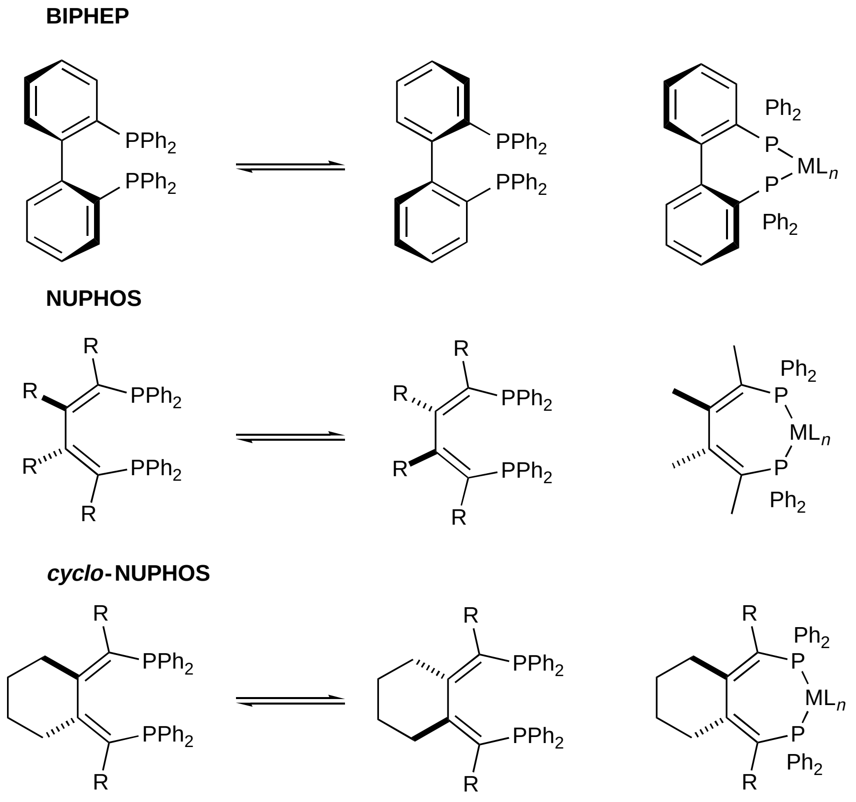

Figure 6 Structures of the normally unresolvable ligands BIPHEN, NUPHOS, and cyclo-NUPHOS and their complexes

disadvantage is that use of mixed ligand combinations can lead to the formation of multiple catalysts under the reaction conditions. In this case, the situation is further complicated by the propensity of titanium complexes to aggregate.[29] Mechanistic studies on a system containing multiple catalysts would be extremely difficult, because the most abundant complex may not be the most active.

3.3 Asymmetric Catalysis with Normally Unresolvable Ligands

Basic coordination chemistry serves as one of the underlying principles in the design, development, and understanding asymmetric catalysts. By taking advantage of strong, kinetically stable metal-ligand bonds, new enantioenriched catalysts have been prepared that contain ligands that cannot be resolved at room temperature. With proper choice of the metal center, however, the barrier to racemization of the metal-ligand assembly is significantly higher than that of the free ligand.

One class of ligands that racemizes readily at room temperature is based on atropisomeric bidentate phosphines such as BIPHEP, NUPHOS, and cyclo-NUPHOS (Figure 6). For example, the barrier to racemization of BIPHEP is 22 kcal mol^{-1},[30] making it very difficult to resolve. The metallocycle formed on binding to a substitutionally inert metal significantly increases the barrier to racemization.

When *rac*-(BIPHEP)$PtCl_2$ was treated with Na_2[(*S*)-(BINOLate)], a kinetic 1:1 ratio of the (BINOLate)Pt(BIPHEP) diastereomers was isolated. Heating this mixture to 92–122 °C resulted in equilibration of the mixture to form a 95:5 ratio with the (*S*,*S*)-diastereomer being thermodynamically favored (equation 4). Interconversion of the diastereomers likely proceeds by dissociation of a phosphorus from platinum, rotation, and recoordination. The minor (*R*,*S*)-diastereomer was isolated cleanly by fractional precipitation.[31]

Two routes were developed to eliminate the BINOLate ligand from the platinum (Figure 7). Reaction of the [(*R*)-BIPHEP]Pt[(*S*)-BINOLate] with hydrochloric acid gave [(*R*)-BIPHEP]$PtCl_2$. The dichloride [(*R*)-BIPHEP]$PtCl_2$ was then subject to two equivalents silver triflate to furnish the Lewis acidic triflate [(*R*)-BIPHEP]$Pt(OTf)_2$. Alternatively, [(*R*)-BIPHEP]Pt[(*S*)-BINOLate] was converted directly to the triflate [(*R*)-BIPHEP]$Pt(OTf)_2$ by exposure to triflic acid.

The stereochemical stability of the resolved (BIPHEP)Pt derivatives was next examined. The possibility of racemization of the [(*R*)-BIPHEP]$Pt(OTf)_2$ was addressed by treatment

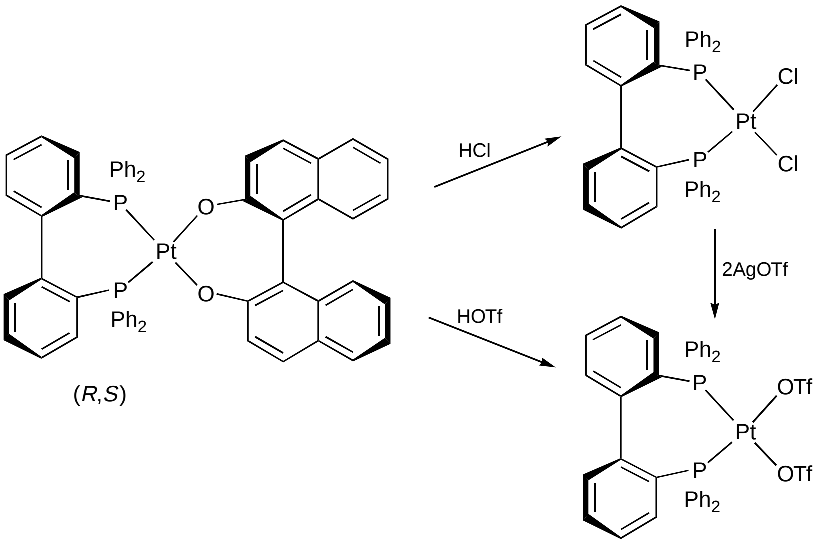

Figure 7 Reaction of [(*R*)-BIPHEP]Pt[(*S*)-BINOLate] with acids gives (*R*)-(BIPHEP)PtX_2 of high enantiopurity

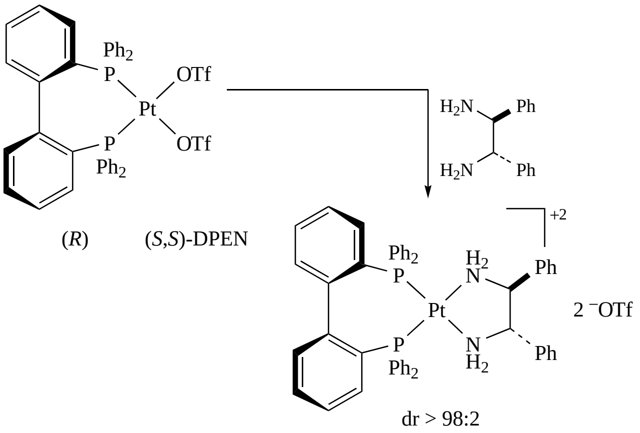
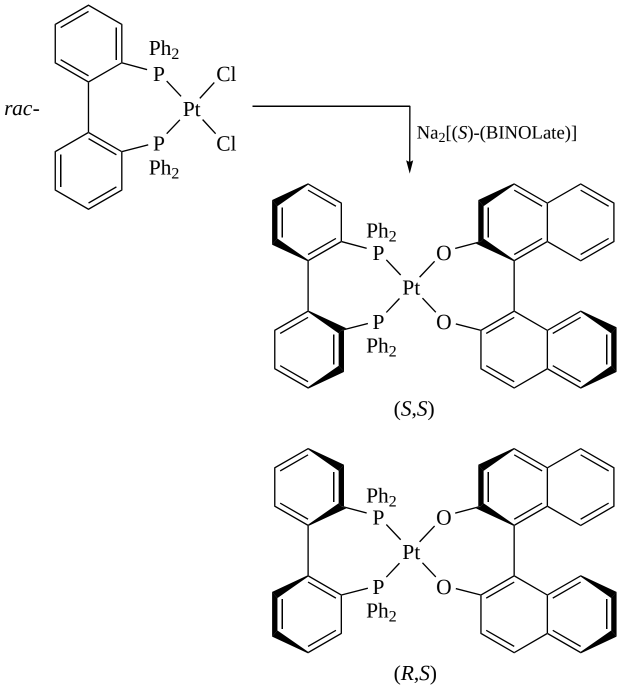
with the resolved diamine (*S*,*S*)-DPEN (equation 5). Examination of the resulting diamine adducts by ^{31}P NMR spectroscopy indicated that the [(*R*)-BIPHEP]Pt$(OTf)_2$ was produced in 98% ee. To determine the stability with respect to racemization of [(*R*)-BIPHEP]Pt$(OTf)_2$, a sample was allowed to stand for 8 h at room temperature then treated with (*S*,*S*)-DPEN. The diastereomeric ratio was determined to by 98:2 indicating that racemization of [(*R*)-BIPHEP]Pt$(OTf)_2$ was slow in solution at room temperature.



(5)



(4)

The stability of (BIPHEP)PtX_2 compounds with respect to racemization over several hours at room temperature suggested that these compounds could be employed as catalysts at room temperature or below. To explore this possibility, [BIPHEP]Pt$(OTf)_2$ was employed in the asymmetric Diels–Alder reaction as illustrated in equation (6). Freshly generated [(*R*)-BIPHEP]Pt$(OTf)_2$ promoted the asymmetric Diels–Alder reaction forming the product in 94:6 endo:exo ratio with the ee of the major diastereomer of 92–94%.[31] The enantiomeric excess of the catalyst [(*R*)-BIPHEP]Pt$(OTf)_2$ was not diminished over the course of the reaction, as determined by quenching the reaction at >90% conversion with (*S*,*S*)-DPEN and subsequent ^{31}P NMR analysis of the resulting mixture. The facial selectivity of the asymmetric Diels–Alder reaction catalyzed by [(*R*)-BIPHEP]Pt$(OTf)_2$ was the same as observed with [(*R*)-BINAP]Pt$(OTf)_2$ with the same

reagents.[32]

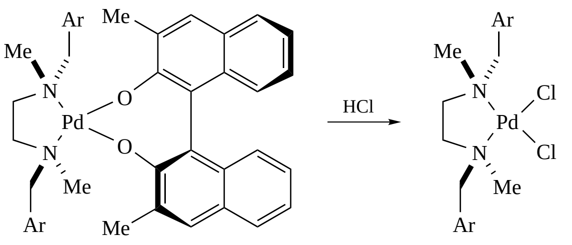
(6)

This, and related systems,[33,34] illustrate that bidentate phosphine ligands that are not resolvable at room temperature can adopt stereochemically robust coordination modes when bound to substitutionally inert metals. The importance of chelating phosphines (*see Chelating Ligands*) in asymmetric catalysis, and the difficulties often encountered in their resolution, should render this nontraditional strategy useful.

Application of N-chirality in Asymmetric Catalysis. Another class of ligands that cannot normally be resolvable is amines. Free amines with three different substituents are not usually considered chiral, because they undergo rapid lone pair inversion at nitrogen with rates on the order of 5×10^5 s^{-1} at rt.[35] Coordination of amines to substitutionally inert metals freeze nitrogen inversion generating *N*-chiral ligands (Figure 8). Dissociation of the amine ligand from the metal, however, will lead to inversion.

In an effort to synthesize enantioenriched diamine complexes, prochiral diamines were mixed with K_2[(*R*)-Me_2-BINOLate] and palladium acetate resulting in the formation of the two diastereomers (Figure 9).[36] These diastereomers were both C_2-symmetric and assigned as the (*R*,*R*)/(*R*) and (*S*,*S*)/(*R*) configurations based on NMR and X-ray crystallographic studies. The major diastereomer was separated from the minor by crystallization.

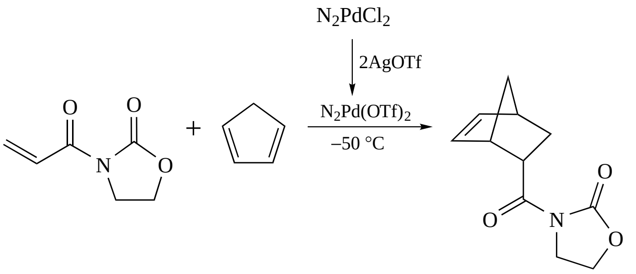
Treatment of the pure (*R*,*R*)/(*R*) diastereomers with HCl allowed isolation of the dichlorides, which were determined to be configurationally stable at nitrogen (equation 7).



(*R*,*R*)/(*R*) (*R*,*R*)-N_2PdCl_2

(7)

These catalyst precursors, abbreviated N_2PdCl_2 in equation (7), were then employed in the asymmetric Diels–Alder reaction of *N*-acryloyl oxazolidinone with cyclopentadiene (equation 8).



20% ee

(8)

Although the catalysts typically gave very high endo/exo ratios, the enantioselectivities were low. It was found that the catalyst did not undergo racemization at nitrogen under the reaction conditions, indicating that the poor enantioselectivities reflect the inability of the catalyst to efficiently convey the stereochemical information. This may be due to the similarity in size of the Me and CH_2Ar substituents on the chiral diamine ligand. Nonetheless, this example is illustrates that asymmetric catalysts with only *N*-chirality are feasible and potentially useful in asymmetric catalysis.

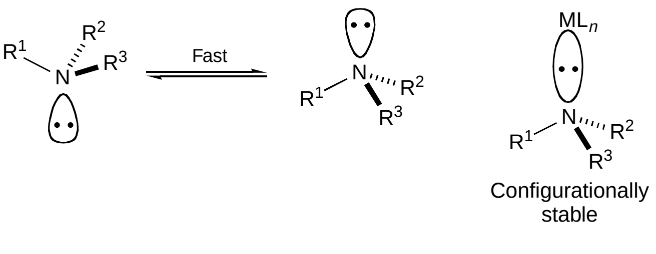


Figure 8 Nitrogen inversion is typically rapid at room temperature. Coordination of the lone pair to a metal center can freeze nitrogen inversion

3.4 Chiral Poisoning

It is often found that the resolution of chiral ligands is frequently as difficult as the syntheses of the ligand themselves. To circumvent tedious resolutions, a strategy that involves the use of racemic ligands in asymmetric catalysis has been developed and is termed chiral poisoning.[37,38] The benefit of this approach is that racemic ligands are usually significantly less expensive and easier to access than their enantioenriched counterparts. The chiral poisoning strategy entails generation of a racemic catalyst and selective inhibition of one catalyst enantiomer with a chiral resolved ligand P* (the poison). The binding of the chiral poison to the racemic catalyst would give rise to diastereomeric adducts, which would

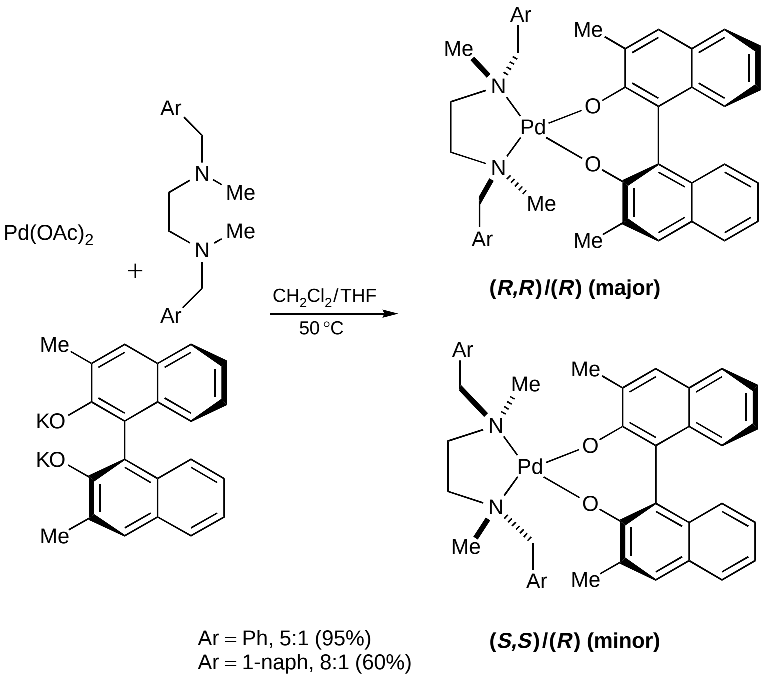

Figure 9 Synthesis of complexes with *N*-chiral diamine ligands

have different association constants. In an ideal scenario the poison binds tightly to one catalyst enantiomer completely disabling it, leaving the other enantiomer free to promote the enantioselective reaction. This situation is illustrated schematically in Figure 10.

An example of how well chiral poisoning strategy can work is illustrated by the asymmetric hydrogenation of β-keto esters. Activation of the enantioenriched (Xyl-BINAP)$RuCl_2(dmf)_n$ precatalyst provides a highly enantioselective catalyst for the asymmetric hydrogenation of β-dicarbonyl compounds.[39,40] Application of the chiral poisoning strategy in this system entailed identification of suitable enantioenriched poisons. After screening several potential poisons it was found that 0.5 equivalents the diamine (*S*)-3,3′-dimethyl diaminobinaphthyl, (*S*)-DM-DABN, selectively coordinated to the [(*S*)-Xyl-BINAP]$RuCl_2$ center (Figure 11). Due to an unfavorable steric interaction of the 3,3′-dimethyl substituents on the diamine with the Xyl-groups on the chelating phosphine[41] the [(*R*)-Xyl-BINAP]$RuCl_2(dmf)_n$ does not bind the (*S*)-DM-DABN. This steric repulsion is shown in Figure 12.

This system has been applied to the asymmetric hydrogenation (*see Hydrogenation*) of methyl 3-oxobutanoate as illustrated in Table 3. Use of racemic (Xyl-BINAP)Ru complex with (*S*)-DM-DABN gave essentially identical enantioselectivity to the use of enantioenriched (Xyl-BINAP)$RuCl_2(dmf)_n$ precatalyst.[41]

These results demonstrate the power of the chiral poisoning strategy under the optimal conditions. Deviations form such ideal behavior can result from incomplete inhibition of one of the enantiomers of the precatalyst. In this case, an excess of the poison may be necessary. It is also possible that the poison inhibits both catalyst enantiomers, but to different degrees. These situations decrease the effectiveness of the chiral poison strategy.

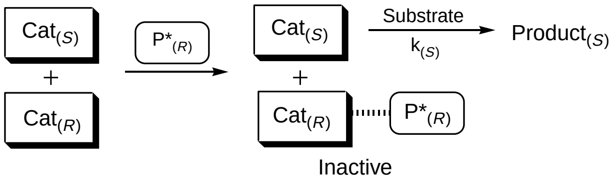

Figure 10 Idealized chiral poisoning involves complete deactivation of one enantiomers of the racemic catalyst, $Cat_{(R)}$ in this example, by the resolved poison $P^*_{(R)}$

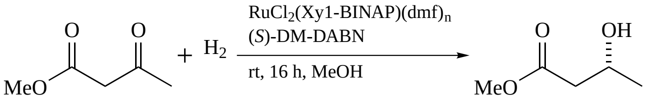
Table 3 Comparison of the chiral poisoning strategy to the traditional use of chiral resolved BINAP derivative



Cat.	(*S*)-DM-DABN	Yield (%)	Product ee (%)

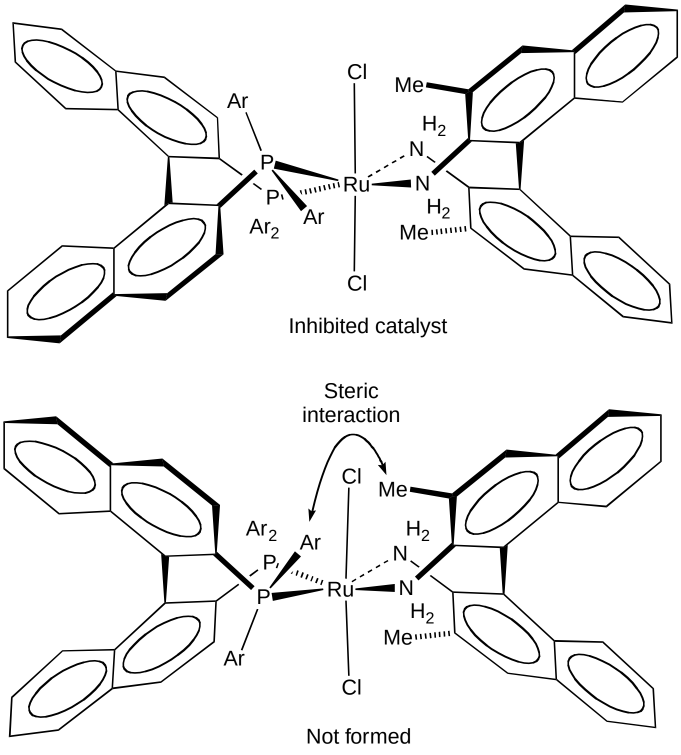

Figure 12 Three-dimensional drawings of the binding of the (*S*)-enantiomer of the precatalyst with the (*S*)-DM-DABN. The (*R*)-enantiomer of the precatalyst does not bind (*S*)-DM-DABN owing to a repulsive interaction between two aryl groups on the phosphine and the 3,3′-dimethyl groups on the diamine

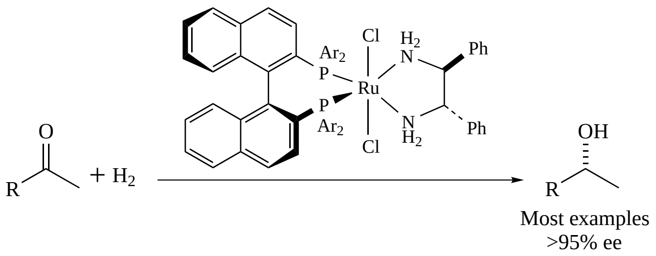
3.5 Addition of Chiral Additives: Asymmetric Activation

An alternative to the approach chiral poisoning that also involves use of racemic catalysts has been called asymmetric activation.[42,43] In this strategy, a racemic catalyst is reacted with resolved activator that selectively activates one enantiomer of the racemic catalyst precursor. This process involves binding a resolved ligand to a racemic catalyst, resulting in the formation of diastereomeric catalysts. There are several scenarios in which this mixture of diastereomers can give high enantioselectivity. Either both catalysts must give the same enantiomer of the product with high ee, or one of the diastereomeric catalysts must be highly enantioselective *and* significantly more active than the other diastereomer. The advantage of this method over chiral poisoning is that the resultant catalyst system can exhibit greater activity and enantioselectivity than the enantioenriched precatalyst.

3.5.1 Asymmetric Activation of Racemic Hydrogenation Catalysts

Asymmetric hydrogenation of prochiral ketones is an important method for the preparation of chiral secondary alcohols. Until recently, however, such reactions were limited to substrates with pendent metal binding sites, like β-keto esters.[39] Many of the catalysts that efficiently hydrogenate C–C double bonds exhibit little or no reactivity with isolated ketones. This discrepancy may be ascribed to the different binding modes of alkenes and ketones, and the chemoselectivity of catalysts for these groups. While substrates with C–C double bonds can form metal π-complexes, this binding mode is uncommon for ketones. The distinct characteristics of the C–C and C–O π-bonds suggest that catalyst selective for these groups will likely operate by dissimilar mechanisms. This has indeed been found to be the case, and mechanistic investigations indicate that the ketone reduction proceeds by an unexpected pathway that does not involve coordination of the substrate to the metal center.

Ruthenium catalysts bearing diamine and bidentate phosphine ligands, illustrated in equation (9), exhibit high enantioselectivity and efficiency in the reduction of ketones.[39,44–46] Before the application of this catalyst to asymmetric activation can be illustrated, important mechanistic information will be outlined.



(9)

Detailed experimental and theoretical investigations have provided an accurate picture of the unique mechanism of these remarkable hydrogenation catalysts. The active catalyst is believed to be the dihydride (Figure 13), which is generated by combining the precatalyst in equation (9), alkoxide base, dihydrogen, and the ketone in isopropanol. Analogous compounds have been prepared and characterized crystallographically.[47] The first step in the catalytic cycle is

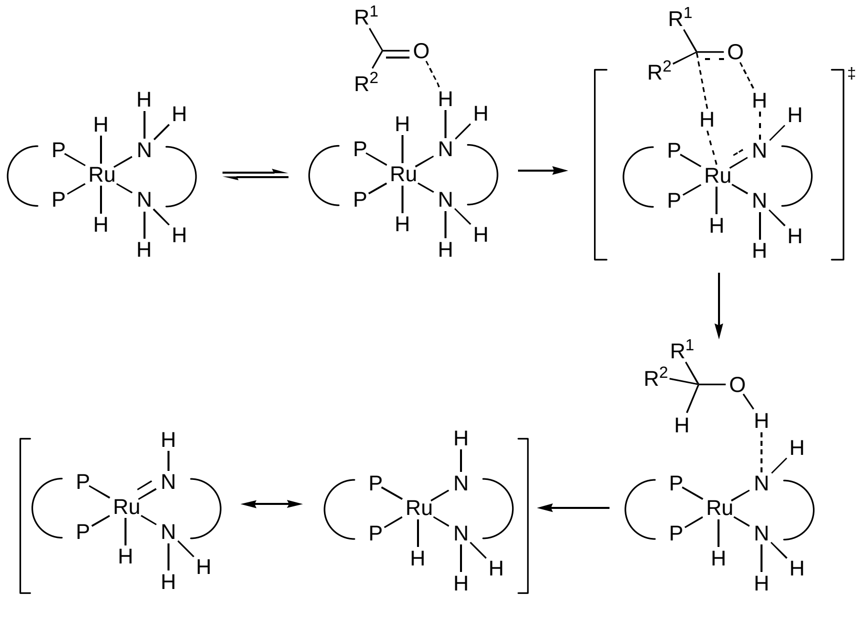


Figure 13 Proposed mechanism for hydrogenation of ketones with (BINAP)RuH_2(diamine) derivatives

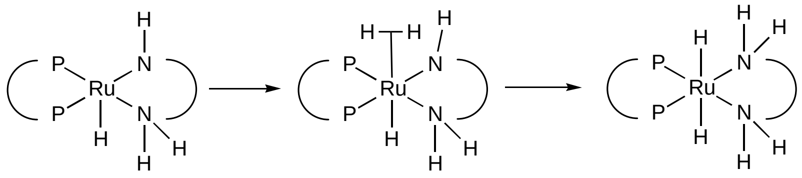

Figure 14 Proposed mechanism of heterolytic cleavage of dihydrogen

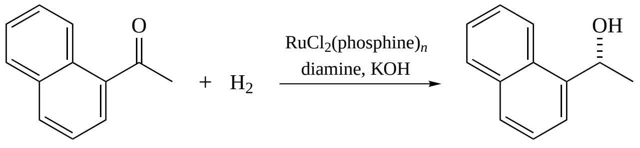
believed to be formation of a weak interaction between the ketone substrate and the catalyst, as shown in Figure 13. From this hydrogen-bonded intermediate, facile hydrogenation takes place through a six-membered transition state, resulting in formation of the chiral alcohol and the Ru-amide. Late transition metal amide complexes of this type are very reactive,[48–50] and have been characterized in model systems.[47]

The heterolytic cleavage (*see Heterolytic Cleavage*) of dihydrogen is the turnover-limiting step in the catalytic cycle (Figure 14). It likely occurs via initial formation of a dihydrogen complex (*see* ***Hydrogen Bonding & Dihydrogen Bonding*** followed by proton abstraction by the amide nitrogen to give the dihydride complex. Consistent with this hypothesis, a first-order dependency on the ruthenium catalyst and the dihydrogen is observed. The reaction is zero order in ketone concentration. Additionally, $\Delta S^{\dagger}$ is on the order of -25 cal molK^{-1}, suggesting a highly ordered transition state.

It is interesting to note that these hydrogenation catalysts are 18 electron species and need not open up a coordination site to generate a 16 electron intermediate, as observed with many alkene hydrogenation catalysts. The bifunctional nature of these catalysts allows them to access an unconventional second-coordination sphere hydrogen transfer mechanism. Activation of the ketone through a hydrogen-bond from the ligand eludes to the power of such subtle interaction in enantioselective catalysis.

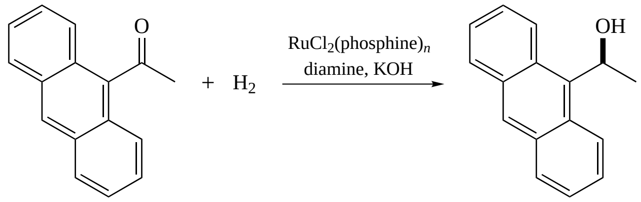
This system for the asymmetric hydrogenation of ketones has been employed in the asymmetric activation using a racemic BINAP derivative. Combination of $RuCl_2$[(*S*)-Xyl-BINAP](dmf)$_n$ (Xyl = 3,5-C_6H_3-Me_2) and (*S*,*S*)-DPEN gave the precatalyst $RuCl_2$[(*S*)-Xyl-BINAP][(*S*,*S*)-DPEN], which exhibited 99% enantioselectivity in the reduction of 1-acetylnaphthone to the (*R*)-alcohol (equation 10).



Phosphine	Diamine	% ee
(*S*)-Xyl-BINAP	(*S*,*S*)-DPEN	>99 (*R*)
(*R*)-Xyl-BINAP	(*S*,*S*)-DPEN	56 (*S*)
(*rac*)-Xyl-BINAP	(*S*,*S*)-DPEN	90 (*R*)

(10)

The catalyst composed of the mismatched ligands, (*R*)-Xyl-BINAP and (*S*,*S*)-DPEN, was much slower and furnished the (*S*)-alcohol with 56% ee (equation 10). Employing *racemic* Xyl-BINAP and (*S*,*S*)-DPEN gave a 50:50 mixture of diastereomeric ruthenium complexes that reduced 1′-acetylnaphthone to the (*R*)-alcohol with excellent enantioselectivity (90%).



Phosphine	Diamine	% ee
(*S*)-Tol-BINAP	(*S*,*S*)-DPEN	40 (*R*)
(*R*)-Tol-BINAP	(*S*,*S*)-DPEN	81 (*R*)
(*rac*)-Tol-BINAP	(*S*,*S*)-DPEN	80 (*R*)

(11)

Interestingly, when the precatalyst $RuCl_2$[(*S*)-Tol-BINAP][(*S*,*S*)-DPEN] (Tol = 4-C_6H_4-Me) was employed in the reduction of 9-acetylanthracene the enantioselectivity was only 40% (equation 11). In contrast, use of $RuCl_2$[(*R*)-Tol-BINAP][(*S*,*S*)-DPEN] resulted in a reduction of the ketone with 81% ee. Employing *racemic* Tol-BINAP and (*S*,*S*)-DPEN gave (*R*)-alcohol with essentially the same enantioselectivity as the enantioenriched (*R*)/(*S*,*S*)-catalyst.

It is noteworthy that in the reduction of 1′-acetylnaphthone the catalyst with the (*S*)/(*S*,*S*)-configuration was the fastest and most enantioselective while in the hydrogenation of 9-acetylanthracene the catalyst with the (*R*)/(*S*,*S*)-configuration gave the highest enantioselectivity, and exhibited a higher turnover frequency.

These high enantioselectivities indicate that the diastereomeric catalysts not only have different enantioselectivities, but must have very different TOFs. Whenever diastereomeric catalysts are applied together in the same reaction, the product ee is governed by the enantioselectivity of each of the diastereomeric catalysts *and* their relative rate.[51–54] This fact complicates reaction optimization. Nonetheless, the results outlined in equation (10) and (11) illustrate how well the chiral activation strategy can work with the correct combination of chiral ligands *and* substrate. It is expected that there

will be a great deal of future activity in asymmetric catalysis employing asymmetric activation.

3.6 Asymmetric Activation of Enantioenriched Lewis Acid Catalysts

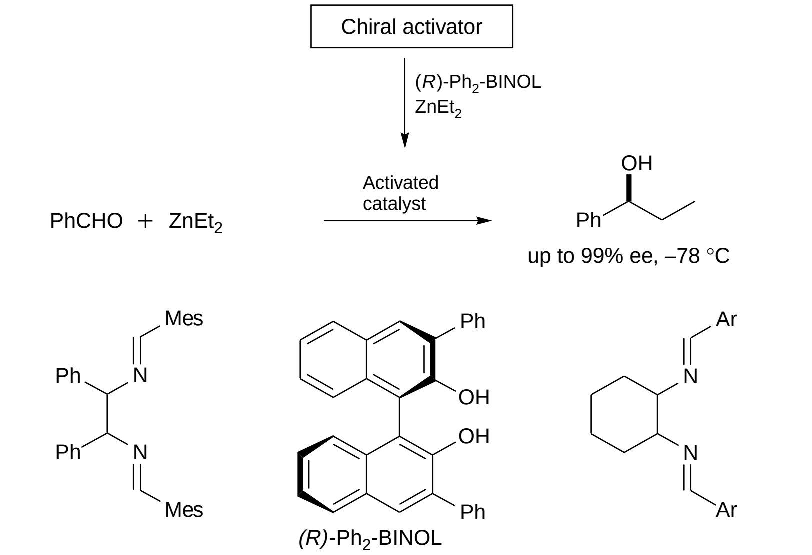
In the previous example, the asymmetric activation strategy was used to increase the efficiency and enantioselectivity of one catalyst in a diastereomeric mixture of catalysts. This technique can also be applied to resolved asymmetric catalysts. An example of this strategy[42] involves the zinc catalyzed asymmetric addition of alkyl groups to aldehydes.[55,56]

Organozinc catalysts are known to promote the asymmetric addition of alkyl groups to aldehydes with high enantioselectivity.[57] In the case of catalyst generated from (*R*)-3,3-diphenyl BINOL (Ph_2-BINOL) and diethylzinc, however, the asymmetric addition is slow and proceeds in low enantioselectivity (Figure 15). When the catalyst was prepared in the same fashion, followed by addition of enantiopure diimine ligands, new catalysts formed that exhibited increased efficiencies and enantioselectivities. The levels of enantioselectivity of the catalysts were then optimized by screening enantiopure diimine ligands. The best catalyst in this study was derived from (*R*)-Ph_2-BINOL and the (*S*,*S*)-diimine with the stilbene diamine backbone and 2,4,6-trimethylbenzaldehyde (Figure 15). Combination of diimine with Ph_2-BINOL gave a highly enantioselective catalyst that generated 1-phenyl-1-propanol of 90% ee at 0 °C and 99% ee at −78 °C. This catalyst optimization process illustrates the power of asymmetric activation to maximize catalyst efficiency and enantioselectivity.

The asymmetric activation strategy is clearly a useful technique in the optimization of asymmetric catalysis. Racemic catalysts can by selectively activated with enantioenriched activators, resulting in the generation of highly enantioselective catalysts. Resolved catalysts can also be activated with enantioenriched activators, with the potential of increasing their efficiency and enantioselectivity. As illustrated above, this approach can be applied in a combinatorial fashion allowing generation of a large number of catalysts from a small library of ligands.

3.7 Optimization of Enantioselective Catalysts Using Achiral and Meso Ligands

The traditional method for the optimization of asymmetric catalysts involves the synthesis and screening of chiral ligands.[1] As pointed out in previous sections, the resolution of chiral ligands, or their components, can be demanding and time-consuming. In the sections that follow catalyst enantioselectivity and efficiency are maximized by use of achiral and *meso* ligands. The achiral additives can be divided into three classes: (1) achiral ligands with



(*R*)-Ph_2-BINOL

3.7.1 *Optimization of the Enantioselective Alkylation of Aldehydes Employing Achiral and Meso Ligands*

In the proceeding section on asymmetric activation, (Ph_2-BINOLate)Zn(diimine) complexes containing two resolved ligands were employed in the asymmetric alkylation of aldehydes. In this study, both the Ph_2-BINOL and diimine could be varied to optimize catalyst enantioselectivity (Figure 15).[55,56] A different approach to catalyst optimization in this system would involve the use of one resolved ligand and one achiral or *meso* ligand (Figure 16). This strategy could be termed *achiral activation* based on its relation to asymmetric activation. In the study outlined below, the focus was on using achiral or *meso* ligands with *chiral conformations*. These ligands are attached to a metal coordinated to a resolved ligand.[58,59] Using this strategy, numerous catalysts can be synthesized from each resolved ligand by combination with an array of achiral and *meso* ligands. One advantage of such an optimization process is that many more achiral and *meso* ligand precursors and ligands are commercially available than enantiopure ligands. The greater variation in ligand components allows generation of catalysts with more diverse chiral environments. This, in turn, increases the likelihood of finding a suitable catalyst. Finally, the cost of achiral and *meso* ligands is less than that of related enantiopure materials.

As proof of principle, and to demonstrate the potential utility of the use of achiral and *meso* ligands in asymmetric catalysis, the catalyst optimization was performed using a single enantioenriched ligand, (*S*)-Ph_2-BINOL. In the asymmetric additions to benzaldehyde with $ZnEt_2$ and 10 mol% (*S*)-Ph_2-BINOL, in the absence of additional ligands, (*S*)-1-phenyl-1-propanol of 44% ee was slowly generated (Table 4, entry 1). After 28 h at 0 °C, conversion to the alcohol was only 83%. Subsequent experiments were performed with achiral or *meso* ligands and Ph_2-BINOL using 10 mol% loading of each of these ligands. Three equivalents of diethylzinc were used relative to benzaldehyde. Although

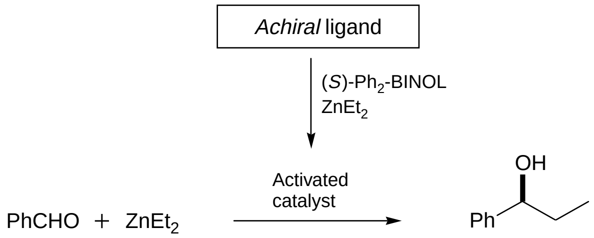

Figure 16 Activation of a chiral catalyst with an achiral or *meso* ligand with chiral conformations can result in an increase in the enantioselectivity of the catalyst

several classes of achiral and *meso* diimines and diamines were employed, with only a few representative examples are listed in Tables 4 and 5. Diimines derived from ethylene diamine were employed and found to lead to enantioselectivities ranging from 52% ee of the (*S*)-enantiomer to 87% ee of the (*R*)-configuration of the alcohol product (Table 4, entries 2–5).

Imine ligands were also prepared based on the 2,2′-diaminobiphenyl backbone. These ligands will bind to zinc and adopt chiral binding modes. The barrier to interconversion of such complexes will be significantly higher than the free ligands, because ring strain will be incurred in the transition state to atropisomerization of the metallocycle. As depicted in Figure 17, the two enantiomeric conformation of the zinc-bound diaminobiphenyl-based ligands are diastereomeric in the presence of the (Ph_2-BINOLate)Zn moiety. If the difference in energy of these diastereomers is large, the equilibrium could lie far to the side of the more stable diastereomer resulting in resolution of the diaminobiphenyl ligand. The chiral conformations of the biphenyl diimine ligands extend the chiral environment of the catalyst (Figure 17). Use of these ligands and (*S*)-Ph_2-BINOL in Figure 16 generated catalysts that exhibited up to 96% enantioselectivity at −45 °C (Table 4, entry 7).

It is interesting to note that catalyst derived from imines of 2,4,6-trimethylbenzaldehyde were found to result in the most enantioselective catalysts with resolved, achiral, and *meso* ligands in the asymmetric addition (Figure 15 and Table 4). This suggests that the placement and orientation of the 2,4,6-trimethylphenyl groups plays a crucial role in the stereoinduction.

In the examination of other nitrogen-based ligands with this catalyst system, it was observed that achiral and *meso* diamines had a marked impact on catalyst enantioselectivities. The simple diamines, TMEDA and *N,N,N′,N′*-tetraethylethylene diamine were found to exhibit the opposite enantiofacial selectivity (Table 5). While TMEDA formed a catalyst that gave the (*S*)-enantiomer of the product in 64% enantioselectivity (0 °C), catalyst based on *N,N,N′,N′*-tetraethylethylene diamine generated the (*R*)-enantiomer in up to 72% ee.

Secondary diamine ligands are particularly interesting because they result in addition of another stereochemical element to the catalyst. Coordination of secondary diamines to zinc stops nitrogen inversion, creating two new stereogenic centers directly attached to the catalyst binding site.[60,61] This coordination is likely to be reversible, permitting equilibration of the configuration at nitrogen through a 3-coordinate zinc intermediate. The C_2-symmetric (Ph_2-BINOLate)Zn is expected to bind the diamine in a C_2-symmetric fashion to minimize steric interactions between the diamine and the Ph_2-BINOLate ligand. Positioning of the nitrogen stereocenters in close proximity to the zinc binding site is expected to have a significant impact on the catalyst enantioselectivity in the asymmetric C–C bond forming

process. Examination of secondary diamines (Table 5, entries 3–5) in Figure 16 resulted in generation of the secondary alcohol with up to 76% enantioselectivity. This is the highest enantioselectivity obtained for the (*S*)-enantiomer in these investigations.

Diamines with pendent biphenyl groups were also employed in the asymmetric addition reaction in Figure 16 (Table 5, entries 6 and 7). It was predicted that atropisomerization of the biphenyl moiety in these ligands would have a low barrier. Interaction of the stereochemically label biphenyl

moiety with the (Ph_2-BINOLate)Zn center is expected to influence the biphenyl stereochemistry and extend the chiral environment of the resulting catalyst.

The catalysts prepared with atropisomeric ligands in entries 6 and 7 gave the product with enantioselectivities as high as 92% at −45 °C. It is interesting to note that catalysts derived from these ligands exhibited greater enantioselectivity than when *N,N,N′,N′*-tetraethylethylene diamine was employed (Table 5, entry 2). Taken together, the results in Tables 4 and 5 clearly indicate the benefit of screening achiral ligands on catalyst enantioselectivity.

The impact of achiral ligands on the TOF of the catalyst in this system was then examined by following reaction conversions with various catalysts. In the absence of both Ph_2-BINOL and diamine ligands, the reaction of diethylzinc with benzaldehyde is very slow, exhibiting about 1% conversion after 8 h at 0 °C. When Ph_2-BINOL was employed in the asymmetric addition to this substrate, the catalyst TOF increased exhibiting 25% conversion after 2 h. To evaluate the TOF of zinc centers bearing diimine derived from ethylene diamine and 2,4,6-trimethylbenzaldehyde (Table 4, entry 5) or the *meso* diamine (Table 5, entry 7), these ligands were combined with diethylzinc and benzaldehyde (no added Ph_2-BINOL). After 2 h it was determined that the reaction with the diimine proceeded to 20% conversion. The reaction with the *meso* diamine was 51% complete in 2 h. Use of Ph_2-BINOL with the diimine or *meso* diamine resulted in a considerable increase in the TOF, with both reactions reaching completion in under 15 min.[59] These observations indicate that the achiral ligands have a great impact on the catalyst reactivity as well as the catalyst enantioselectivity.

The catalytically active species in these asymmetric addition reactions are believed to be 4-coordinate (Ph_2-BINOLate)Zn(diimine) and (Ph_2-BINOLate)Zn(diamine) complexes. Support for this hypothesis was gained by synthesis and structure determination of the (Ph_2-BINOLate)Zn(diamine) incorporating the *N,N′*-di-*tert*-butyl diamine. The structure of this compound is illustrated in Figure 18. This catalyst likely coordinates the aldehyde substrate generating a 5-coordinate zinc species with an activated aldehyde. Addition of the ethyl group from $ZnEt_2$, possibly by a pathway that involves coordination of the $ZnEt_2$ to a BINOLate oxygen, results in product formation.

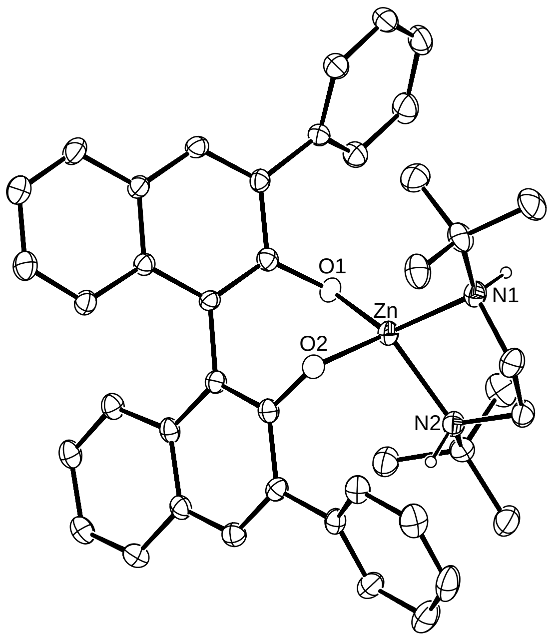

Figure 18 Structure of (Ph_2-BINOLate)Zn(diamine). The diamine nitrogens have the expected (*R*,*R*)-configurations

In this study of catalyst optimization with achiral and *meso* ligands, a single chiral ligand, (*S*)-Ph_2-BINOL, was employed and led to enantioselectivities between 96% (*R*) and 76% (*S*).[59] This study definitively demonstrates that asymmetric catalysts can be optimized by screening achiral and *meso* ligands. This approach can be adapted to other asymmetric catalysts and holds great promise in asymmetric catalysis.

3.7.2 *Use of achiral additives without chiral conformations*

The addition of achiral additives lacking chiral conformations to asymmetric catalysts can enhance catalysts enantioselectivity.[62] The exact nature of the interaction between the additive and the chiral catalyst, however, is often not clear. The additives usually contain Lewis basic groups, and can behave as ligands by coordinating to catalysts and changing the metal geometry and/or catalyst aggregation state.

A remarkable example of the impact of achiral ligands on an enantioselective process involved a (BINOLate)Yb-based system.[63,64] In this study, a Lewis acid catalyst was prepared by reacting $Yb(OTf)_3$ with BINOL, followed by addition of two equivalents of *meso*-(1,2,6)-trimethylpiperidine (Figure 19). A speculative structure of the resulting catalyst is illustrated. This complex was found to be an excellent catalyst for the asymmetric Diels–Alder reaction of 3-acyl-1,3-oxazolidin-2-ones with cyclopentadiene (Figure 20).

During this study, the authors noted that aging of the catalyst in the absence of substrate resulted in a decrease in the enantioselectivity in the Diels–Alder reaction. Aging the catalyst in the presence of the substrate, however, provided the most enantioselective catalyst. These results suggested that the substrate stabilized the catalyst. The authors then examined the ability of various substrate-like additives to stabilize the catalyst. It was found that some additives not only stabilized the catalyst, but also impacted the catalyst enantioselectivity. When 3-acetyl-1,3-oxazolidin-2-one was used as additive the endo (2*S*,3*R*)-product was formed with 93% ee. In contrast, acetylacetone derivatives led to a reversal of the facial selectivity. Using the additive 3-phenylacetylacetone as the additive resulted in formation of the (2*R*,3*S*)-product in 81% enantioselectivity. In both instances, the configuration of the chiral ligand was the same: (*R*)-BINOL. A similar reversal of enantioselectivity with these additives was observed when other substrates were employed.

The achiral additives likely bind to the catalyst in a bidentate fashion, and in doing so change the chiral environment around the substrate-binding site. This example illustrates the potential impact that additives can have on catalytic asymmetric reactions.

3.7.3 *Metal Geometry-Induced Ligand Asymmetry*

Ligand binding modes can play an important role in the enantioselectivity of a catalyst. Some ligands are symmetric in certain metal geometries, but become asymmetric when the metal binds to an additional ligand. This property can be particularly useful in asymmetric catalysis if the achiral ligand adopts an asymmetric binding mode upon coordination of the substrate. Under these circumstances the achiral ligand can impact the chiral environment of the catalyst, changing the

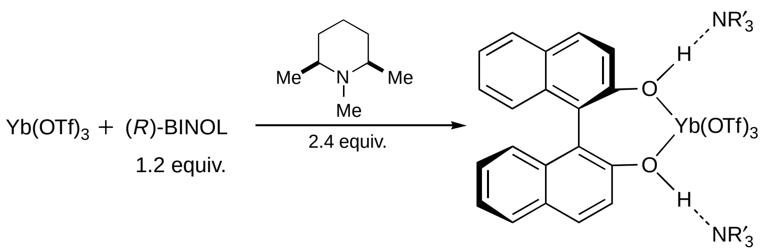

Figure 19 Preparation and proposed structure of chiral Yb(III) triflate Lewis acid

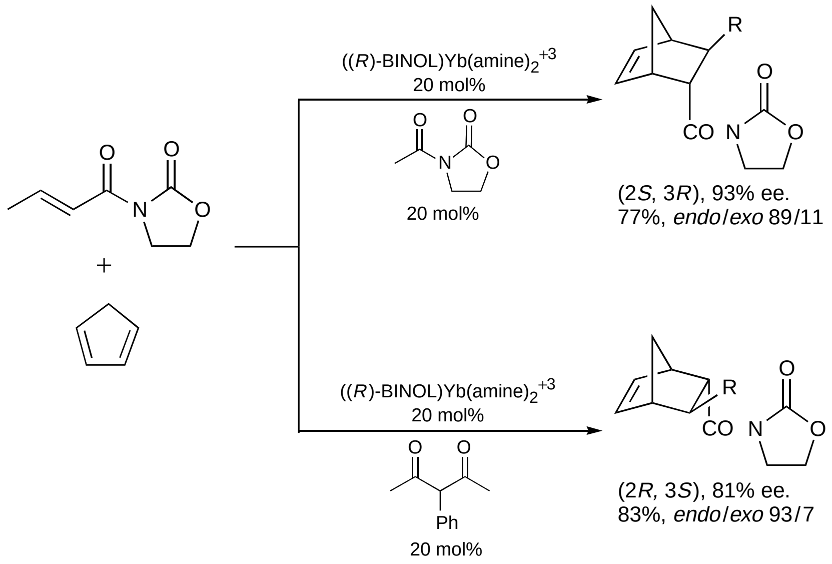

Figure 20 Asymmetric Diels–Alder reaction with achiral additives

enantioselectivity. An example of such a system is illustrated in the following paragraphs.

Compounds of the type (MBP)TiX_2 (MBP = methylene bis(phenoxide) and X = Cl, Figure 21) are achiral, because they possess a plain of symmetry. Upon coordination of a Lewis basic ligand L, however, a 5-coordinate (MBP)TiCl_2 (L) complex is generated. The apical and equatorial oxygens may be inequivalent by virtue of their binding sites (Figure 21). As a result, the (MBP)Ti metallocycle is chiral and (MBP)TiCl_2 (THF) exists as a racemic mixture.[65]

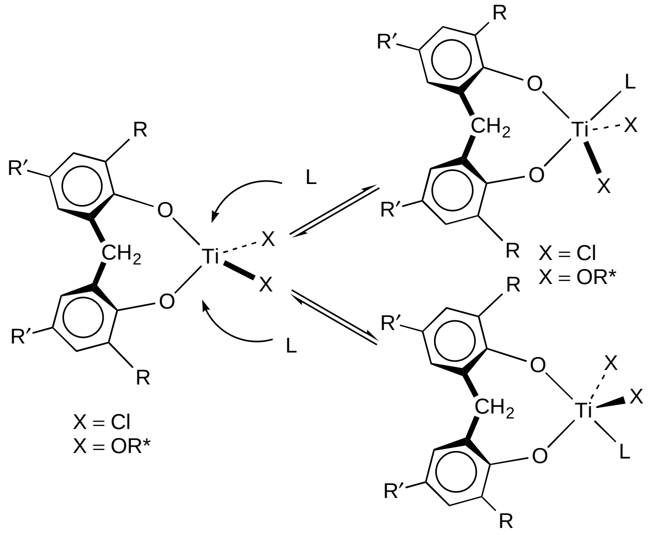

Figure 21 When X = Cl, L = THF two enantiomeric 5-coordinate titanium centers are possible. When X = OR* and L = aldehyde substrate, diastereomeric 5-coordinate titanium complexes may form

The objective of this study was to use the chirality of the (MBP)Ti metallocycle in the trigonal bipyramidal geometry to bias the chiral environment of an enantioselective catalyst. Theoretically, if it were possible to replace the THF in one of the enantiomers of (MBP)TiCl_2(THF) for a substrate, the (MBP)Ti metallocycle would provide a chiral environment for the substrate. Attack on the bound substrate by an achiral reagent would generate a non-racemic product. Substitution of chiral, enantioenriched ligands for the chlorides would cause the configuration of the (MBP)Ti metallocycle to be biased. If the biasing of the enantiomeric forms of the (MBP)Ti metallocycle is efficient, this metallocycle might adopt a single enantiomeric form (Figure 21). In this study, readily available chiral alkoxide ligands were used to introduce asymmetry into the catalyst.

A series of achiral derivatives of MBP-H_2 (20 mol%) were used with Ti(OR*)$_4$ derived from the (*S*)-enantiomer of 1-phenyl-1-propanol in the asymmetric addition to aldehydes (Figure 22). The results of this study are compiled in Table 6. Inspection of the enantioselectivities using various (MBP)Ti-derivatives clearly illustrates that addition of different achiral MBP ligands can have a significant impact on the ee of the product [9% (*R*) to 83% (*S*)]. MBP-H_2 ligands with small R groups were found to be less enantioselective. Nonetheless, when R = H (entries 1 and 2, Table 6), the catalysts exhibited significant differences in enantioselectivity from that of the background reaction in entry 10 [9% ee (*R*) vs. 39% ee (*S*)]. In this example, the background reaction is promoted by the chiral alkoxide complex Ti(OR*)$_4$. Increasing the bulk of the MBP ligand to R = *t*-Bu resulted in an increase in enantioselectivities (entries 6–8). A further increase in ee was observed when R = adamantyl (83% ee, entry 9). Thus, modification of the achiral MBP ligand

resulted in a change in ee of over 90% between entries 2 and 9.

As shown in this example, substrate binding may increase the number of stereochemical elements in a catalyst. In these investigations, it is proposed that a change in metal geometry from tetrahedral to trigonal bipyramidal on coordination of a substrate can induce chirality in the (MBP)Ti metallocycle (Figure 21). Once in an asymmetric binding mode, the (MBP)Ti moiety can contribute to, or even dominate, the relay of asymmetry to the substrate. The asymmetry of the bound MBP ligand is illustrated in the ORTEP diagram in Figure 23. An *N*,*N*-dimethylamine plays the role of a substrate analog in this example. The principle of geometry-induced ligand asymmetry can be applied to optimization of other asymmetric catalysts.

3.8 Combinatorial Methods for Catalyst Generation

Combinatorial chemistry has been successfully employed in the search for new drug candidates, and has had a significant impact on the pharmaceutical industry. High throughput strategies allow the simultaneous generation of many compounds. The idea of using such methods for the synthesis and screening of chiral ligands and catalysts is an attractive, yet formidable challenge. Three issues to be

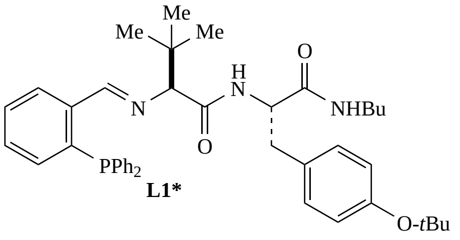
considered in designing catalyst systems for high throughput screening are (1) sources of diversity, (2) catalyst synthesis, and (3) catalyst screening.[66]

Modular ligands and catalysts are ideal for high throughput screening. They are composed of subunits that can be easily interchanged to generate large numbers of catalysts with a wide range of steric and electronic properties. In metal-based catalyst, the metal can also be varied, providing additional diversity.

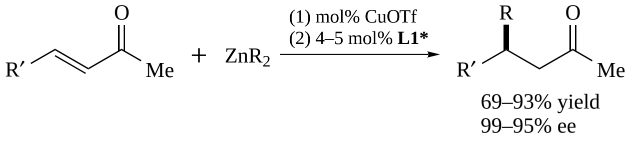
One of the requirements of this approach is that catalyst synthesis must be accomplished with clean, high-yielding reactions to avoid time-consuming purification steps. This requirement often limits the classes of ligands and catalysts that are amenable to high throughput methods.

Assaying the enantioselectivity and activity of individual catalyst is often the most difficult and time-consuming aspect of high throughput screening. Most reports involve screening each catalyst individually

Ligands incorporating amino acids fulfill these guidelines and have been used to develop highly enantioselective catalysts for several reactions. A series of peptide-based catalysts for the asymmetric conjugate addition of organozinc reagents to enones has been reported. Closely related ligands derived from dipeptide phophine ligands have been shown to give excellent enantioselectivities for cyclic enones[67] (equation 12) and acyclic enones.[68] However, these ligands were not optimal in the conjugate addition of trisubstituted enones.[69]



L1*



(12)

In developing new ligands for these substrates, the points of diversity are the amino acid residues (AA1 and AA2), the substituents on the phosphine and the metal center (Table 7). Each of these subunits can be varied, leading to a large number of catalysts. Variation of the amino acids was explored, because peptidic systems can be easily prepared in parallel by solid phase protocols. As shown in Table 7, ligand **L1*** which was successfully used with cyclic enones (equation 12) gave 85% ee. Substitution of *tert*-leucine for valine led to a decrease in enantioselectivity and a significant loss in efficiency (**L2***). Surprisingly, substitution of an achiral

98

glycine for the phenylalanine in both **L3*** and **L4*** resulted in an increase in enantioselectivity in each case. Dropping that amino acid residue resulted in the optimal catalyst in this study.

As seen in Table 8, the resulting catalyst system gave excellent enantioselectivities with a range of enones and dialkylzinc reagents.

This example illustrates how screening peptide-based ligands can be useful in the development of catalysts. These catalysts could not be rationally designed based on related ligands or understanding of the mechanism. Related nonmetal-based catalysts employing peptide-based ligands have also been optimized using these techniques. These studies employed large libraries of compounds.[70]

4 FINAL PERSPECTIVE

This brief summary of alternative approaches to asymmetric catalysis is not meant to be complete or comprehensive. There are many excellent examples that could have been included in this work and would have served equally as well. Nonetheless, the goal of this section is to expose the reader to concepts in catalyst design and optimization that have not been extensively explored and to inspire those interested in pursuing investigations in this area to take a nontraditional approach.

Glossary

Barbier reaction: reaction of an organic halide with a substrate and metal
Grignard reaction: reaction of a preformed organometallic solution
Grignard reagent: in this article, will refer to the solution prepared by reaction of an alkyl halide with magnesium metal, without implication as to molecular species actually present

1 INTRODUCTION

Victor Grignard found in 1900 that solutions of organomagnesium halides may be prepared easily by the reaction of an organic halide with magnesium metal in diethyl ether, and that these solutions undergo useful reactions with many kinds of substrates.[1] This discovery ushered in a new era in organometallic chemistry and provided chemists with a powerful and versatile reagent for synthesis of a wide variety of organic and organometallic compounds. Along with lithium, magnesium remains almost unique among the metals in its ability to react directly and conveniently with a wide variety of organic halogen compounds to produce an organometallic reagent.

The most prominent chemical property of organomagnesium compounds is their ability to deliver an *effectively* 'anionic' organic group (alkyl, aryl, vinyl, etc.) with *Nucleophile* or base properties. As nucleophilic alkylating reagents, their important reactions include nucleophilic displacement of less basic leaving groups from saturated carbon atoms or other elements, addition to carbonyl groups and other unsaturated functions, and nucleophilic substitution at the acyl group of carboxylic acid derivatives. They also can transfer an electron as a reductant.

In contrast, organoberyllium compounds are not as easily prepared by direct reaction of beryllium metal with organic substrates. They are less nucleophilic than their magnesium congeners, and have not found a unique niche in organic or organometallic synthesis. The high toxicity of beryllium and its compounds is likely responsible for the latter. There is, however, a substantial body of interesting chemistry, and it is useful to contrast the chemistry of magnesium compounds with their lighter analogs. Indeed, synthetic beryllium research is currently experiencing a revival, after decades of little activity. Important new work on substituted beryllocenes, as well as the advent of beryllium–silicon chemistry are discussed in Sections 6.4 and 6.7, respectively.

The classic monograph of Kharasch and Reinmuth,[2] with its voluminous tables, is still a useful source of information on organomagnesium chemistry. General surveys have appeared in 'Comprehensive Organometallic Chemistry',[3–5] in 'The Chemistry of the Metal–Carbon Bond',[6] and elsewhere.[7] Especially noteworthy are two recent compilations that cover virtually every aspect of Grignard chemistry.[8,9] The most recent surveys of organoberyllium chemistry are in 'Comprehensive Organometallic Chemistry II',[10] and the dedicated volume of the Gmelin series.[11] Details not explicitly referenced may also be found in these general reviews; reviews pertinent to limited aspects are referenced in relevant locations herein. In the case of serial compilations, the latest edition is generally cited.

2 BONDING AND STRUCTURE

Beryllium and magnesium have a formal oxidation state of $+2$ in their compounds (*see Oxidation Number*); other oxidation states appear to exist only as transient reaction intermediates. Therefore, organometallic compounds of general formula R_2M and RMY may exist, in addition to the nonorganometallic MY_2.

Though conceptually simple, monomeric unsolvated R_2M or RMY species are infrequently encountered. The metal center is a Lewis-acidic site with a strong tendency to coordinate basic solvents or ligands (*see Lewis Acids & Bases*). Grignard reagents are most commonly made in ether, and it is frequently impossible to drive off all of the solvent without thermal decomposition. R_2Mg compounds are more easily freed of ether by heating under vacuum, but R_2Be may remain solvated even in the vapor phase. In competition with solvation, the metal centers may also be linked into dimers or higher polymers by bridging ligands 'Y^-', or by organic groups which

bridge via electron-deficient multicenter bonds (*see Electron Deficient Compound* and *Multicenter Two-electron Bonding*). In any given instance, the actual structure, degree of association, and coordination number of the metal will be a function of the basicity of the solvent, the coordinating/bridging tendencies of the Y^- and organic groups, the acidity of the metal center (as influenced by the electronegativities of the attached groups), and the steric requirements of the various components (*see* ***Coordination Numbers & Geometries***). In general, THF (tetrahydrofuran) is more basic and less bulky than Et_2O, $(i\text{-Pr})_2O$ coordinates less strongly, and *Chelating Ligands* bind strongly. F^- and Cl^- bridge more effectively than the higher halides, and among organic groups, methyl and alkynyl are good bridging groups (Me_2Mg is reported to crystallize solvent-free from diethyl ether).

Recent reviews have surveyed X-ray and electron diffraction structures of organomagnesium compounds[12,13] (*see* ***Diffraction Methods in Inorganic Chemistry***); literature citations for both metals are also included in other reviews.[4,8,9]

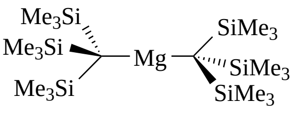
2.1 The Metal-to-carbon Bond

The electronegativities of beryllium and magnesium on various scales lie in the vicinity of 1.6 and 1.35, respectively, substantially less electronegative than carbon at about 2.55 (*see Electronegativity*). Simple C–Be and C–Mg bonds should therefore be quite polar, with Pauling 'ionic characters' of about 20 and 30% respectively (*see Ionic Character*). Molecular orbital calculations (*see* ***Molecular Orbital Theory***) also indicate highly polar, perhaps essentially ionic, C–Mg and C–Be bonds, though specific conclusions vary depending on the basis set, type of calculation, and the interpretation.[14–17]

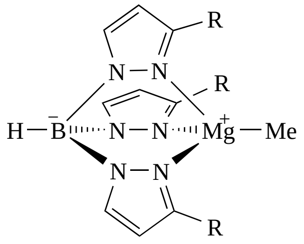
Thermochemical data on organoberyllium and -magnesium compounds are not very extensive. A number of enthalpies of formation for Grignard reagents have been determined via measurement of their heats of hydrolysis,[18,19] and bond dissociation energies have been measured for Np_2Mg.[20] An attempt has also been made using theoretical calculations in combination with experimental data to develop a set of consistent *Bond Energies* for lithium, beryllium, and magnesium compounds.[21]

2.2 Unsolvated Monomers

Several magnesium and beryllium compounds, including Cp_2Mg, $Cp^*{}_2Mg$, Cp(Np)Mg, Np_2Mg, $MgBr_2$, MgI_2, Cp(Me)Be, Me_2Be and $(t\text{-Bu})_2Be$ have been studied in the gas phase. All have the linear geometry predicted for sp *Hybridization* at the metal, as do the extremely hindered (**1**), as well as $(tert\text{-Bu}_3Si)_2Be$ (Section 6.7), in the crystal. C–Mg and C–Be *Bond Lengths* are 211.6–212.6 and 169.8–170.6 pm, respectively. Some [tris(pyrazolyl)hydroborato]metal derivatives (*see Tris(pyrazolyl)borates*) are unsolvated monomers, with approximately tetrahedral geometry about the metal (e.g. (**2**); C–Mg, 212 pm; C–Be, 170.8).[8] Certain β-diketiminateMgR complexes are also monomeric, and exhibit a trigonal planar coordination geometry for magnesium when R is sterically demanding (e.g. R = t-Bu).[22]



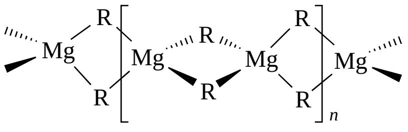
(**1**)



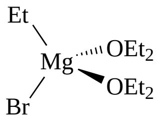
(**2**)

2.3 Solvent-free Aggregates and Polymers

Solid unsolvated Me_2Be, Me_2Mg, and Et_2Mg have polymeric linear chains of metal atoms linked by bridging alkyl groups (**3**) oriented in a distorted tetrahedron around the metal. The bond distances (C–Mg, 224 and 226 pm; C–Be, 193 pm) are longer than in the monomer, since one-electron pair is shared between two bonds in the electron-deficient bridge. The M_2C_2 rings have small angles at the carbon (75°, 72°, and 66°) that maximize overlap of the single carbon orbital with orbitals on the two metal atoms. Higher homologs are usually associated as dimers or small oligomers in noncoordinating solvents, and mass spectra indicate some association of alkylberylliums even in the gas phase. Ph_2Mg also crystallizes in polymeric chains with the phenyl rings perpendicular to the chain direction (C–Mg, 226 pm). Magnesium acetylides containing a cubic $Mg_4(\mu_3\text{-C})_4$ core have recently been prepared; they are the first MgR_2 compounds to exhibit this typically 'organolithium-type' structural motif.[23]



(**3**)



(**4**)

2.4 Solvated or Coordinated R_2M and RMX Monomers

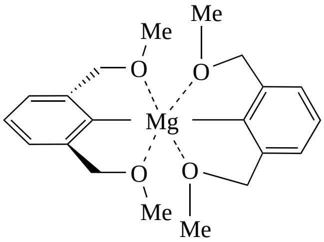
Additional coordination sites in the monomer may be occupied by solvent molecules. Besides solvation by ethers, complexes with a variety of other donors have been studied in solution or isolated, and a number of crystal structures have been reported. Among oxygen ligands, HMPA (hexamethylphosphoramide) is especially basic. In general, nitrogen as a ligating atom is more basic than oxygen, though frequently more hindered, and sulfur is weaker. The chelating diamine TMEDA (tetramethylethylenediamine) is particularly noteworthy for forming stable, monomeric, and often sublimable crystalline complexes. Potential ligands such

as water or ammonia, with acidic hydrogens, react to cleave the C–M bond, but there is evidence for the existence of complexes of alkylberyllium compounds with ammonia and amines at low temperatures, and complexes of $(PhC{\equiv}C)_2Be$ with primary amines have been isolated. Comparing metals, the larger size of Mg (1.4 Å) can allow a higher coordination number than for Be (1.12 Å); compare $[Mg(Mesityl)_2(THF)_2]$ with $[Be(Mesityl)_2(Et_2O)]$.

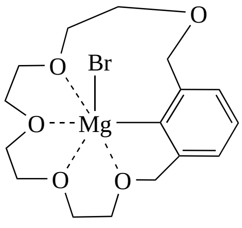
Coordination of two ether or other ligand donors with approximately tetrahedral geometry is most common, and the crystal structure (**4**) probably represents the 'typical' Grignard reagent. Similar coordination of R_2Mg (e.g. $Ph_2Mg(THF)_2$) and R_2Be compounds appears likewise to be the norm. The latter also form less crowded (probably) trigonal 1:1 adducts. Ligand electronegativity determines coordination strength, which decrease as: $MX_2 > RMX > R_2M$. In the four-coordinate complexes, the geometries are distorted from tetrahedral; the C–Mg–C or C–Mg–X angle is usually greater than that expected for tetrahedral geometry, probably reflecting a tendency toward sp hybridization. C–Mg bond distances are mostly in the range 213–219 pm (occasionally up to 234 pm with bulky ligands). Mg–Br and Mg–Cl lengths are 2.44–2.51 and 2.33 pm; Mg–ligand distances are 203–204 pm for oxygen and 215–224 pm for nitrogen

Octahedral tetraetherates and trietherates, respectively, of $MgBr_2$ and MeMgBr with THF have been isolated. $MgI_2(THF)_3$ approximates a trigonal bipyramid, while the cation of $[MgI(THF)_5][I_3]$ assumes a distorted octahedron.[24]

Some unusual coordination numbers and distorted geometries have been found in complexes with *Crown Ethers*, other polyethers, and cryptands (*see Cryptands & Cryptates*), and in organomagnesium compounds with internally coordinating ether or crown ether side-chains. Two examples are (**5**) and (**6**). In crown ether complexes of Et_2Mg and Ph_2Mg, a linear R_2Mg molecule is threaded through the cavity of the crown ether. Other cases of either lower or higher (e.g. (**7**)) coordination numbers are known.



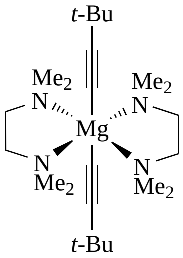
(**5**)



(**6**)

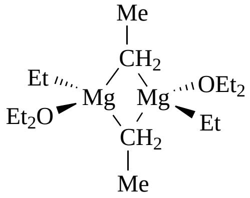
2.5 Species Associated via Solvent or Other Ligands

Colligative property measurements imply that R_2Mg compounds are monomeric up to high concentrations in the

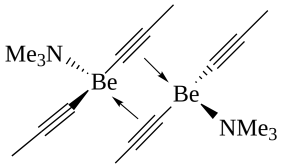


(**7**)

more basic THF, partially associated at higher concentrations in diethyl ether, and associated above the dimer stage in diisopropyl ether.[25] Me_2Be in diethyl ether is monomeric, but oligomeric species exist in dimethyl sulfide, and a series of complexes may be formed with dimethyl ether. Association is probably via M–C–M bridges, as in the proposed centrosymmetric dimer structure (**8**) of $[Et_2Mg(OEt_2)]_2$. Crystals of $(p\text{-tol})_2Mg$ from THF contain both monomeric units and dimers similar to (**8**); the dimer structure (**9**) has bridging which is not electron deficient.[10]



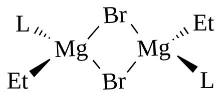
(**8**)



(**9**)

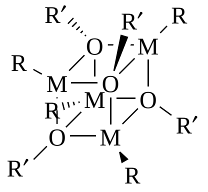
Halide is usually better at bridging than alkyl. RMgCl, RMgBr, and RMgI are monomeric in THF, but the fluoride is a dimer. In Et_2O the fluorides and chlorides are dimeric; bromides and iodides are monomeric in dilute solutions, with apparent association of 2–4 in concentrated solution.[25] (However, an IR/Raman study concluded that EtMgBr is monomeric to high concentrations.[8]) The doubly halide-bridged structure (**10**) for $(EtMgBrL)_2$ (L = $i\text{-}Pr_2O$ or Et_3N) is probably typical for dimers. The Mg_2Br_2 unit is nearly square, with Mg–Br distances slightly longer than in the monomers. The C–Mg bonds (209 and 218 pm) and the bonds to the ligands are similar to the monomers. However, it is likely that a variety of species may be present in any given solution, and a structure which crystallizes may not predominate in solution. For instance, although EtMgBr is probably associated in concentrated ether solution, the crystals consist of monomers. Spectroscopic analysis of an EtMgCl etherate at low temperature indicate both bridging and terminal ethyl groups, and crystals separating from a THF solution have a cluster structure of composition $[EtMg_2Cl_3(THF)_3]_2$ with five- and six-coordinate magnesium.

Other 'Y^-' groups can also be bridging. Numerous RBeOR′ and RBeSR′ compounds have been isolated. Unsolvated

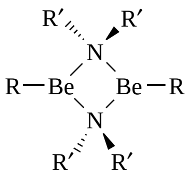


(**10**)

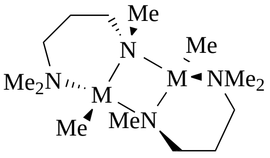
tetramers are common; $(MeBeOSiMe_3)_4$ has the 'cubane' structure (**11**), and other Be and Mg tetramers are probably similar. Other degrees of association (dimer, trimer, polymer) are found. Solvated $RMgOR'$ and $RMgSR'$ complexes are often dimeric. Coordinated solvent is lost more easily from $RMgOR'$ than from analogous Grignard reagents. Dialkylamido groups also bridge strongly. Unsolvated compounds $RMNR'_2$ tend to form dimers and trimers (Be), probably with tricoordinate metal as in (**12**). Solvated monomers, dimers, and polymeric aggregates have been demonstrated. An internally coordinated dimer (**13**) is formed in the reaction of R_2M with $MeNHCH_2CH_2NMe_2$.



(**11**)



(**12**)



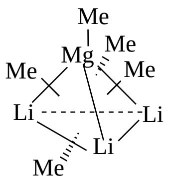
(**13**)

Organomagnesium hydrides (RMgH) with THF solvation are stable. They form dimeric and oligomeric structures associated through bridging hydrides.

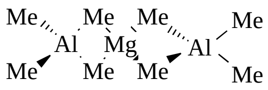
2.6 Ate Complexes

Coordination of an anionic ligand to the metal of R_2M or RMY produces a complex with a negative *Formal Charge* on the metal: an ate complex (*see Ate Complexes*). Et_2Be forms a number of complexes with the stoichiometry $M(Et_2Be)_2Y$, where M is an alkali metal or quaternary ammonium ion, and Y is Cl, F, or SCN. The anion Y^- may form a single bridge between two Et_2Be molecules. Other stoichiometries and ligands are also reported.

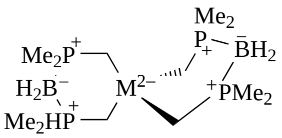
The reaction of two organometallic compounds may also form an ate complex. For example, PhLi and Ph_2Mg react to form $LiPh_3Mg$ and Li_2Ph_4Mg, while $Li[(t\text{-}Bu)_3Be]$ is formed from $(t\text{-}Bu)_2Be$ and $(t\text{-}Bu)Li$. At high ratios of MeLi, both Me_2Be and Me_2Mg form 3:1 complexes Li_3MMe_5. An operational description is that one reactant (the more ionic compound with the more electropositive metal) transfers alkyl anions to the other. Thus the four methyl groups in Li_2BeMe_4 form a distorted tetrahedron around the beryllium, with longer distances to the lithium ions. However, this description is oversimplified. The low-temperature nuclear magnetic resonance (NMR) spectrum of Li_3MgMe_5 has three different methyl resonances, suggesting structure (**14**), related to the MeLi tetramer. Ate complexes with zinc and aluminum compounds also form. Electron-deficient bridge-bonded structures, exemplified by the X-ray structure of (**15**), are generally proposed. NMR studies show rapid intramolecular and intermolecular exchange processes, and equilibrium with the constituent organometallic compounds. Methyl, ethyl, or phenyl has usually been the organic group; bulkier alkyl groups are less inclined to participate. Compound (**16**) is an unusual internal ate complex.[10,11]



(**14**)



(**15**)



(**16**)

Alkali hydride ate complexes also exist, including MR_2BeH, MR_2MgH, and other compositions, although it appears that KR_2MgH compounds are unstable with respect to KR_3Mg and MgH_2[26] Structural features include hydride bridges and electron-deficient bonding to the alkali metal. In a dimer of $NaEt_2BeH$, the bridging hydrides bind also to the ether-solvated sodium atoms. Ate complexes are also formed in reactions with diborane, $NaBH_4$, AlH_3, and $(Li/Na)AlH_4$.

2.7 Disproportionation/Redistribution (Schlenk) Equilibria

In 1929, Schlenk and Schlenk proposed that Grignard reagents should be represented by the equilibrium of equation (1), rather than simply RMgX. Primary evidence was the precipitation of solvated MgX_2 by addition of dioxane to a Grignard reagent solution, leaving dialkylmagnesium in solution. A 1:1 mixture of MgX_2 and R_2Mg has properties identical to the Grignard reagent. The Schlenk equilibrium was apparently discredited for a period of years by a report that radioactive magnesium did not exchange between $MgBr_2$ and Et_2Mg; the redistribution reaction was then envisaged

to yield a $MgX_2 \cdot R_2M$ complex. Subsequently, exchange was indeed demonstrated, and additional evidence has thoroughly confirmed the reality of the equilibrium.[25,27]

$$MgX_2 + R_2Mg \rightleftharpoons 2RMgX \quad (1)$$

Convincing evidence for the Schlenk equilibrium comes from NMR. Chemical shifts of RMgX and R_2Mg are generally different enough to allow the distinction, provided the equilibration rate is slow. Variable-temperature NMR has allowed determination of the equilibrium constant and thermodynamic and kinetic parameters for the exchange in a number of examples.[9,25,27] Additional evidence has come from calorimetry, IR, polarography, and kinetics of reactions in mixtures of various ratios of MgX_2 and R_2Mg. The issues of association (dimerization), solvation, and redistribution have also been addressed by ab initio MO calculations for MeMgX (X = Cl and Br) with Me_2O; the calculational results corroborate conclusions derived from experiment.[28] A similar equilibrium exists with beryllium compounds.

Several useful generalizations may be made.[25] In diethyl ether, RMgX generally predominates quite strongly ($K \sim 50-1000$ at room temperature; $\Delta H^\circ \sim -10$ to $-20\,\mathrm{kJ\,mol^{-1}}$). In THF, the equilibrium constant is deceptively close to the statistical value of 4; however, it results from a substantially positive ΔH° ($10-25\,\mathrm{kJ\,mol^{-1}}$) and a large positive ΔS° ($40-100\,\mathrm{J\,mol^{-1}\,K^{-1}}$). Of the species in the equilibrium, MgX_2 is the most exothermically solvated, and probably has a larger coordination number in THF. Reaction in the forward direction of equation (1) in THF (compared with diethyl ether) would then be more endothermic, but also would increase entropy by liberating solvent molecules. RMgX also predominates in less basic ethers, as well as in triethylamine and HMPA, and for RMgF dimers. Excess MgX_2, often present from formation of the Grignard reagent, would further drive the equilibrium in that direction.

The rate of the Schlenk exchange is slowed by bulky R groups and stronger solvation. For the methyl Grignard reagent, exchange is fast on the NMR timescale except at very low temperatures, but it is slow even at room temperature in THF for *t*-butyl or neopentyl reagents. Exchange probably occurs in a bridged intermediate formed by displacement of a solvent molecule from the monomer. The Schlenk-type equilibrium of RBeX compounds also lies well to the right.

The Schlenk equilibrium also influences the nature of materials which are isolated from solutions. MgX_2 may selectively precipitate, and solids of composition RMg_2X_3 have been obtained. Disproportionation of RMgX may also occur on desolvation, and 'Grignard reagents' prepared in noncoordinating hydrocarbon solvents are generally deficient in halogen because of partial precipitation of MgX_2. Other RMY compounds or their coordination complexes may also disproportionate, for example, etherates of some $RMgSR'$ and $RMgNR'_2$ and some N-coordinated RBeY. RMgF and $RMgOR'$ have little tendency to disproportionate, and the exchange between R_2Mg or R_2Be and an alkoxide is often a useful synthesis for $RMOR'$.[4,10]

2.8 Ionization

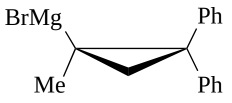
In simple alkyl or aryl organomagnesium compounds, there is no indication of ionization of the carbon–magnesium bond to a carbanion. Ethereal solutions of Grignard reagents have low but significant conductivities, probably from ionization as in equation (2) (or to more highly associated species). In HMPA, ionization is much more extensive. $MgBr_2$ is completely dissociated and EtMgBr is about 30% dissociated to $EtMg^+$ and Br^- ions. Bromine NQR (nuclear quadrupole resonance) studies in the solid state indicate that Mg–Br bonding is essentially ionic. Conductivities of R_2Mg compounds are low, even in HMPA. However, if the R^- ion is delocalized, bonding to the metal will be more ionic, and dissociation may occur (see Sections 6.4 and 6.5).

$$2RMgX \rightleftharpoons RMgX_2^- + RMg^+ \quad (2)$$

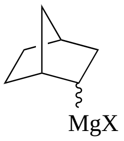
Coordination to a crown ether or a cryptand can also induce ionization. For example, an X-ray crystal structure of the complex between Np_2Mg and 2,1,1-cryptand showed it to consist of R_3Mg^- and cryptand-complexed RMg^+ ions.[8]

2.9 Configurational Stability of the C–Mg Bond

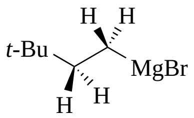
When a Grignard reagent is formed by reaction of an alkyl halide with magnesium metal, the stereochemical configuration at the α-carbon is randomized. Radical intermediates in the formation of the Grignard reagent (see Section 4.2) are held responsible. Very rarely, as in the formation of (**17**), is there incomplete racemization.[8]



(**17**)



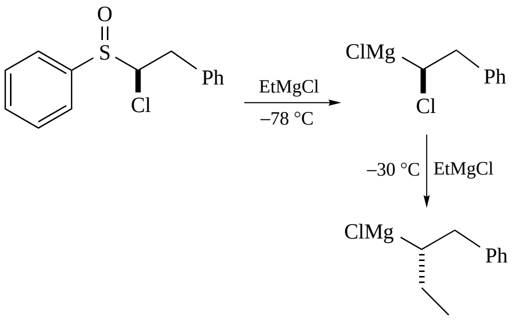
(**18**)



(**19**)

It is also possible for the C–Mg bond to invert configuration after it is formed. If a Grignard reagent can be obtained with one configuration predominant, then conversion to its enantiomer or diastereomer might be observed during a period of standing or heating. The extreme configurational stability of (**17**) (no racemization in 30 min at 120 °C) is attributed

to the strain of a planar carbon in the three-membered ring. Interconversion of the diastereomers of (**18**) is also measurably slow.[29] The faster inversion rates of primary C–Mg bonds may be studied by NMR lineshape techniques. The α-hydrogens of (**19**) are magnetically nonequivalent, but are interconverted by inversion of configuration.[8] The rate is second order in monomeric organomagnesium, faster in diethyl ether than in THF, and faster for Cl^- than Br^-. These observations are consistent with a mechanism in which inversion occurs during transfer or exchange of the alkyl group between magnesiums. Inversion is much slower than the total rate of exchange, which occurs predominantly with retention. Recently, stereospecific exchange of the sulfoxide of an enantiomerically pure α-chloroalkylsulfoxide for a magnesium, and subsequent carbenoid homologation (a reaction step that avoids free radical intermediates) has been used to prepare a chiral (93% enantiomeric excess), non- α-heteroatom stabilized Grignard reagent, (**20**) (equation 3). (**20**) is generated as one component of a mixture of Grignard reagents and sulfoxides, and racemizes with a half-life of five hours at $-10\,°C$.[29]



(3)

(**20**)

3 SPECTROSCOPY

A variety of spectroscopic techniques has made invaluable contributions to understanding the structure and reactions of organoberyllium and -magnesium compounds. In this section, general spectroscopic features will be discussed, but their applications will not be detailed.

3.1 Nuclear Magnetic Resonance[4,8,11]

In ^1H NMR (*see Nuclear Magnetic Resonance*), the most characteristic feature of an organomagnesium compound is the high-field position of the protons α to the magnesium. This resonance is at $\delta - 1.5$ or higher for methyl Grignard reagents, and in the vicinity of 0 ppm for secondary ones. R_2Mg resonate at higher field than RMgX, (coordination by base also produces an up-field shift), while R_3Mg^- species resonate at higher field still. The α-hydrogens of alkylberyllium compounds absorb at similarly high fields.

The ^{13}C resonance of the α-carbon of an organomagnesium compound is also shifted to high field, but not so distinctively. A substantial body of data has been tabulated,[30–32] and correlation equations have been given which are reasonably successful at predicting α-, β-, and γ-shifts based on those of the corresponding hydrocarbon.[33,34] In an aryl- or vinylmagnesium compound, the sp^2 α-carbon resonance appears at quite low field (164 ppm for PhMgBr); ortho carbons and the central carbon of the allyl group in allylmagnesium bromide are also deshielded.

Although quite broad, ^{25}Mg resonances of organomagnesium compounds have been reported.[35] The shift is sensitive to solvation and ligand electronegativity, and resonances for the Schlenk equilibrium species have been reported. Beryllium-9 NMR spectra are more informative than those of ^{25}Mg.[36] In addition to a broader chemical shift range, a much smaller quadrupole moment makes for narrower line widths, allowing observation of couplings with other elements (e.g. ^1H, ^{13}C, ^{11}B, ^{19}F, ^{29}Si, ^{31}P).

3.2 Vibrational Spectroscopy[4,8,10]

C–Mg stretching frequencies typically appear in the IR spectrum in the range $360-650\,cm^{-1}$. R_2Mg and RMgX species can be distinguished. Mg–X vibrations in the lower frequency ranges have also been identified. Vibrational assignments have also been made for alkyl- and halogen-bridged associated species. The C–Be stretching frequencies of Me_2Be and $(t\text{-Bu})_2Be$ have been assigned as 1081 and $450\,cm^{-1}$. Bridging and terminal hydrogens in RBeH fall at about 1310–1350 and $1800\,cm^{-1}$, and the Mg–H stretching frequency (probably bridging) is at $1250-1300\,cm^{-1}$. IR studies of matrix-isolated (nonsolvated) MeMgX monomers now include all the halides (X = F–I), but peak intensities are weak, and correspondence with calculated spectra remains poor.[14]

3.3 Electronic Spectra[4]

Saturated organomagnesium compounds do not generally have a maximum in the near UV region, although in solutions a tail from shorter wavelength bands extends to 250 nm. Periodic reports of a maximum in some samples could result from charge transfer. Aryl Grignard reagents have an absorption around 250 nm, of greater intensity than the 'benzenoid' bands of simple aromatic compounds, and a solvent-dependent shoulder to longer wavelength.

3.4 Mass Spectra[4,10]

Because of the limited volatility of most organomagnesium and -beryllium compounds, there have been fewer mass spectrometric data reported. With Cp_2Mg, positive and negative fragment ions from cleavage of the metal–ring bonds are observed. Mass spectra of Me_2Be vapor show the presence

of associated species with up to eight Be atoms, and associated species are also seen in the spectra of Et_2Be and Ph_2Be.

4 PREPARATION

4.1 Direct Reaction of Organic Halogen Compounds with the Metal

The classical method for formation of a Grignard reagent, as originally described by Victor Grignard in 1900, is the reaction of an organic halide in ether solution with magnesium metal (equation 4). Typically, this is an exothermic reaction but, as a heterogeneous process, one which may not start immediately. The Grignard reagent is sensitive to moisture and oxygen.

$$RX + Mg \longrightarrow RMgX \qquad (4)$$

In the customary procedure, the magnesium is placed in a dried apparatus under an inert atmosphere of nitrogen or argon. The magnesium may be activated (if necessary), and a small portion of the halide is added to initiate the reaction in concentrated solution. The remainder of the halide in more dilute solution is added at a rate sufficient to maintain the desired temperature (often reflux). Cooling may be needed to moderate the reaction after initiation. Stirring or heating is often continued longer to assure complete reaction, and in the case of less-reactive halides it may be necessary to heat throughout an extended reaction period. Commercial magnesium turnings sold specifically for Grignard reagents are usually satisfactory, and the reaction frequently starts vigorously with gentle warming after a short induction period. Carefully dried solvents improve ease of formation and minimize loss of the reagent by hydrolysis.

The solution so obtained is usually used directly in synthetic applications, frequently without even separation from excess magnesium. Otherwise, the reagent may be transferred by syringe, cannula, or decantation and filtration, or modified by replacement of the solvent or addition of other reactants or catalysts.

The magnesium is critical to the success of a Grignard reagent preparation. An oxide film or other surface blockage may cause an induction period by excluding halide from the underlying magnesium surface. There are numerous recipes for activation, which apparently remove or break through this film. Physical activation may be achieved by crushing or grinding the magnesium turnings or prolonged stirring without solvent.[8,9] Sonication helps remove absorbed water, shortens the induction period, and increases the subsequent rate.[8,9] Variously recommended chemical activation pretreatments[8,9] include heating dry with a small amount of iodine, stirring with a preformed Grignard reagent solution, or reaction with one of a variety of activating reagents, for example, Br_2, $AlBr_3$, $Si(OEt)_4$. The magnesium may then be washed with fresh solvent. Formation of a difficult Grignard reagent may be helped by entrainment: carrying out the reaction in admixture with a reactive halide. 1,2-Dibromoethane is often preferred, as it affords only ethylene and $MgBr_2$. Impurities in the magnesium, amalgamation, or transition metal salts may be activating, but may also decrease the yield or affect subsequent reactions. For mechanism studies, extremely high purity magnesium obtained by sublimation or zone refining may be used.

A number of specially reactive forms of magnesium have been used to reduce induction periods, and also for unreactive halides or low reaction temperatures. They include metal slurries made by reduction of a magnesium salt by potassium or lithium metal ('Rieke' magnesium), lithium naphthalene, or potassium-intercalated graphite, and finely divided metal produced by condensation of magnesium vapors in an organic solvent.[8] The anthracene–magnesium complex (see Section 6.3) may be used in stoichiometric amount as a magnesium source or as a catalyst, or pyrolyzed to deposit a reactive magnesium residue.[8,9]

The most common solvents for preparation of Grignard reagents are diethyl ether and THF. The latter is especially useful for making Grignard reagents from aryl and vinyl halides, particularly the relatively unreactive chlorides. A number of other ethers (e.g. butyl, isopentyl, anisole), HMPA, and tertiary amines have also been used. Although a coordinating solvent is generally needed for their facile formation, it is possible to prepare many Grignard reagents in hydrocarbon solvents in the presence of a molar (or less) equivalent of coordinating base: 1M toluene solutions have been prepared.[37] The degree of solvation of a Grignard reagent influences its reactivity, a phenomenon that will be briefly described here. Additions of Grignard reagents to ketones and nitriles, ligand substitution with alkoxysilanes, and oxirane ring openings proceed faster in less-nucleophilic ethers; rates decrease in the order: $t\text{-}Bu_2O > Et_2O >$ THF. Partial replacement of ether by toluene accelerates the rate of reaction of Grignard reagents with hydrazones, 1-alkynes, alkylethoxysilanes (but not with alkylchlorosilanes), and increases the ratio of addition to reduction product (Section 5.6.1) with ketones. These effects are attributed to the greater ease of coordination of substrate to Grignard reagent in solvents of lower solvating ability, although the situation for ketones is more complex.[37,38] Additives or cosolvents, typically bases or unsaturated species, are often used to increase yields or enhance selectivity, especially in reactions mediated by transition metals (see Sections 5.4 and 5.5). The relatively (vs. e.g. HMPA) inexpensive and low-toxicity 1-Methyl-2-pyrrolidinone, NMP, is increasingly popular.

Unsolvated 'Grignard reagents' have also been formed by cocondensation of magnesium vapor with the organic halide at low temperature, and allowing the resulting matrix to warm.[9] Cluster Grignard reagents, $PhMg_4X$, ($X = F$, Cl, Br), theoretically predicted to be stable, have

been similarly prepared, and characterized by MALDI-TOF (matrix-assisted laser desorption/ionization-time of flight) mass spectrometry and elemental analysis. The identities and ratios of hydrolysis/deuterolysis products confirm the presence of Mg–C and Mg–Mg bonds (equation 5). Most recently, room temperature transmetalation reactions in solution have been used to prepare the analogous alkyl derivatives from the phenyl reagents and alkyl halides. This work has implications for the mechanism of Grignard reagent formation (Section 4.2)[39]

$$(C_6H_5)Mg_4X + 7H_2O \longrightarrow C_6H_6 + Mg(OH)X + 3Mg(OH)_2 + 3H_2 \quad (5)$$

Reactivity in Grignard reagent formation varies in the sequence I > Br > Cl > F. Fluorides are particularly unreactive, but Grignard preparation has been reported with metal vapor[39] and matrix-isolation[14] techniques, Mg anthracene, and most efficiently, with 'Rieke' magnesium. Side reactions with iodides, and to a lesser extent bromides, may lower the yield of the reagent.

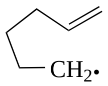
The most common side reactions[8] in Grignard reagent formation are coupling and disproportionation of the organic groups (equation 6). These are particularly prominent with benzylic, allylic, and tertiary halides. They may be the consequence of radical intermediates in the formation reaction or may result from reaction between the organometallic and unreacted halide (see Section 5.5). The latter process is promoted by transition metal compounds. A sizeable excess of magnesium, more solvent, and (for allylic and benzylic) use of the chloride at low temperature in THF are often beneficial. Abstraction of hydrogen from the solvent (or other hydrogen donors) also produces R–H solvolysis products and other radical-derived products. The effects of a number of variables on the formation of reagent have been studied.[8]

$$2RX + Mg \longrightarrow \left\{ \begin{array}{l} MgX_2 + R\text{–}R \\ \text{or} \\ MgX_2 + R(+H) + R(-H) \end{array} \right. \quad (6)$$

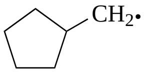
Organic halides also react with beryllium metal to form organometallic RBeX products. The reaction does not appear to be as facile as with magnesium, and may require activation with $BeCl_2$ or $HgCl_2$ or extensive heating. Surprisingly, acyl halides also react with beryllium metal to form acylberyllium halides, RCOBeX (see Section 6.6).

4.2 Mechanism of Grignard Reagent Formation[8,9]

There is considerable agreement that the formation of Grignard reagents involves intermediate radicals.[4,8,9] Evidence includes the trapping of intermediates by radical traps, CIDNP (chemically induced dynamic nuclear polarization) observations, and the occurrence of characteristic radical reactions (equation 6) such as disproportionation, solvent attack, coupling, and isomerization, for example, cyclization of the 5-hexenyl radical (**21**) to the cyclopentylmethyl radical (**22**). The rate of reaction is proportional to the concentration of organic halide in solution and to the surface area of the magnesium. With iodides and more reactive alkyl bromides, for example, cyclopentyl, the rate is affected by mass transport, but other bromides and chlorides react at a rate controlled by chemical processes at the surface.[9,40]

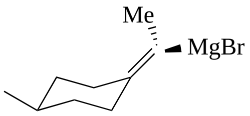


(**21**)



(**22**)

The initial step is heterogeneous electron transfer to the organic halide. In the case of simple alkyl halides, the radical anion so formed decomposes very rapidly into alkyl radical and halide ion. Beyond this point, details of proposed mechanistic schemes vary. Radical pairs [R··MgX] have been proposed, but the multiplet polarization patterns in the CIDNP effect appear to be consistent only with [R··R] pairs,[41] and involvement of radical pairs may only be ancillary to the formation of RMgX. A currently unresolved controversy concerns the nature of the organic radicals. Applying the extensive database on *homogenous* radical chemistry, product distributions for rearranging radicals have been fit to a kinetic model in which the radicals diffuse freely between the magnesium surface and the solution. Reactions leading to by-products compete with reaction of the radicals at the surface to form the Grignard reagent. This 'D-model' ascribes no special properties to radicals on or near the surface. Opposed to this view are a number of observations (comprising the A, for adsorption, model) including the retention of configuration in formation of Grignard reagents (**17**) and (**23**), which seem to require that the radical intermediates behave in a special fashion, presumably because of their association with the surface. The surface-bound radicals are, however, ill-defined. Variations of these models invoke Mg^I intermediates, Mg_n clusters, and radical chain processes as key components of modified mechanisms.[42,43]



(**23**)

Indications that the mechanism of formation of Grignards from aryl halides differs from that of simple alky halides has prompted recent study. Both dianions, ArX^{2-} (X = halogen), and extremely short-lived aryl radicals are proposed as intermediates or transition states.[42,44]

4.3 Formation by Exchange with Previously Formed Organometallic Compounds

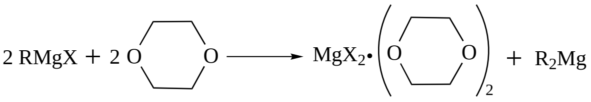
4.3.1 Alkylation of a Beryllium or Magnesium Salt

Exchange generally occurs between the organometallic compound of an electropositive metal and the salt of a less electropositive one. This reaction is effectively a nucleophilic substitution by the organometallic 'carbanion' on the electrophilic metal center, resulting in formation of a more 'ionic' salt and a more 'covalent' organometallic compound. In this method, organoalkali starting materials may serve as the alkyl source. Organolithium compounds are most used because of their synthetic accessibility by routes which do not start with the organic halide. Organoberyllium compounds may also be made starting with Grignard reagents. Illustrative examples are shown in equations (7) and (8). Essentially the same process may be used to replace the halogen of RBeX or RMgX, forming R_2Be or R_2Mg.

$$\mathrm{MeO(CH_2)_4MgX} \xrightarrow[\text{ether}]{\mathrm{BeCl_2}} \mathrm{[MeO(CH_2)_4]_2Be} \qquad (7)$$

$$\mathrm{Ph_3\overset{+}{P}{-}\overset{-}{\ddot{C}}H_2} + \mathrm{MCl_2} \longrightarrow \mathrm{(Ph_3\overset{+}{P}{-}CH_2)_2M2Cl^-} \qquad (8)$$

The Schlenk equilibrium (see Section 2.7) may also be viewed as an example of the same reaction class: one organomagnesium group alkylates the other magnesium. A 'Grignard reagent' may be prepared by mixing R_2Mg and MgX_2 in equimolar proportions; or starting with RMgX, the Schlenk equilibrium serves as a source of R_2Mg compounds. Magnesium halides form complexes with a number of ligands which are considerably less soluble than the other species in the equilibrium, so that nearly quantitative precipitation of the halide occurs, leaving R_2Mg in solution (equation 9). Dioxane was first used for this purpose, but diglyme, pyridine, and other solvents are also useful. The R_2Mg compounds formed in this fashion are likely to contain trace amounts of MgX_2, dioxane or both.



(9)

It should be noted that the same class of reaction, in which the organomagnesium compound serves as the source of the nucleophilic organic group, forms the basis of an important synthetic application in organometallic chemistry (see Section 5.4).

4.3.2 Redox Exchange of Magnesium or Beryllium Metal with Organometallic Compounds

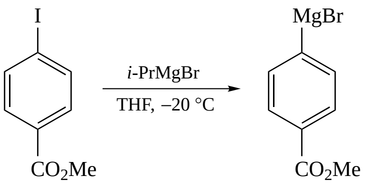
An organometallic compound of a less electropositive metal may also serve as the source of the alkyl group by exchange with a more active metal. This reaction is useful for making R_2Mg compounds from mercury or (less commonly) zinc or silicon alkyls. The product is free of the traces of halide or dioxane which may remain when magnesium halide is precipitated from a Grignard reagent, and in hydrocarbon solvents unsolvated R_2Mg is formed. A modification produces RMgX compounds. Beryllium appears to be less reactive, but does behave similarly. Examples are given in equations (10) and (11).

(10)

$$\mathrm{H_2C{=}C{=}CH_2} \xrightarrow[\text{steps}]{\text{several}} \mathrm{RHg(CH_2)_3HgR} \xrightarrow[\text{THF}]{\mathrm{Mg/MgBr_2}} \mathrm{BrMg(CH_2)_3MgBr} \qquad (11)$$

4.3.3 Metal–Halogen Exchange

Some examples of this process are given in equations (12) and (13). Unless the organic halide has electronegative substituents, the exchange is relatively slow, may not have a favorable equilibrium, and may suffer from competitive Wurtz-type coupling. Previously, this methodology was constrained by the sensitivity of many organic functional groups to reaction with Grignard reagents (see Section 6.2.) Currently, however, the low-temperature exchange reactions of derivatized aryl (bearing an ester, nitrtile, or imine function), heteroaryl (e.g. halogenated pyridines, pyrimidines, and thiophenes), heterocyclic (e.g. pyrroles, pyrazoles, uracils), cyclopropyl or alkenyl iodides with i-Pr_2Mg or i-PrMgBr yield a wide array of functionalized Grignard reagents.[45] Trialkylmagnesates, R_3MgLi, extend the method to arylbromides, including electron-rich species. Oxidative addition of activated Mg to aryl bromides and heteroaryl halides yields similar results.[46,47]



(12)

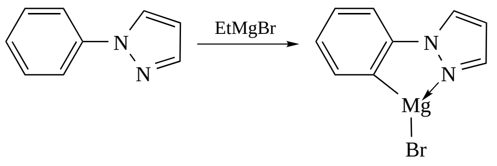
$$\mathrm{CBr_4} \xrightarrow[-75\,^{\circ}\mathrm{C,\ THF}]{i\text{-PrMgCl}} \mathrm{CBr_3MgX} \qquad (13)$$

4.3.4 Metal–Hydrogen Exchange; Metalation[8]

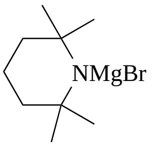
Organomagnesium compounds are kinetically less-reactive bases toward weakly acidic hydrogens than organolithium compounds. Usually, Metalation using an organomagnesium compound is practically limited to acid hydrogens with pK_a of about 25 or lower. This includes alkynes (equation 14) and derivatives of cyclopentadiene, indene, and fluorene. Even

these are not formed quickly in ether solvents, but addition of HMPA markedly increases the reactivity; the less acidic diphenylmethane reacts at 100 °C. Some polyhalogenated compounds are relatively easily metallated, as are aromatic ring positions ortho to O or N substituents (equation 15) and some heteroaromatics. Magnesium amide bases, for example, (**24**) or BuMgN(i-Pr)$_2$ effectively magnesiate a variety of substrates, the latter regioselectively.[48] The alkyl amide and s-BuMgBu are alkane soluble and commercially available.

$$2PhC\equiv CH \xrightarrow{\text{s-BuMgBu}} (PhC\equiv C)_2Mg \quad (14)$$



(15)



(**24**)

Abstraction of acidic protons α to a carbonyl or nitrile function can occur in competition with desired Grignard addition reactions (see Section 5.6). In HMPA, this is the major reaction, and is useful for preparing magnesium enolates of carbonyl compounds, sulfones, and so on.

4.4 Addition of C–Mg and H–Mg to Carbon–Carbon Multiple Bonds

4.4.1 Carbometalation

Addition of an organomagnesium bond to an alkene, alkyne, or a benzenoid ring generates a new organomagnesium compound. With simple alkenes, addition occurs only under strenuous conditions. This reaction will be discussed later, with appropriate examples, as a reaction of organomagnesium compounds in the Section on Amides and Lactans..

4.4.2 Hydrometalation[8,9]

MgH_2 adds to ethylene at high temperatures, and the addition to alkenes in general can be catalyzed by boron, aluminum, and zinc alkyls, and by titanium halides. The latter reagents also catalyze an exchange between Grignard reagents and alkenes (equation 16) which can be synthetically useful. Under like conditions, most internal acetylenes exhibit cis addition of ‘HMgX’ (from RMgX) to the triple bond. The catalyzed reactions involve titanium hydride intermediates.

(16)

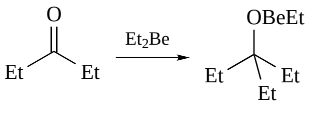
Terminal alkenes react relatively readily in ether (80 °C) with RBeH, but internal ones are less reactive. The addition is slowed but not completely inhibited by coordination with ether or NMe_3. Rearrangement of (t-Bu)$_2$Be to the i-Bu compound occurs by Be–H elimination and re-addition in the opposite sense.

4.5 Formation of R$_2$Mg

A number of methods discussed in the foregoing sections are specifically useful for forming R_2Mg compounds. These include precipitation of magnesium halide from a Grignard reagent, the transition metal-catalyzed reaction of active (prepared with Mg–anthracene) MgH_2 with terminal olefins, the reaction of a magnesium halide or Grignard reagent with an organolithium, and exchange of a dialkylmercury compound with magnesium metal. The relative merits of various methods have been discussed.[49] Other methods of narrower applicability include the Metalation of alkynes and other acidic hydrocarbons with R_2Mg.

4.6 Other RMY Compounds

The reaction of R_2Be or R_2Mg compounds with one equivalent of O–H, S–H, N–H, or other acidic hydrogen leads to compounds of the stoichiometry RMY. Variants include the reaction of an alkyl chloride with magnesium and alcohol (or NaOR′) in hydrocarbon solvent. MeBeCN has been prepared from Me_2Be and HCN. Redistribution reactions of R_2M with $M(Y)_2$ have been used to form the alkoxides, thiolates, and amides. The addition of R_2M to one equivalent of an aldehyde, ketone, epoxide, or imine also leads to RMOR′ or $RMNR'_2$ species (equation 17). Dialkylmagnesiums react like Grignard reagents in alkylation and carbonyl addition reactions.



(17)

Hydride compounds (RMH) are formed in a number of ways, but have most often not been isolated and purified. Redistribution of R_2Mg with MgH_2 has produced pure RMgH and RMg_2H_3. Mixtures containing organoberyllium or -magnesium hydrides have resulted from exchanges involving borohydrides, aluminohydrides, and some other metal hydrides. They are also formed as intermediates in the thermal decomposition of R_2Mg or R_2Be compounds, and a number of RBeH complexes have been isolated.

5 REACTIONS OF ORGANOBERYLLIUM AND -MAGNESIUM COMPOUNDS

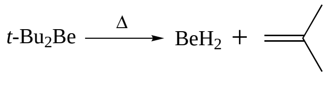
Most of the chemistry of organoberyllium and -magnesium compounds is associated with the basicity of the organic groups bound to the metal, either in the Brønsted–Lowry or the Lewis (nucleophile) sense. Also associated with their electron-rich character is the potential to function as reducing agents by loss of an electron, and there is increasing evidence that many formally nucleophilic reactions occur, in fact, by a mechanism involving electron transfer (*see* ***Electron Transfer Reactions: Theory***). The metal atom is also an electrophilic or Lewis-acidic site, and electrophilic interaction with the metal doubtless plays a role in many of their nucleophilic reactions.

Shortly before the successful preparation of organomagnesium compounds by Victor Grignard, his mentor, Philippe Barbier, had discovered that reaction of an aldehyde or ketone and an alkyl halide in the presence of magnesium metal led to formation of an alcohol, essentially as in the 'Grignard reaction'. The use of the older technique, referred to as the Barbier method or as the 'in situ' reaction, holds advantages in some cases.[8]

As noted previously, much less attention has been directed to synthetic applications of beryllium organometallics.

5.1 Thermal Decomposition

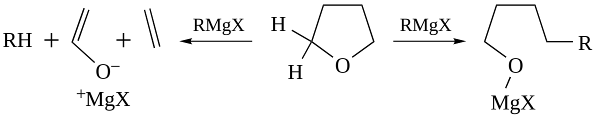
When a β-hydrogen is present, decomposition may occur by *β-Elimination* of an alkene with formation of a M–H bond (equation 18). Tertiary alkyl groups are most easily eliminated. A polar, probably cyclic process is likely, but there is evidence for homolytic cleavage in the decomposition of $(t\text{-Bu})_2Mg$. Hydrogen is subsequently formed at higher temperature. The decomposition of gaseous $(t\text{-Bu})_2Be$ is the primary source of unsolvated BeH_2, which is of interest as a high energy propellant and as a fuel source for nuclear fusion reactors. If β-elimination of hydrogen is not possible, thermal stability is greater. Ph_2Mg decomposes at 280 °C to biphenyl and magnesium metal. Me_2Mg and Me_2 both decompose above 200 °C to yield methane and a residue $(CH_2M)_n$.



(18)

Appropriately located functional groups also lower the thermal stability. The preparation and stability of a number of these is noted in Section 6.2.

Solutions of Grignard reagents also decompose at temperatures in excess of 100 °C by attack on the solvent.[50] From either diethyl ether or THF, ethylene is among the products. In the latter case, the reaction follows two major pathways (equation 19).



(19)

5.2 Redox Chemistry

In the electrolysis of ethereal Grignard reagent solutions, magnesium species migrate toward both electrodes. At the anode, one-electron oxidation produces organic radicals which combine, disproportionate, react with solvent or other solutes, or attack the electrode (e.g. Pb → PbR_4). Tertiary alkyls are oxidized most easily, and methyl and phenyl least easily. At the cathode, magnesium is deposited, and alkyl radicals appear to be formed also. There are two reduction waves, corresponding to MgX_2 and RMgX.

Organomagnesium and -beryllium compounds are very sensitive to oxidation by air. The reaction appears formally to be a simple addition to the O–O bond. However, it is clearly established that Grignard reagents react by the radical chain process shown in Scheme 1. The subsequent reaction to produce the alkoxide is less clear mechanistically. Sulfur and selenium form analogous products. Grignard and organoberyllium compounds may also be oxidized by other peroxides. Autoxidation of aryl Grignard reagents often is accompanied by chemiluminescence resulting from emission by biaryls.

In the Kharasch reaction (equation 20), Grignard reagents are in effect oxidized by organic halides in the presence of transition metal salts, most commonly cobalt. The Grignard reagent produces mostly disproportionation products (or the biaryl from ArMgX), and products from the organic halide are derived from the corresponding radical. It is likely that the transition metal is alkylated by the Grignard reagent, and that the resulting intermediate decomposes by nonradical pathways to metal species which then abstract a halogen atom from the organic halide.

$$\text{ROO}\cdot + \text{RMgX} \longrightarrow \text{ROOMgX} + \text{R}\cdot$$
$$\text{RMgX} + \text{ROOMgX} \longrightarrow \text{2ROMgX}$$

Scheme 1

5.3 Reaction as a Brønsted Base: Formation of C–H Bonds[8]

Organometallic compounds of Be and Mg are 'hydrolyzed' by O–H, N–H, S–H, and other hydrogens more acidic than the conjugate acid of the R^- of the organometallic. In practice, this reaction may be quite slow for weak carbon acids which do not coordinate as ligands to the metal. The reaction has been discussed as the metalation reaction (Section 4.3.4) and for the formation of RMY compounds (Section 4.6). It is also used for indirect reduction of organic halides to hydrocarbons via conversion to the Grignard reagent and hydrolysis, and for introducing a deuterium or tritium label.

5.4 Nucleophilic Displacement at Atoms other than Carbon: Alkylation

The organic group of an organometallic compound will alkylate another more electronegative element by displacement of halide or other suitable leaving group (equation 21). The reaction is a nucleophilic displacement which derives its driving force from formation of the more ionic product MXY. Organolithium and -magnesium compounds, because of their ease of formation and the electropositive character of the metal, are most often used for this purpose. Fewer examples have been reported with organoberyllium compounds, although they themselves are often formed in this way (Section 4.3.1).

$$\text{RMgX} + \text{Y–Z} \longrightarrow \text{R–Z} + \text{MgXY} \qquad (21)$$

Organomagnesium compounds are less reactive as nucleophiles than organolithium compounds, it may be more difficult to separate products from the magnesium salts, and the presence of halide and ether solvent in a Grignard reagent can be disadvantageous. However, one may use the dialkylmagnesium instead of a Grignard reagent, and work with a hydrocarbon suspension rather than an ether solution. The lower reactivity may be an advantage by allowing sequential partial alkylation, and the Grignard reagent has less tendency to form ate complexes (Section 2.6).

Alkylations of a number of metals were among the earliest reported reactions of Grignard reagents, and this reaction remains an important method for the synthesis of organometallic compounds. The alkali metal and higher alkaline earth metal cations are too electropositive to be alkylated by Grignard reagents, but in principle, displacement at any other metal center is feasible. Since this reaction is discussed in other articles as it may apply to the preparation of organometallic compounds of the various metals, only general comments will be made here. A halide ion is the most common leaving group, although OR^-, SR^-, and other anions may be displaced. Reactivity of R_2Mg is greater than that of RMgX, and reactions are usually faster in THF than in diethyl ether. The center to be alkylated decreases in reactivity as electronegative leaving groups are replaced by organic groups, often allowing controlled replacement of leaving groups to produce partially alkylated or mixed polyalkylated products.

As noted, a bimetallic ate complex may be formed instead of a simple alkylation product. For example, addition of Me_2Mg to $ZnCl_2$ in excess of the stoichiometric 1:1 ratio forms the ate complex Me_4ZnMg. A particularly important instance is with Cu^I halides. Complexes of stoichiometry $RCuMgX_2$ or R_2CuMgX, referred to as *Normant Complexes*, are useful reagents in organic synthesis (see Sections 5.5, 5.6.2, and 5.8). There are varied recipes, including other Cu^I salts, and Me_2S or $P(OR)_3$ as additional ligands.[6,8] An active area of study is the catalysis of reactions of Grignard reagents by transition metal salts or complexes. The active reagents in these catalyzed reactions are undoubtedly transition metal species, produced via alkylation by the Grignard reagent.

Many useful synthetic methods involve alkylation of nonmetals by Grignard reagents. Displacement at a halogen leads to an organic halide. This reaction may be useful for replacing one halogen by another, for characterizing the organic group of a Grignard reagent, or when the organomagnesium compound is formed in an indirect fashion. The most obvious reagent for such a displacement is molecular halogen itself, but it can lead to mixtures of products if the halogen is different from that of the Grignard reagent. Organic halogen compounds may serve as alternative halogen sources, for example, 1,2-dibromoethane, hexachloroethane, *N*-chlorosuccinimide, or 1-chloro-2-iodoethane. Perchloryl fluoride and N_2F_2 have been used, but may present explosion hazards.

Oxygen (see Section 5.2) and the other group 16 elements react with organomagnesium compounds. Some other displacements at oxygen and sulfur are shown in equations (22–24).

$$\text{ArMgBr} + (\text{EtO})_2\text{BO–O-}t\text{-Bu} \longrightarrow \text{ArOH} \qquad (22)$$

$$\text{RMgCl} + (\text{CF}_3\text{SO}_2)_2\text{O} \longrightarrow \text{R}-\overset{\overset{\text{O}}{\|}}{\underset{\underset{\text{O}}{\|}}{\text{S}}}-\text{CF}_3 + \text{CF}_3\text{SO}_3\text{MgCl} \qquad (23)$$

$$\text{RMgX} + \text{MeSSMe} \longrightarrow \text{RSMe} + \text{MeSMgX} \qquad (24)$$

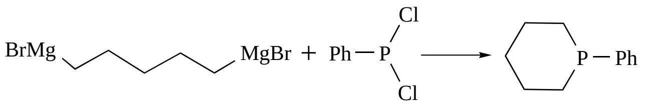
Primary amines may be made by the reaction of an excess of Grignard reagent with chloramine, methoxyamine, or other O-substituted hydroxylamines (equation 25). Reactions with N-chloroamines and N-substituted hydroxylamines are not as routinely successful, because of competing displacement on the halogen. Displacements at P–X or P–OR bonds are useful for synthesis of trialkylphosphines. Similar displacements also occur with $POCl_3$ and its derivatives. Three organic groups can be introduced in PCl_5.

$$\text{RMgCl} + \text{H}_2\text{NOMe} \longrightarrow \text{R–NH}_2 \qquad (25)$$

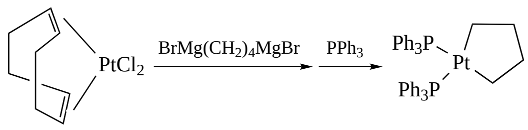
Alkylation of group 14 halides is also important synthetically. A number of reactions of R_3SnX compounds

with methyl Grignard reagents have been studied kinetically. The reactions occur with low activation enthalpies but large negative entropies of activation. A cyclic four-center mechanism has been proposed to explain the results. Some alkylations, however, probably occur by single-electron transfer (SET) from the Grignard reagent to the substrate, followed by homolytic bond cleavages and recombinations. This mechanism is discussed in the next section in connection with displacement reactions at carbon.

Alkylation of a compound with multiple leaving groups by a di-Grignard reagent can produce a ring. Many important heterocycle and metallacycle syntheses have followed this route. Examples are in equations (26) and (27).



(26)

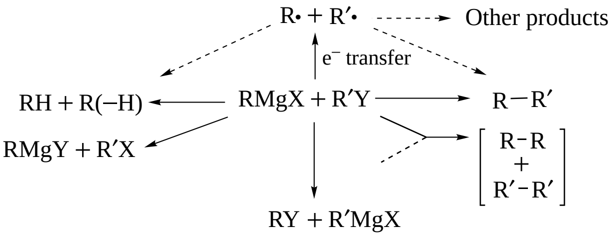


(27)

5.5 Displacements at Carbon: ‘Crossed Coupling’ Reactions

A nucleophilic displacement by an organometallic compound at carbon generates a new C–C bond (Scheme 2). Although a general reaction, its success may be limited because of competing side reactions. These are also outlined in Scheme 2. As a nucleophilic substitution, β-elimination to alkene is an important competitor, becoming progressively more dominant for secondary and tertiary substrates. Metal–halogen exchange, displacement by the halide of the Grignard reagent, and radical processes resulting from SET also occur. Grignard reagents are less reactive than organolithium compounds and give good yields only in the more favorable situations. The partially delocalized allylic or benzylic Grignard reagents are relatively effective.

Of the halide leaving groups, iodide is most easily displaced, but also most reactive in metal halogen exchange; bromide and chloride are successively less reactive. Grignard



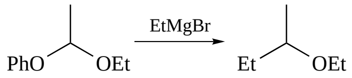
Scheme 2

reagents often couple in quite good yield with methyl iodide and methyl or primary alkyl sulfates or sulfonates (i.e. tosylates). Allylic and benzylic halides and α-haloethers and -sulfides also undergo easy displacement.

Alkoxide ions are generally poor leaving groups, but are displaced under special circumstances. Ring opening of the strained oxirane and oxetane rings by addition of a Grignard reagent is such a reaction, and provides a synthetically useful two- or three-carbon chain extension (equation 28). With substituted oxiranes, the Lewis-acidic activity of the magnesium affects the regiochemistry of the addition, and preliminary rearrangement of the oxirane leads to additional products.

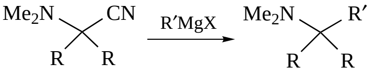
(28)

Alkoxide ions may also be displaced from orthoesters and acetals (e.g. equation 29), including paraformaldehyde. A carbocation generated from any of these structures would be stabilized by conjugation with the adjacent lone pair (i.e. **25**). The substrate may initially form an ion pair assisted by the Lewis-acidic magnesium, or at least react by a transition state with enhanced cationic character. Grignard reagents appear to be more effective than organolithium compounds, and the lithium reagent is also more likely to deprotonate the acetal. Leaving group reactivity is in the sequence $ArO^- > RO^- > RS^- > R_2N^-$. Alkoxy groups may also be displaced from propargyl and allylic ethers (often with attack at the 3-position) and from the homoallylic ether (**26**). Under forcing conditions, aryl alkyl ethers (especially methyl) are cleaved (equation 30). Another generally very poor leaving group, cyanide, is displaced from α-aminonitriles in a useful amine synthesis (equation 31), and biaryls can be prepared by the (Ni-catalyzed) coupling of benzonitrile with aryl Grignard reagents.[51]

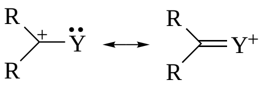


(29)

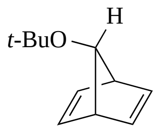
$$\mathrm{ArOMe + MeMgI \xrightarrow{150\,^{\circ}C} ArOMgI + Me_2O} \tag{30}$$



(31)



(25)



(26)

A variety of mechanisms may participate in the displacement reactions surveyed above. Some displacements, including tosylates and some epoxide ring openings, occur with the high degrees of inversion of configuration expected

for an S_N2 reaction. As noted above, electrophilic assistance by the magnesium may be important. In other cases, SET, radical formation, and recombination may be involved, as shown in Scheme 2. A number of reactions which are formally displacements at an unsaturated or aromatic carbon probably occur by a mechanism of addition followed by elimination of a leaving group. As such, they are more closely related to the addition reactions which are covered in Section 5.8.

Addition of a transition metal compound can effectively promote displacement reactions by organomagnesium compounds, often minimizing the side reactions which limit the use of the Grignard reagent itself. Normant reagents or Grignard reagents with catalytic amounts of Cu^I salts are reactive in displacements of halide not only from alkyl halides but also aryl, vinyl, and alkynyl halogen compounds. Complications in additions to oxiranes are often reduced or eliminated. A number of displacements of other leaving groups are also catalyzed by copper salts. These include RO^-, RS^-, OH^-, and OAc^- groups, most commonly from allylic and propargyl substrates. The utility of Ni and Pd catalysts, which are more useful with less-reactive alkenyl and aryl substrates, has been extended to aryl chlorides with the application of bulky, electron-rich (often phosphine-derived) ligands.[52] Inexpensive and nontoxic Fe catalysts are an important recent development, as they enable cross-coupling reactions that are exceptionally fast even at low temperatures, and in the absence of added ligands. Mechanistic studies indicate that in certain cases, 'inorganic Grignard reagents', of monomer composition $Fe(MgCl)_2$, are the active species, likewise able to oxidatively add unactivated aryl chlorides.[53,54] In reactions with Cu catalysts, allylic leaving groups are usually more easily displaced than their saturated analogues, Chiral complexes have been used to achieve asymmetric cross-coupling.[8] These topics are also noted in other articles from the viewpoint of the various transition metals.

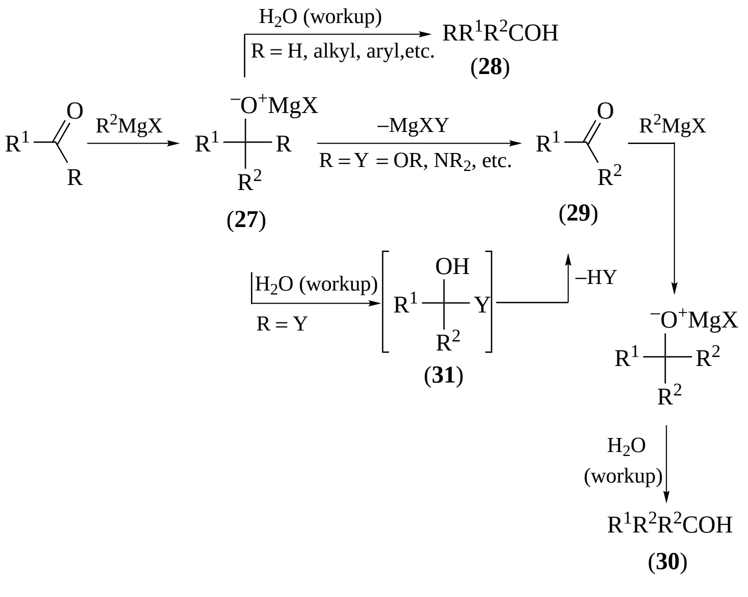
5.6 Addition and Substitution at Carbonyl Carbon[8,9]

The addition of organomagnesium reagents to aldehydes and ketones, yielding an alcohol after workup, is their most important organic synthetic reaction, and customarily bears the title 'The Grignard Reaction'. With the derivatives of carboxylic acids the initial adduct may suffer loss of a leaving group, regenerating a new carbonyl compound, which in turn may undergo further addition. Scheme 3 summarizes these processes.

5.6.1 *Addition to Aldehydes and Ketones*[8,9]

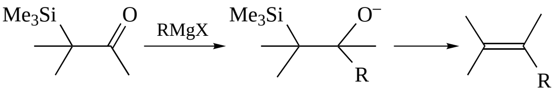
The addition of R_2Mg or RMgX to an aldehyde or ketone is usually very rapid, occurring essentially with mixing. Only with severe steric hindrance, low temperatures, or both, is the reaction noticeably slow. It is generally preferred in competition with displacement of an alkyl halide or addition to most other unsaturated functional groups. Reaction with an acyl halide is usually more rapid, and a Grignard reagent will normally abstract the OH proton ('be hydrolyzed') before adding to the carbonyl of a hydroxyaldehyde or -ketone.

The alkoxide (**27**) is the initial product of addition to the carbonyl group (Scheme 3). Workup with aqueous acid generates alcohol (**28**) and water-soluble magnesium salts. However, with sensitive alcohols this workup may lead to dehydration. Milder workup can be achieved by acidifying with aqueous ammonium chloride, or by hydrolyzing with a minimal amount of water, and attempting to filter or



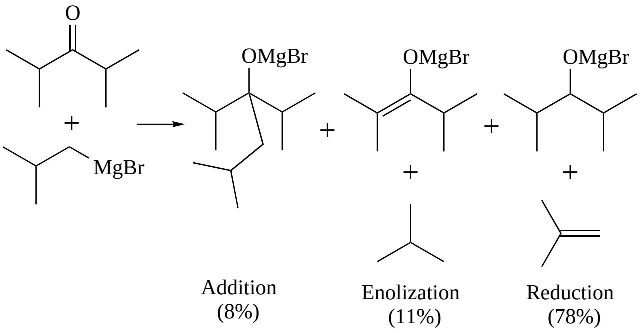
Scheme 3

decant from the frequently gelatinous magnesium salts. The magnesium alkoxide itself may be useful without hydrolysis to the alcohol. It may be acylated by reaction with an acid chloride, undergo elimination to an alkene with a suitable neighboring leaving group (equation 32), or react intramolecularly as a nucleophile.



(32)

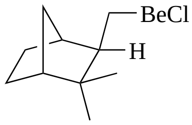
Despite its apparent simplicity, the addition of a Grignard reagent to an aldehyde or ketone is subject to side reactions which may limit its utility. The transfer of a β-hydrogen from the organomagnesium compound to the carbonyl carbon reduces the ketone to a secondary alcohol rather than producing the expected tertiary alcohol. The alkyl group of the Grignard reagent becomes an alkene. This pathway is more important with sterically hindered ketones and bulky Grignard reagents. Enolization of the carbonyl compound, with the organomagnesium acting as a base, is another side reaction which is more important with substantial steric hindrance. Addition is promoted by lower temperatures, a less-polar medium (Section 4.1), and by the addition of salts. A classic comparison of normal addition, reduction, and enolization is shown in equation (33). When electron transfer occurs between an organometallic and a carbonyl compound, ketyl radicals are formed (see discussion below).



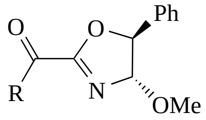
(33)

Organoberyllium compounds react with aldehydes and ketones in a fashion similar to organomagnesium compounds. Reduction competes with addition, and (**32**) is quite effective for asymmetric reductions.[10]

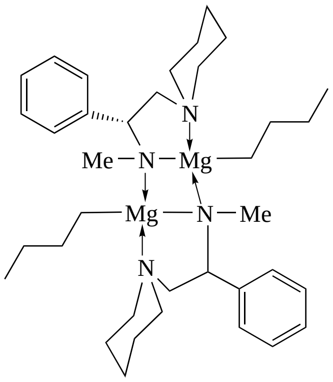
There have been numerous studies of the stereochemistry of the Grignard addition, and attempts to control it. The configuration of a new chiral center generated when a Grignard reagent adds to an aldehyde or ketone is influenced by chiral centers present in the carbonyl compound, in the Grignard reagent, or in chiral solvents or chelating ligands. Examples of structural features designed to control stereochemistry include a carbonyl moiety with an introduced chiral auxiliary (**33**), a chiral organomagnesium amide (**34**),[55] and a chiral ligand additive (**35**).[56] Grignard reagents chiral at the (octahedrally coordinated) metal[57] (**36** depicts Δ-cis-[(p-$CH_3C_6H_4$)MgBr(dimethoxyethane)$_2$]) or the metal-bearing carbon (**20**)[29] are now known. The Y group in RMgY also influences the degree of stereoselectivity.[58]



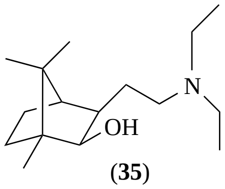
(**32**)



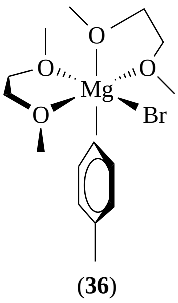
(**33**)



(**34**)

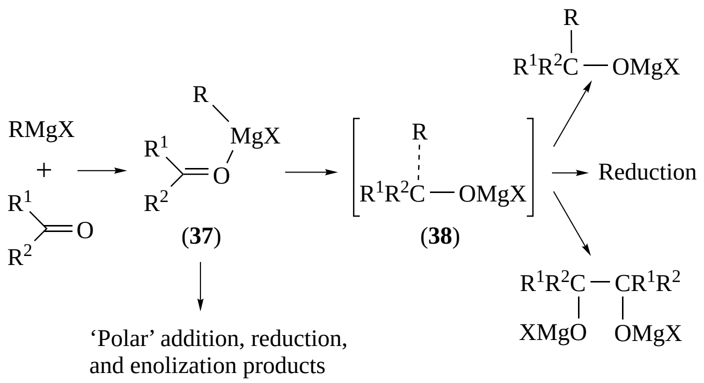


(**35**)



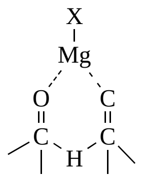
(**36**)

Although the addition of a Grignard reagent to a carbonyl group is readily visualized as a polar nucleophilic addition reaction, evidence has accumulated to suggest that many Grignard additions proceed by an alternative SET mechanism (Scheme 4). The polar process could take place as a cyclic rearrangement of an initially formed coordination complex (**37**). Cyclic transition states (**39**) and (**40**) have also been proposed for reduction and enolization. Alternatively, homolytic cleavage would produce a radical pair (**38**). The

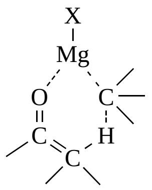


Scheme 4

alkyl and ketyl radicals of this pair can collapse to simple 1,2-addition product, transfer a hydrogen atom to produce reduction product, or diffuse apart. In the latter case the ketyl could either abstract hydrogen from solvent (leading also to reduction product), or dimerize to the pinacol. While early evidence suggested that SET was a side reaction induced by transition metal impurities, subsequent data, including that from radical rearrangement probes, CIDNP enhancements, and isotope effects, implied that many, or possibly all, Grignard additions to aromatic ketones involved SET, and that it may not be limited to aromatic substrates.[8,9,25,59] However, reactions of aldehydes with the chiral (**20**), where the sec-alky radical functions as an ultrafast racemization probe, proceed with retention of configuration, a result consistent with both a polar mechanism and a virtually instantaneous coupling of ketyl and alkyl radicals.[29]



(**39**)



(**40**)

When a carbon–carbon double bond is conjugated to the carbonyl group, simple 1,2-addition to the carbonyl has a competitor in the conjugate or 1,4-addition, resulting in net addition to the carbon–carbon double bond. This situation will be discussed in connection with the addition to carbon–carbon unsaturation (Section 5.8)

5.6.2 Substitution and Addition Reactions with Carboxylic Acid Derivatives

The general picture in Scheme 3, with R = Y, outlines the paths available when an organometallic compound reacts with a carboxylic acid derivative. The eventual product of the reaction depends first upon whether the initial adduct (**27**) survives the reaction conditions, or decomposes to ketone (**29**). If (**29**) is formed before workup, then its reactivity relative to the original acyl compound determines whether it or alcohol (**30**) is the product.

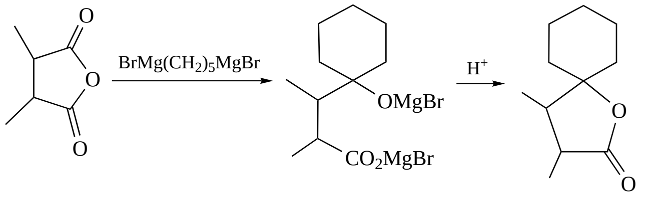
Carboxylic Acids and Carboxylate Ions. Acid–base reaction with a Grignard reagent rapidly converts a carboxylic acid into its anion. The carboxylate ion, either from a carboxylic acid substrate or as a preformed salt, is relatively unreactive, but does undergo either single addition to produce an aldehyde or ketone or double addition to produce an alcohol. Sometimes, as in equation (34), the carbonyl compound may be formed in good yield, but the analogous synthesis with a lithium reagent is more frequently used. More commonly, these products are encountered as side reactions in the carbonation of an organomagnesium compound.

$$2PhMgBr + HCO_2H \longrightarrow \underset{(81\%)}{PhCHO} \quad (34)$$

Acyl Halides and Anhydrides. The carbonyl of an acyl halide is at the high end of the reactivity range, and the halide ion is a very good leaving group. Hence, the reaction rapidly forms the ketone. With one equivalent of organometallic at low temperature, especially with some steric hindrance, the less-reactive carbonyl of the ketone may survive unreacted. Otherwise, it is converted to the tertiary alcohol in high yield. More commonly, if a ketone synthesis is sought the Grignard reagent is converted to another organometallic with attenuated reactivity. Historically, organocadmium compounds served this purpose, but the currently popular choice is a Normant reagent (a magnesium organocuprate). Manganese, zinc, and iron salts have also been used. Another helpful ploy is to use HMPA as solvent; in this medium the ketone is rapidly deprotonated to the unreactive enolate. With aromatic acid halides in particular, electron transfer may form the acyl radical, which dimerizes to produce an α-diketone.

Chloroformates, chlorocarbamates, and phosgene are similarly reactive toward organomagnesium compounds. The first two provide useful syntheses of esters and amides, respectively, but phosgene usually leads to the tertiary alcohol.

Carboxylic anhydrides are similar to the halides, producing ketones by reaction with one equivalent of organometallic, but easily reacting with an excess of the reagent. Cyclic anhydrides produce lactones as final products with two equivalents of organometallic (equation 35).

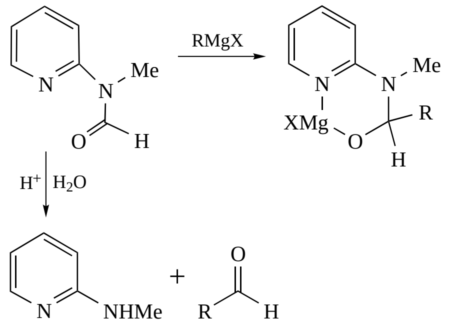


(35)

Esters, Lactones, and their Sulfur Analogs. The ester carbonyl is inherently less reactive than a ketone, so that alcohols are the normal products of addition of a Grignard reagent to an ester. The reaction is useful for forming tertiary alcohols (or secondary from formates) with two 'R' groups identical. Cyclic alcohols may be made using di-Grignard reagents. If the organic groups are somewhat bulky, addition may be stopped at the ketone stage. With some lactones, reaction with one equivalent of reagent is also favored (Scheme 5). Ring strain may enhance the reactivity of the ester group, while the cyclic hemiketal anion (**41**) would partially protect the carbonyl group of the product.

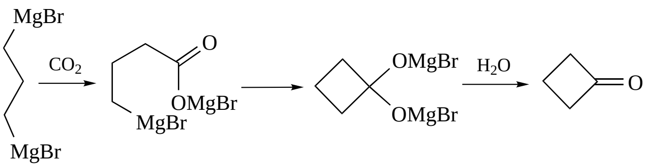
Similar considerations apply to thioesters and -lactones, although they are less studied. Generally, the thioester carbonyl is more reactive toward nucleophiles.

Amides and Lactams. The amide carbonyl group is less reactive than that of aldehydes or ketones, but the intermediate formed on addition of one equivalent of organomagnesium compound is relatively stable to elimination of a magnesium dialkylamide, and so protects against the second addition. Aldehydes, in particular, can be synthesized usefully (equation 36). Under forcing conditions a second addition occurs.



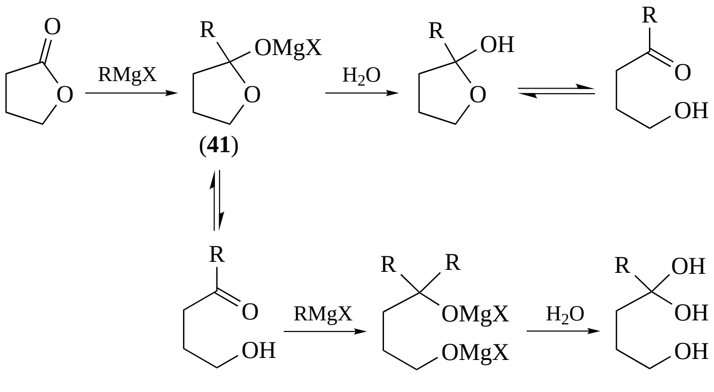
(36)

Carbon Dioxide, Isocyanates, Ketenes, etc. The carboxylation (or carbonation) of organomagnesium compounds is of major importance, both as a synthesis of carboxylic acids and as a means of characterizing the organometallic compound. Customarily, the organomagnesium solution is added to 'dry ice'. Under these conditions the temperature is kept low and the concentration of CO_2 high, minimizing further reaction of the organometallic with the initially formed magnesium carboxylate. If dry CO_2 is bubbled through a Grignard reagent or passed over the solution, multiple addition is more probable (equation 37).



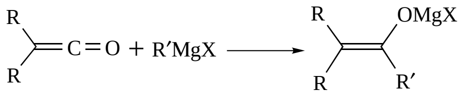
(37)

The cumulated double bonds of ketenes, isocyanates, and carbon suboxide are also very reactive. Disubstituted ketenes yield enolate ions (equation 38), which may be protonated to ketones or used in situ. The very high reactivity

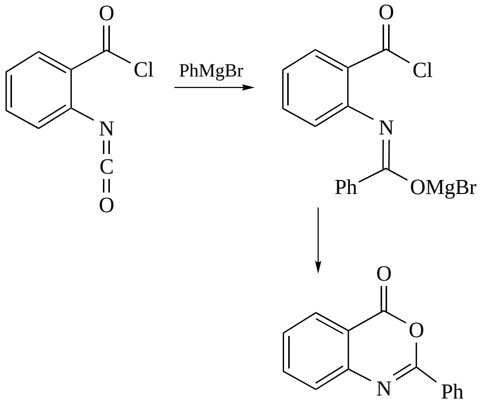


Scheme 5

of an isocyanate is illustrated in equation (39). In simpler examples an N-substituted amide is formed after hydrolysis; the reaction is useful as an amide synthesis, and to characterize the organometallic.



(38)

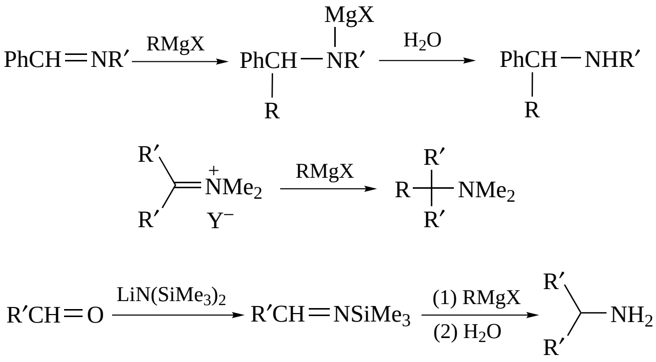


(39)

5.7 Addition and Substitution at C-Nitrogen and C-Phosphorus Unsaturation

5.7.1 Addition and Substitution to Carbon–Nitrogen Unsaturation

Addition to the C=N of an imine forms the magnesium amide, which is hydrolyzed to an amine. Isolated C=N double bonds of simple imines are relatively unreactive toward organomagnesium compounds, and may instead be deprotonated at the α-position. Oximes and other N-substituted imines may react better, although an alternative sequence can produce aziridines. Imminium ions, because of their positive charge, are more reactive, and are useful in making tertiary amines. N-Silylimines yield primary amines after hydrolysis. Grignard reagents also add to one C=N of carbodiimides to produce amidines, and to nitrones to produce hydroxylamines. Some varied examples are shown in Scheme 6.

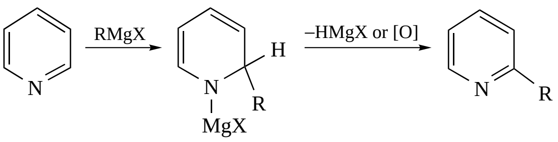


Scheme 6

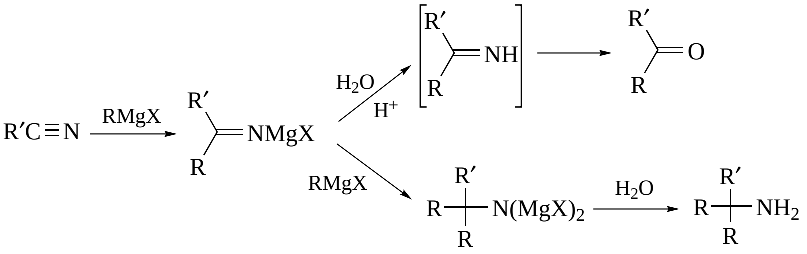
Addition of organomagnesium compounds to the triple bond of a nitrile, followed by hydrolysis of the resulting imine, is an important synthesis of ketones (Scheme 7). The imine salt has also been alkylated, acylated, or silylated. An important side reaction is abstraction of an α-proton (the equivalent of enolization). A second equivalent of organometallic can add to the remaining double bond of the first adduct, leading after hydrolysis to a t-carbinylamine. With excess nitrile, a complex series of condensations may occur. A useful synthesis of nitriles is a displacement reaction on the cyano group of a cyanate (equation 40).

$$R'\text{–}OCN \xrightarrow{RMgX} R'OMgX + RCN \qquad (40)$$

Addition can also occur to the formal ring double bonds of a nitrogen heteroaromatic compound. The usual preference is for addition adjacent to the nitrogen (equation 41), but this may be modified by substitution, cryptand complexation, quaternization, or copper salt catalysis. Pyridine N-oxides may yield deoxygenated product.



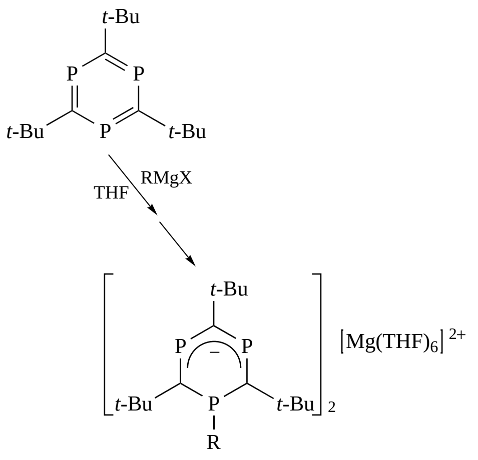
(41)



Scheme 7

5.7.2 Addition and Substitution to Carbon–Phosphorus Unsaturation

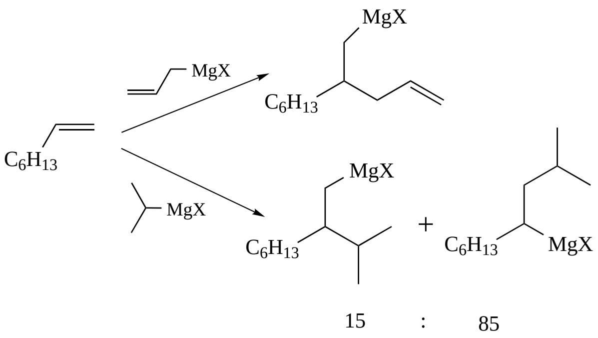
1,3,5-triphosphabenzene initially undergoes 1,4 addition with Grignard reagents (the R group of the Grignard adds to phosphorus) to ultimately yield unusual diorganomagnesium salts containing a $Mg(THF)_6$ dication, and $C_3(t\text{-Bu})_3P_2P$ anions bearing a partially delocalized charge (equation 42).[60] The phosphaalkyne PC(t-Bu) adds 'RMgCl' to yield the phosphavinyl Grignard reagent RP=C(t-Bu)MgCl, which crystallizes as the chloride-bridged dimer.[61] The polarity of addition (MgX bound to carbon) is opposite to that observed for nitriles.



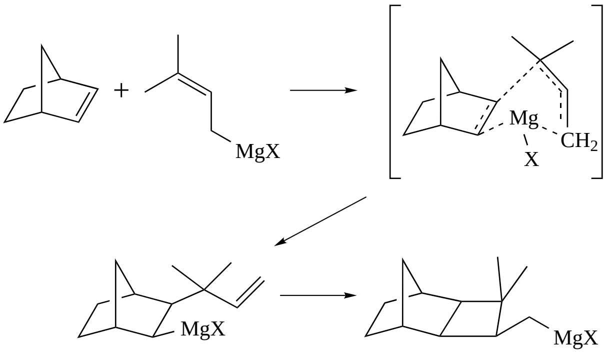
(42)

5.8 Addition to Carbon–Carbon Unsaturation

Carbon–carbon multiple bonds are usually much less reactive to addition of organomagnesium compounds than carbonyl groups. While the coordination of the magnesium to the negatively polarized carbonyl oxygen helps bring together the reacting entities in a 'Grignard reaction', a carbon–carbon multiple bond does not complex strongly enough to magnesium to displace ether solvation. Nevertheless, reactions do occur, and are sometimes quite useful synthetically. Since the product of the addition is itself an organometallic compound, this reaction has been briefly noted earlier in Section 4.4.1. Addition of Grignard reagents to simple unactivated alkenes or alkynes occurs only under relatively strenuous conditions, and then usually with secondary, tertiary, benzylic, and allylic Grignard reagents. Under forcing conditions the ethyl Grignard reagent will add to ethylene. In additions to terminal alkenes, the orientation in equation (43) predominates.[8] The addition of allylic Grignard reagents is most facile, although it still is not competitive with the more common 'Grignard reactions'. Most of the reaction occurs with 'inversion' of the allyl group; a cyclic mechanism is proposed, and the process has been dubbed the 'magnesium-ene' reaction (e.g. equation 44). As shown, rearrangements may follow the initial addition (see also below). In its intramolecular form it is a powerful ring synthesis method.



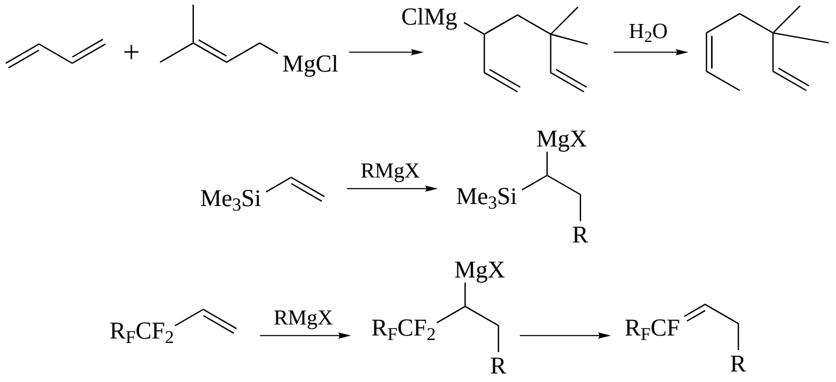
(43)



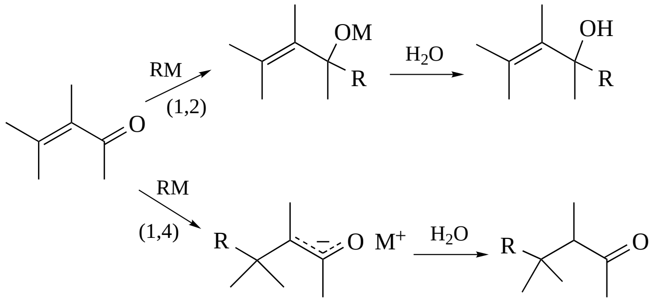
(44)

Additions occur more easily if a 'carbanion' with resonance or inductive stabilization is formed in the addition. Thus, fulvenes are very reactive, vinylsilanes and highly fluorinated alkenes somewhat less so. Styrene, 1,3-dienes, and enynes are more reactive than isolated alkenes, and Grignard reagents may be used to initiate anionic polymerization of styrenes, dienes, and acrylic monomers. Strained alkenes such as norbornenes and cyclopropenes are also more reactive. Examples of additions facilitated by resonance or substitution are shown in Scheme 8.

An extreme of activation is found when the double bond is conjugated to a strongly electron-withdrawing substituent, most importantly, carbonyl or cyano. The competition between '1,2-addition' to the C=O or C≡N and 'conjugate' or '1,4-addition' to the C=C is important synthetically (Scheme 9). Generally, lithium reagents give mostly 1,2-, Grignard reagents more 1,4-, and complete 1,4-addition can be approached using cuprates or Cu^I catalysis. Steric factors affect the product distribution: α,β-unsaturated aldehydes give mostly 1,2-addition even with Grignard reagents. An electron transfer mechanism[62] gives predominantly 1,4-addition. This is favored by HMPA in the solvent, with tertiary alkyl Grignard reagents, and Cu catalysis. The product of the 1,4-addition is an enolate ion, which is usually inert to further addition. On hydrolysis a saturated carbonyl compound is obtained, corresponding effectively to 3,4-addition to the C=C. As in the case with 1,2-addition, stereocontrol of the new C–C bond may be achieved.[63] Reactions with quinones can be quite complicated, with 1,2-addition to one or both carbonyl groups, 1,4-additions to the ring double bonds,



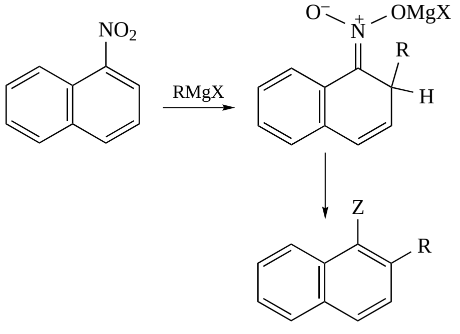
Scheme 8



Scheme 9

and additional pathways (including reductions) resulting from electron transfer.

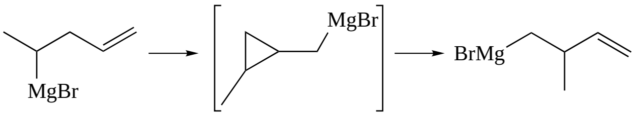
Organomagnesium compounds add to polycyclic aromatic hydrocarbons under forcing conditions, but with electron-withdrawing substituents the addition occurs more easily. Alkyl Grignard reagents add 1,4 and/or 1,6 to nitroaromatics, and the nitronate intermediate may be converted to a number of useful products (equation 45). Aryl Grignards yield hydroxylamines (by means of a 1,2 process), which can be reduced to diarylamines.[64]



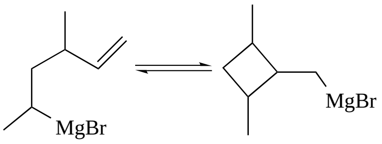
(45)

Z = NO_2, NO, NH_2, Cl

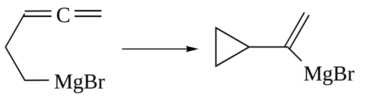
Intramolecular additions are also facilitated. Many organomagnesium rearrangements have been reported which consist of either intramolecular additions to a carbon–carbon double or triple bond, the reverse ring-cleavage, or a sequence of such processes (equations 44, 46–48). Mechanistic studies suggest that the intramolecular processes, and by implication organomagnesium additions to C=C in general, are concerted processes occurring via a four-centered transition state.[65]



(46)

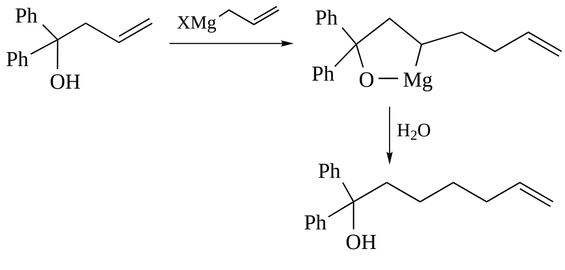


(47)



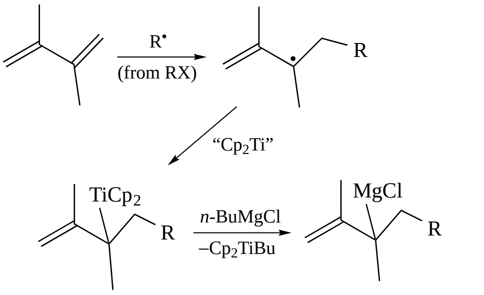
(48)

A Lewis-basic substituent in the alkene can also promote addition of a Grignard reagent to a double or triple bond.[8] Allyl, benzyl, and *t*-butyl Grignard reagents add readily to allylic and homoallylic alcohols and alkynols (equation 49). A magnesium alkoxide, formed initially, apparently assists intramolecularly in the addition. There appear to be multiple mechanistic pathways, with different stereochemistries. OR and NR_2 groups also activate addition.



(49)

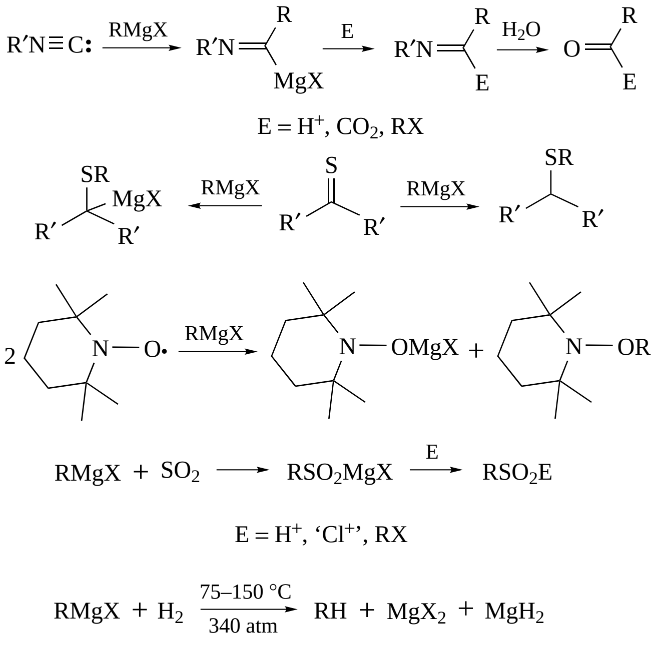
Transition metal salts promote additions, particularly to alkynes, both catalytically and in stoichiometric amounts. Normant reagents or Cu^I catalysis of Grignard reagents are the most explored.[8] Stereochemistry and orientation depend upon substitution, but a syn addition is most common. New chiral zirconocene catalysts have enabled the regio- and stereoselective addition of Grignard reagents (primarily ethyl) to the double bond of allylic alcohols, ethers, and amines.[7,66] A method more general than any previous involves the regioselective addition of alkyl radicals (generated from alkyl halides by electron transfer from a titanate complex) to the terminal carbon of an alkene or diene, followed by transmetalation of a Ti intermediate to the Grignard reagent (equation 50).[67] Alkyl (hindered primary; secondary, and tertiary), vinyl, and aryl halides have been used, and benzyl, α-silylalkyl, and allylmagnesium halides have been formed.



(50)

5.9 Other Reactions

A number of reactions which did not to fit neatly into the foregoing categories are shown in Scheme 10.



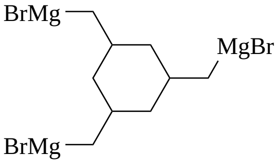
Scheme 10

6 SPECIAL CLASSES OF COMPOUNDS

Several categories of compounds have special features that warrant some consideration as a group.

6.1 Organo-di- and Polymagnesium Compounds[8,9]

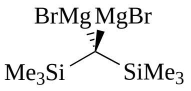
Many di-Grignard reagents can be prepared routinely from the corresponding halo compounds, provided the halogens are sufficiently separated, for example, (**42**), $X(CH_2)_4X$, or *m*- and *p*-dihalo aromatics. Precautions such as dilution, low temperature, and active magnesium (particularly Mg anthracene) may be important for a good yield, particularly where the halide is easily displaced, for example benzylic.



(**42**)

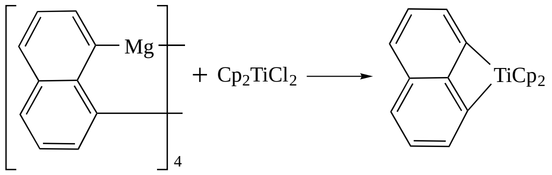
With 1,3-dihalides, elimination to produce a cyclopropane can be a problem. Elimination predominates strongly when the halogens are on adjacent carbons. Aromatic *ortho* di-Grignard reagents and that from 1,2-dibromocyclopropane may be formed because the competing elimination yields a more strained system. $BrMgCH_2CH_2MgBr$ has been made from $LiCH_2CH_2Li$ and $MgBr_2$.

A number of 1,1-di-Grignard reagents have been reported, including $CH_2(MgX)_2$ (X = Br, I, from the dihalide and Mg/Hg), and (**43**). Pyrolyzes of Me_2Mg and Me_2Be produce polymeric (MCH_2).



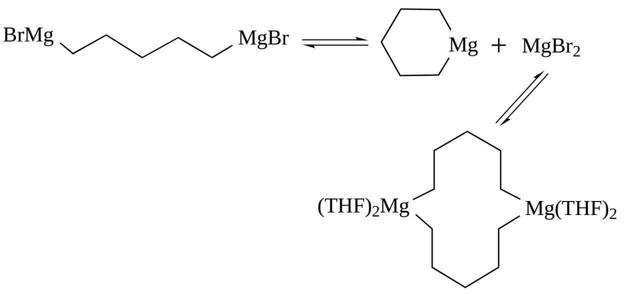
(**43**)

Difunctional Grignard reagents are of interest, because they offer the possibility of ring formation upon reaction with appropriate substrates. Applications include carbocyclic (especially cyclalkanol), heterocyclic and metallacyclic syntheses. Examples are shown in equations (26), (27), (35), (37), and (51). 1,1-di-Grignard reagents also olefinate aldehydes and ketones in a Witting-type manner, although (**43**) is generally of low reactivity.



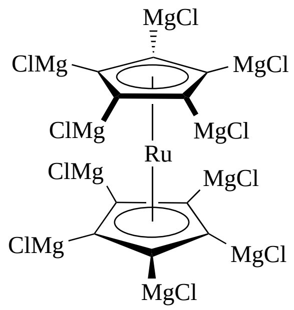
(51)

The structures of dimagnesium compounds are also of interest. With an α,ω-di-Grignard reagent the R_2Mg species in the Schlenk equilibrium can be a magnesiacycle. The cyclic dimer structure in equation (52) has been confirmed by X-ray crystallography. Halide-free organomagnesium compounds from 1,2-dihalobenzene, 1,8-dihalonaphthalene, and 1,2-dihalo-1,2-diphenylethylene have unique tetrameric cluster structures with η^3 bridging organic ligands and a tetrahedral arrangement of magnesiums.[9]



(52)

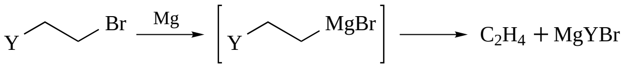
Aromatic groups containing more than two Mg groups are rare. 1,3,5-$C_6H_3(MgBr)_3$ has recently been prepared from the trilithio analogue and $MgBr_2$, while transmetalation of the permercurated ruthenocene yields the decamagnesiated species (**44**). The latter is thought to be oligomeric.[68]



(**44**)

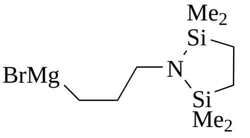
6.2 Functionally Substituted Organic Groups: Protecting Groups

An organomagnesium compound can tolerate a number of additional functional groups on its organic portion. In remote positions, ether, thioether, and tertiary amino groups are quite compatible with the organometallic function and, as noted in Section 2.4, can provide intramolecular 'solvation' of the metal. A halogen substituent is subject to internal displacement ('elimination'), but in many cases a dihalide is converted to a halosubstituted Grignard reagent (if the halogens differ in reactivity), or further to the di-Grignard reagent (see Section 6.1). γ-Substituents are sometimes eliminated, forming a cyclopropane. A β-substituent (equation 53) (Y = halogen, OR, NR_2, etc.), is generally eliminated so readily that no Grignard reagent can be detected. However, Grignard reagents with β-amino groups have been obtained at low temperature, and perfluoroalkyl Grignard reagents have limited stability. *o*-Haloaryl Grignard reagents can also be formed, but these compounds decompose to generate benzyne. Some organomagnesium compounds with α-halogen can be formed at low temperature (equation 13), but decompose on warming, either via free carbenes or to 'carbene-derived' products. Grignard reagents $ROCH_2MgX$ decompose above −15 °C to ethylene and ROMgX. R_3Si and R_3Sn may be in α, β, or more distant positions.

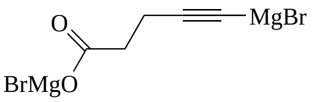


(53)

Functional groups normally reactive to Grignard reagents must be protected either by temporary replacement with an inert moiety or an adjustment (attenuation) of reaction conditions Hydroxyl groups may be protected as *t*-butyl, Me_3Si, or tetrahydropyranyl ethers, or the OH group of a haloalcohol may be converted to an alkoxide before reacting with magnesium metal. Aldehydes and ketones are protected by formation of acetals; (**45**) has protected primary amino groups. The carboxylate group in (**46**) is apparently unreactive enough to be compatible.



(**45**)



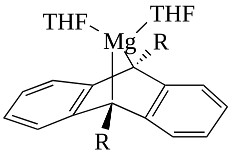
(**46**)

As discussed in Section 4.3.3, the development of extremely mild (−20 to −50 °C) halide–magnesium exchange processes for preparing (unsaturated) Grignard reagents has lessened the importance of protective group strategies.[45] Similarly, Fe catalysts allow alkyl Grignards and aryl electrophiles to cross couple at room temperature or below, conditions compatible with many functional groups (Section 5.5).[53]

6.3 Magnesium–Arene and Magnesium–Diene 'Addition Compounds'

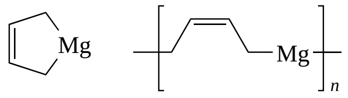
Magnesium reacts with naphthalene and higher polycyclic aromatics in liquid ammonia or HMPA to form the radical ion. Adducts with anthracene and substituted anthracenes form in THF.[9] Depending upon substitution and conditions, they have a variety of structures.[8,9,12] The 1,10-bis(trimethylsilyl) compound had structure (**47**) in the crystal, with magnesium bridging the 1,10-positions (C–Mg =

221–223 pm; C–Mg–C = 78–79°). With anthracene and 1,10-dimethylanthracene the magnesium was coordinated to three THF molecules and was further (232 pm) from the carbons, suggesting a more ionic interaction. Magnesium anthracene compounds serve as active carriers for magnesium atoms, and decompose to deposit a very active finely divided magnesium. Silica and polymer supported Mg anthracene complexes offer certain advantages over Mg (anthracene)$(THF)_3$ in the preparation of Grignard reagents.



(**47**)

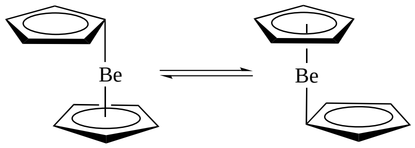
Conjugated dienes also react with magnesium in THF[8] (usually with some activation). With 1,3-butadiene the initial product is THF-solvated $[C_4H_6Mg]$, which can add more butadiene molecules. The 1:1 and 1:2 adducts are reasonably formulated as allylic organomagnesium compounds (**48**) or (**49**). These complexes are diamagnetic, hydrolyze to alkenes with incorporation of two D atoms from D_2O, and undergo reactions typical of Grignard reagents. Net 1,2- or 2,1-addition can be effected, depending on the nature of the electrophiles. Electrophiles with two electrophilic centers can lead to carbocyles, including spiro compounds.[8,9]



(**48**) (**49**)

6.4 Cyclopentadienyl Compounds[69]

Crystalline dicyclopentadienylmagnesium[3,12] has a monomeric sandwich structure, with the rings staggered. Its long ring–metal distance, along with vibrational and photoelectron spectroscopic data, imply ionic character, but other experimental (e.g. ^{25}Mg NMR) as well as theoretical studies suggest significant covalent binding.[35,69] Addition of HMPA to an ether solution leads to solvent-separated ions. $Mg(C_5H_5)_2$ forms adducts with many Lewis bases, and is a useful reagent for the transfer of C_5H_5 groups. Mono π-(C_5H_5)Mg complexes, that is, CpMgX, are generally isolable only as base adducts. The TMEDA adduct of CpMgBr and the dimer $[CpMgMe(Et_2O)]_2$ have the ring bonded nearly symmetrically to the metal and distorted tetrahedral metal geometry; the latter has bridging methyls. In selected ion flow tube studies, the reactivity of Mg^+, $CpMg^+$, and Cp_2Mg^+ ions with small inorganic molecules and straight chain hydrocarbons has been probed. $CpMg^+$ was the most reactive of the three ions.[70] Magnesocenes with substituted cyclopentadienyl ligands, including rings bearing methyl, trimethylsilyl, *tert*-butyl, and methoxy substituents are known. The recently determined solid-state structure of $Mg(C_5Me_5)_2$ reveals the presence of both staggered and completely disordered conformers.[71] The substituted-ring species form stable adducts with N-heterocyclic carbenes.[72]

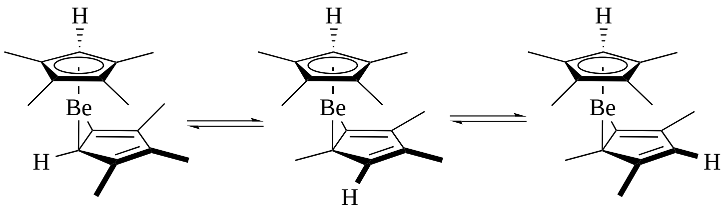


(54)

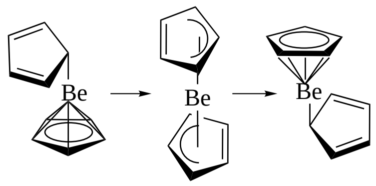
Dicyclopentadienylberyllium[10] has a substantial dipole moment, indicating an unsymmetrical structure. A variety of structures have been proposed, based on different experimental data. The molecule adopts a 'slip-sandwich' structure in the solid and vapor, with the Be atom disordered equally over two sites, and the two rings η^5 and η^1 bonded. Equation (54) depicts the Be atom disorder in the solid-state structure. The metal–ligand bonding is relatively weak: a sharp singlet is observed in the ^{1}H NMR down to −135 °C, indicating rapid averaging of the environments of the two rings. Molecular dynamics calculations credit two ultrafast (activation energies of less than 10 kJ mol^{-1}) processes, a 1,5 sigmatropic shift of the Be(η^5-C_5H_5) unit around the periphery of the η^1- ring (depicted in Scheme 11 for $Be(C_5Me_4H)_2$), and a ring/molecular inversion that interchanges the η^5 and η^1 rings (Scheme 12), for the isomerization.[73] BeCpX complexes (X = H, Cl, Br, Me, CCH, C_5Me_5, BH_4, B_3H_8, B_5H_{10}, and $SiMe_3$ (Section 6.7)) appear to be monomeric in all phases, with C_5H_5–(centroid)–Be distances, where determined, similar to that of the η^5-bonded ring in $Be(C_5H_5)_2$ (147 pm). X-ray diffraction reveals that while the octa- and nonamethylberyllocene derivatives $(C_5Me_4H)_2Be$ and $(C_5Me_4H)Be(C_5Me_5)$ exhibit slip-sandwich η^5/η^1 structures (where the η^1 ring bonds Be via the secondary, i.e C–H carbon), the deca methyl derivative $Be(C_5Me_5)_2$ adopts a ferrocene-type η^5/η^5 structure with parallel rings.[74] Insertion of an isocyanide into the Be–$\eta^1$$(C_5Me_4H)$ σ bond of $(C_5Me_4H)Be(C_5Me_5)$ yields two different iminoacyl isomers (Scheme 13). As these isomers correspond to those depicted in Structure 11, they constitute chemical evidence for the proposed isomerization mechanism. Half-sandwich compounds (C_5Me_5)BeX, where X = Cl, Br, P(t-Bu_2), As(t-Bu_2), Me, t-Bu, CH_2CMe_3, and CH_2Ph have been prepared.[75]

6.5 Allylic and Benzylic Organomagnesium Compounds

Allylmagnesium compounds appear to undergo a rapid allylic shift of the magnesium between the two methylene



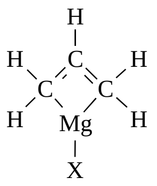
Scheme 11



Scheme 12

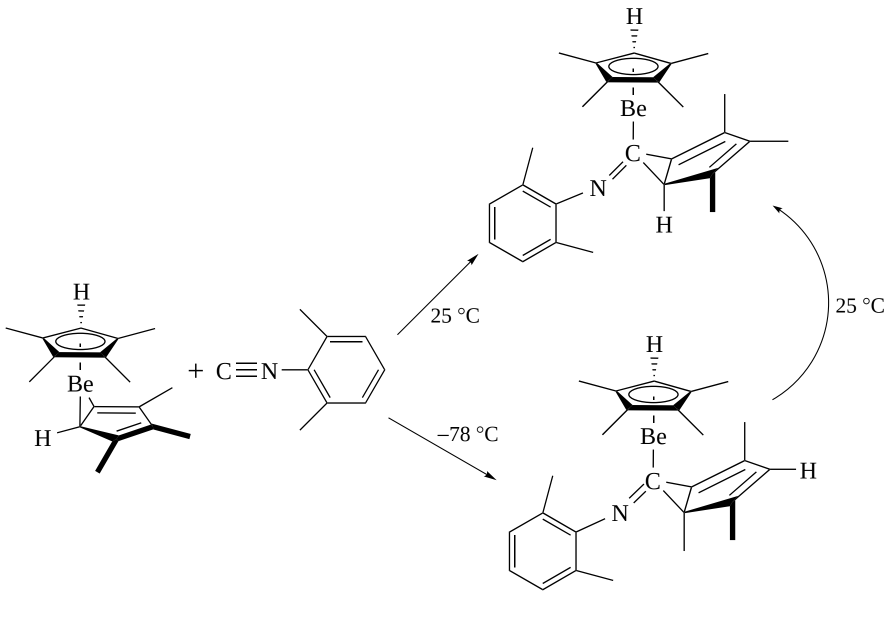
termini of the allyl group (equation 55). An alternative description is an allyl group symmetrically bonded to the magnesium, either covalently bridging η^3 as depicted in (**50**) or as an ion pair. Early NMR and IR data could not distinguish between these alternatives. More recent, higher field ^{1}H and ^{13}C NMR spectra are likewise ambiguous, in that low-temperature spectra exhibit extreme broadening as opposed to separate methylene resonances. IR spectra of 1,1- or 3,3-dideuterated allymagnesium bromide solutions reveal, however, a pair of bands due to the C=C bond stretch, consistent with the rapid equilibration of unsymmetrical allylic isomers.[76]

(55)



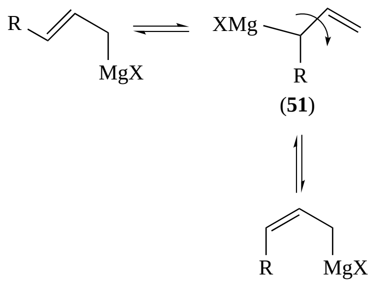
(**50**)

Alkyl substitution (equation 56) destabilizes the allylic isomer (**51**) with the more highly substituted α-carbon, so that it is not detected directly in the equilibrium mixture. However, cis–trans isomerization, rapid on the NMR timescale even at low temperature, likely occurs via rotation about the single bond in the low equilibrium concentration of (**51**). The position of equilibrium has been deduced from ^{1}H NMR coupling constants; with R = Me, the (Z)-isomer is favored



Scheme 13

by about 60:40, but steric hindrance with larger groups shifts the equilibrium toward the (E)-isomer.[77]



(56)

Both allylic and benzylic organomagnesium compounds appear to be more reactive than typical primary compounds. They also both show some tendency to react with rearrangement. In the equilibrium of equation (56), the primary structures dominate heavily, yet addition to carbonyl groups occurs almost exclusively at the secondary allylic position. It appears that this results from reaction of the primary isomers with rearrangement, rather than reaction of a very small equilibrium concentration of (**51**) without rearrangement. With hindered ketones the addition is slightly reversible, and at longer reaction times the less hindered product of addition at the primary allylic carbon appears.[78] A six-center cyclic transition state for addition with rearrangement has been proposed. In other reactions, for example, with Me_3SiCl, mixtures of allylic isomers are frequently formed. Benzylic Grignard reagents react partially at the ortho position.[79]

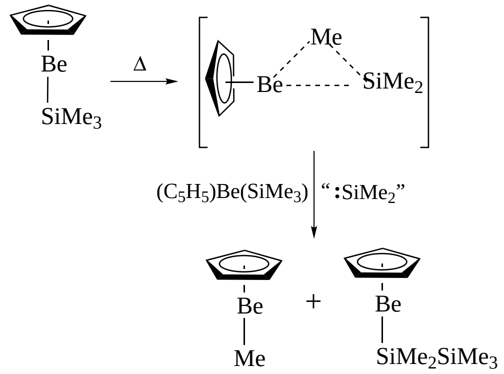
6.6 Acylmetal Compounds

Although beryllium metal is rather sluggishly reactive toward most organic halides, it reacts surprisingly easily with acyl halides in ethyl acetate to form acylberyllium halides. These react normally with ketones by addition, producing hydroxy ketones. With aromatic ketones, electron transfer appears to dominate, as the principal product from the ketone is the pinacol.

Carbon monoxide reacts with Grignard reagents, though more slowly than carbon dioxide. The initial reaction is a 1,1-addition to the carbon, resulting in an acylmagnesium halide. Despite potential applications of such species, the reaction usually leads to mixtures of products, and has not been developed synthetically.[80]

6.7 Bonds to Silicon[81]

Mg–Si bonds have long been inferred in reactions that generate hexaorganodisilanes from halo(triorgano)silanes and either a Grignard reagent or Mg metal (‘Silico-Barbier’ reaction). Similarly, the electrochemical reduction of chloro(triorgano)silanes with sacrificial Mg electrodes yields polysilanes in high yield.[82] Silyl ‘Grignard’ reagents are prepared from magnesium halides and alkali metal silyls. Unlike the symmetrically Br-bridged alkyl Grignards (compare Structure 10), the tetramethylethylenediamine adduct of $(Me_3Si)MgBr$, while not strictly monomeric, exhibits pentacoordinate Mg, and Mg–Br bonds of significantly different lengths.[83] (*tert*-Bu_3Si)MgBr(THF), however, features tetracoordinate Mg with symmetrically bridging bromines.[84] Schlenk equilibria yield the bis(silyl) species, also accessible by metathesis reactions. A number of base adducts of $(R_3Si)_2Mg$, where R = Me, *tert*-Bu, or (Me_3Si),[85] have been characterized by X-ray diffraction. The Mg atoms adopt distorted tetrahedral configurations, with Si–Mg–Si angles between 115° and 133°, and Mg–Si bond lengths of 263 to 268 pm (278 pm for R = *tert*-Bu).



Scheme 14

Beryllium–silicon bonds are a recent development. They are likewise prepared by the reaction of the metal halide with alkali metal silyls, but unlike the Mg analogues, both of the well-characterized Be examples are base-free. While [(*tert*-Bu_3Si)BeCl]$_n$ is oligomeric, the molecular structure of (*tert*-$Bu_3Si)_2Be$ features a perfectly linear Si–Be–Si unit.[84] $CpBe(SiMe_3)$, prepared from CpBeCl and trimethylsilyllithium in pentane, exhibits an intriguing thermal chemistry. The identity of the primary thermolysis products, Scheme 14, implies the participation of silylene intermediates, a contention supported by DFT/NBO (density functional theory/natural bond order) analysis.[86]

Glossary

Aragonite – calcite: polymorph calcium carbonate minerals. Aragonite is orthorhombic, calcite is trigonal (=rhomboedric)
Collagen: the main protein of connective tissue (tendons, skin, muscle, etc.). It contains a lot of glycine, proline, hydroxyproline, and hydroxylysine. Another rare feature of collagen is its regular arrangement of amino acids (triple helix structure)
Corals: animals of the Cnidaria phylum (formerly Coelenterata), with a calcareous skeleton. Sea anemones and jellyfishes are Cnidaria without skeletons
Dentine: also called *ivory*; the inner hard tissue of the tooth. The bulk of a tooth is made up of dentine
Enamel: the outer layer covering the tooth
Frustule: the siliceous 'shell' or exoskeleton of a diatom. It is composed of two valves (epitheca and hypotheca), one overlapping the other, like a pill box and its cover
Mollusks: invertebrates having a soft unsegmented body usually enclosed in a shell. Mollusca mainly includes Bivalvia, Gastropoda, and Cephalopoda
Nacre: nacreous layer or mother-of-pearl; the inner shell layer in some mollusks
Odontoblasts: more or less columnar cells on the outer surface of the pulp of a tooth; specialized cells that contribute to many aspects of tooth structure and function. They give rise to the dentine matrix that underlies the enamel of a tooth
Otoliths: earstones, are small calcareous structures found in the head of all bony fishes (other than sharks, rays, and lampreys)

Abbreviations

ACC = Amorphous calcium carbonate; RNA = Ribonucleic Acid; TEM = Transmission Electron Microscope; XANES = X-ray Absorption Near Edge Structure.

1 INTRODUCTION

Biomineralization is widespread in the biosphere (more than 60 different minerals are produced by 55 phyla, from bacteria to humans) (Figure 1), and refers to the process by which living organisms form minerals.[1] Biominerals have morphological, chemical, and physical properties that are very different from the crystal habits produced inorganically. The main role of these 'biominerals' is mechanical reinforcement of tissues and organs, but the resulting materials have biological functions as diverse as lenses, grinding or cutting appendices, gravity sensors, and guidance systems. One paradox is that these 'minerals' are not composed of only minerals. Organic matrices can be extracted from within these minerals (bone, coral skeletons, mollusk shells, etc.), which are hierarchically organized biocomposites. These specialized macromolecules are involved in biomineralization processes: they enable nucleation and growth of carbonates, phosphates, and other inorganic materials.

2 BIOMINERALS: STRUCTURE AND COMPOSITION

Among all the minerals used by organisms, three categories are widely dominant: silica, calcium phosphates, and calcium carbonates. Calcium phosphate minerals are usually associated with 'vertebrates', where they form bone and the dentine and enamel of teeth. However, phosphate minerals are present in some 'invertebrate' shells, such as Brachiopods, whereas vertebrates used calcium carbonate minerals in eggshells and otoliths. Calcium minerals represent about 50% of all biogenic minerals.

2.1 Silica

The hydrated amorphous mineral silica (opal) is widely used by many plants and animals for structural purposes. Most skeletons are formed by unicellular organisms (diatoms Figure 2(a), radiolarians Figure 2(b)), but silica is also present within multicellular organisms (sponge spicules, plant

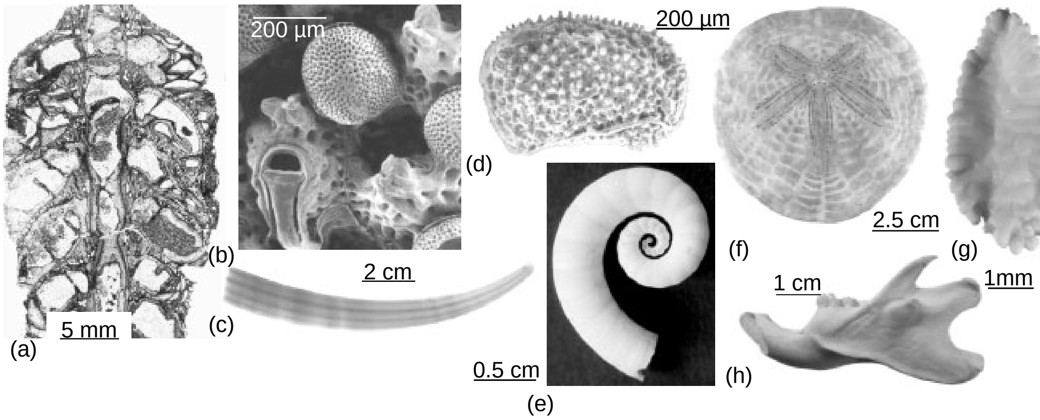

Figure 1 Some examples of mineralized skeletons: (a) Longitudinal section in a mineralizing sponge. (b) Zooids in Bryozoa. (c) Shell of a scaphopod (Mollusks). (c) A siliceous sponge (*Euplectella*) showing the highly organized spicule framework. (d) Transverse section of a giant spicule showing a concentric growing pattern (*Monoraphis*)

phytoliths). Diatom exoskeletons (=frustules) are composed of globular particles and consist of colloidal aggregates.[2] Sponges use specialized cells called *sclerocytes* to synthesize silica spicules, and the shape and arrangement of the spicules depend on the species (Figure 2(c)). The process of extrusion of the spicules is yet poorly understood, but the presence of an axial filament containing proteins suggests they are involved in the formation of the mineral (Figure 2(d)). The transverse section of a spicule shows regular growth lines and an annular organization of nanoparticles of about 70 nm in diameter.[3]

In diatoms (unicellular algae), silica is a composite material containing glycoproteins. The walls are almost pure hydrated silica with small amounts of Al and Fe.

2.2 Phosphates

The main part of the calcium phosphate minerals produced by organisms is crystalline and described as apatite. Nevertheless, this common name conceals a large variety of structures and compositions.

2.2.1 *Bone*

Bone is a true biological tissue, since it contains cells, and is continuously forming and reforming. Different levels of organization have been described, following the progress of microscopes. Adult bone is of two basic architectural, macroscopic types: compact or cortical, and cancellous or spongy, but there is no sharp boundary between them. In compact bone, most of the individual lamellae form concentric lamellae around longitudinal canals (50 µm in diameter) within the bone tissue. These canals typically run parallel to the surface and along the long axis of the bone. The canals and the surrounding lamellae are called a *Haversian system* or an osteon (Figure 3(a)). The cortical and trabecular bones have a hierarchical structure with three or four lower levels. Various models of the plywood structure have been described (Figure 3(b), (c)).[4–6] The basic level of organization is the

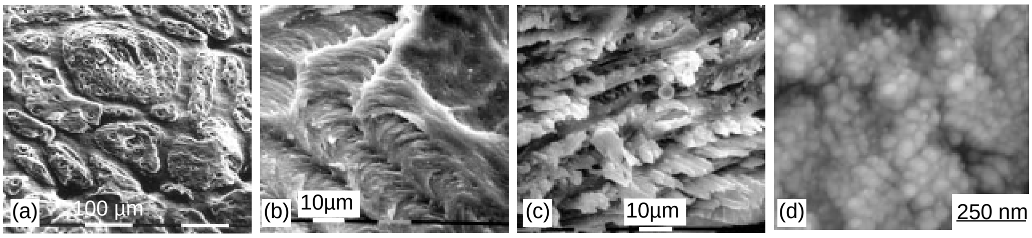

Figure 3 Structures of mammal bone: (a) Haversian systems and osteons. (b) Plywood-like structure with 'twisted' lamella. (c) Lamellar bone showing the different orientations of fibers in successive lamella. (d) Mineralized collagen fibers

relationship between the small crystallites and the organic matrix, mainly composed of collagen fibers. Crystal bones are probably the smallest biocrystals with average dimensions of $50 \times 25 \times 5$ nm.

The mineral fraction of bone is usually called '*hydroxylapatite*', 'carbonated hydroxylapatite', or dahllite. However, bone apatite contains carbonate ions but lacks hydroxyl ions. Polarized light and X-ray diffraction studies have shown that the bone crystal c axes are aligned with the collagen fiber axis. The organo-mineral composition of the bone is clearly shown by infrared spectra (Figure 4). The average chemical composition of mammal bone is illustrated in Figure 5. Na and Mg are mostly associated to the mineral fraction, but S is probably mainly associated with sulfated polysaccharides of the organic matrix. In modern mammals, it has been shown that some elements are sensitive to diet or pregnancy (Sr). The major organic component of bone is type I collagen, and the noncollagenous proteins or NCP contain more than 200 proteins. Four main groups of NCPs are found: proteoglycans, γ-carboxylated (gla)-proteins, glycoproteins, and 'others'. Chondroitin sulfate, heparan sulfate, and keratan-sulfate are present in the side chains of proteoglycans. Almost the entire mineral is found within the collagen fibers. The banding pattern of the collagen is about 70 nm. The alignment of small plates, the thickness of which is about 65 or 140 nm may reflect the collagen matrix (Figure 3(d)).

2.2.2 Dentine (=Ivory)

Dentine structure and chemistry vary between different species. For example, the rodent incisor is an ever growing tooth, and thus differs in the basis of dentine formation from that of the human tooth.

In reptile teeth, under the external thin enamel layer, the dentine shows numerous regular growth lines (Figure 6(a)). Dentine has a highly organized structure, and in reptile and mammal teeth has an array of parallel pores or tubules extending from the central pulp cavity to the dentine–enamel boundary. It is called *orthodentine* (Figure 6(b)–(d)). The average diameter of tubules is about 2 µm. Many other varieties have been described in the fish scales and dermal armors of fossil vertebrates.[7] In some taxa, the dentine may be divided into intertubular and peritubular dentine. The peritubular dentine forms a hypermineralized sheath around the dentinal tubule. The plate-like structures of the apatite crystals of the intertubular dentine have their c-axes parallel to the long axes of the collagen fibrils.

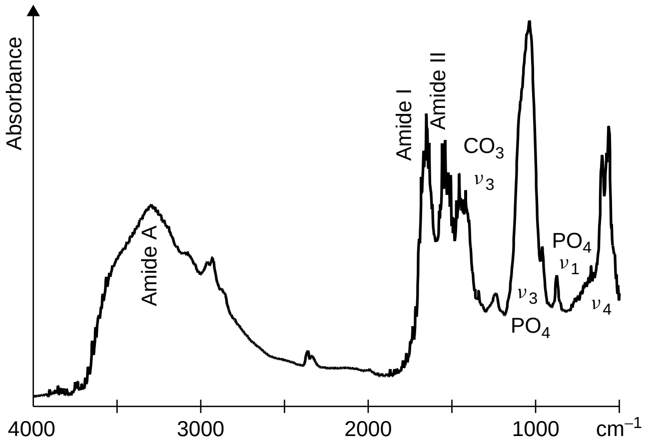

Figure 4 Infrared spectra showing the dual composition of bone with organic (amide) and mineral bands

In human teeth, the mineral fraction constitutes about 70% of the dentine by weight, and about 50% by volume. The average chemical composition is similar to that of bone (Figures 5, 7); however, due to the high Mg contents of ever-growing teeth in mammals (i.e. incisors in rodents and lagomorphs), the profiles are not identical. Sr contents are also different (Figures 5, 7). Ca/P ratio (by weight) is lower than that of bone. As in bone, the fibrous collagen I constitutes about 90% of the organic matrix. The intertubular dentine composition is very similar to that of bones, and consists of a fibrous network of collagen with deposited mineral crystals. The reported maximum differences in the mineral content between peritubular and intertubular dentines vary from 9% to 40%.[8] The peritubular dentine has high P, Ca, and Mg contents, but contradictory results are reported about the presence of collagen. In horse teeth, the peritubular organic matrix is less abundant than the intertubular matrix, both being mainly composed of collagen.[9] In human teeth, the organization of the crystals of peritubular dentine is very similar to that of the adjacent intertubular

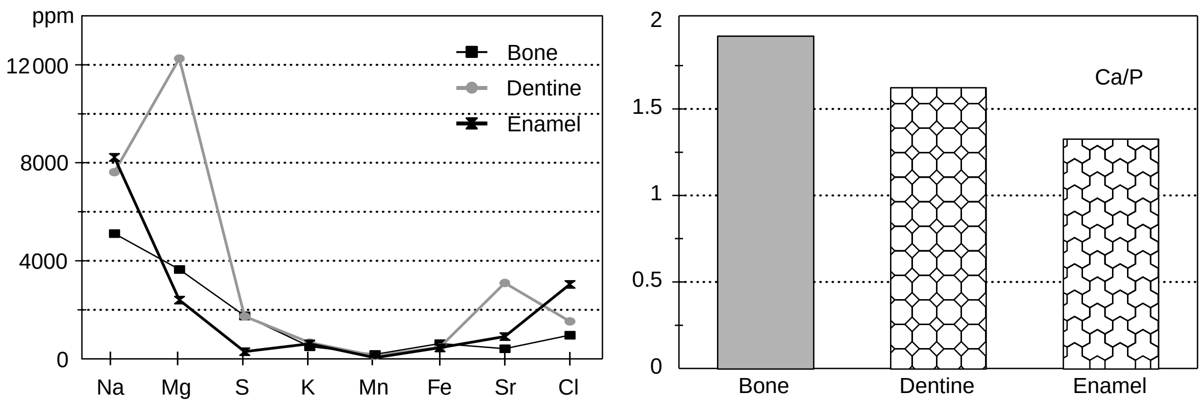

Figure 5 Chemical composition of mammal bone, dentine and enamel, and Ca/P weight ratios

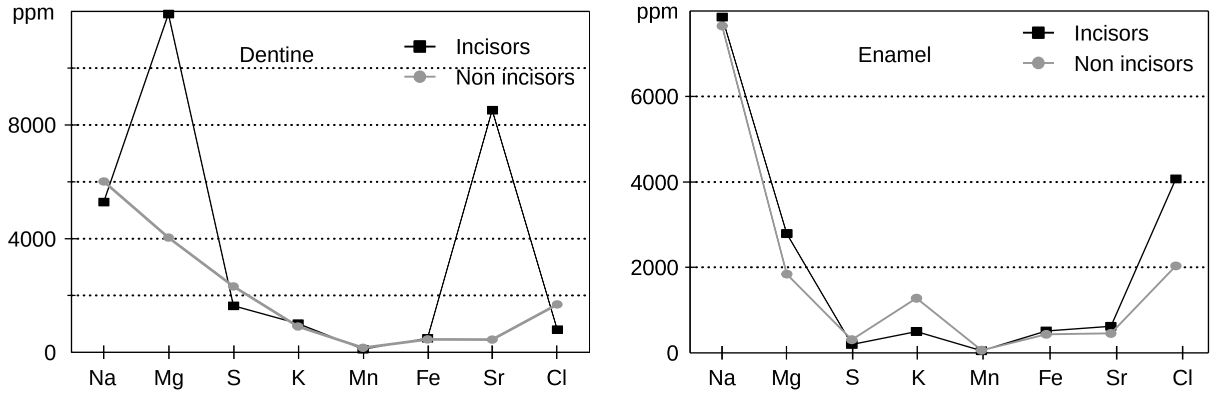
(b) Oblique section of orthodentine showing the tubules. (c) Oblique section of the orthodentine of a small mammal incisor showing the tubules. (d) Transverse section of the orthodentine of a small mammal tooth showing empty and filled tubules



(a) (b)

Figure 7 Chemical composition of rodent teeth: (a) Dentine, showing the difference in Mg contents between the ever-growing incisors and the other teeth. (b) Enamel, with no Mg difference between the ever-growing incisors and the brachyodont teeth

dentine. In human intertubular dentine, the apatite crystals are closely associated with the collagen matrix. The main protein in peritubular dentine has a higher molecular weight and a different aminoacid composition than the phosphophoryns of the intertubular dentine. Both dentines are in structural continuity.

2.2.3 Enameloid – Enamel

Enameloid and enamel compose the outer layer of teeth, and both are usually described as hypermineralized tissues, despite the fact that they differ in their structure, composition, and

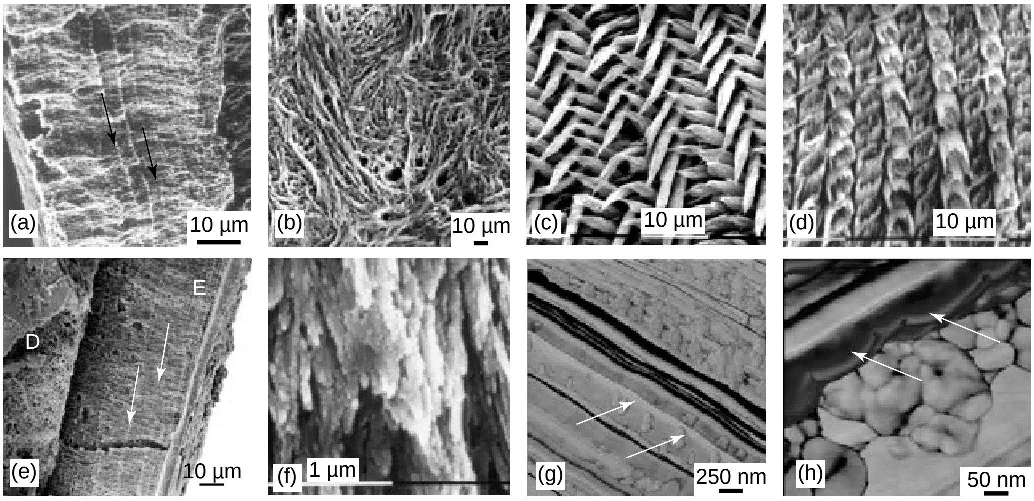


Figure 8 Structure of enameloid and enamel: (a) Ganoine, with incremental lines (arrows) in a fossil fish tooth. (b) Acrodin, with a complex structure, in a fossil fish tooth. (c) Complex and regular pattern of the prismatic enamel in a rodent incisor. (d) Another prismatic pattern in a rodent incisor. (g) Polished and etched section of a tooth of *Crocodylus niloticus*, showing parallel long rods with aggregates and layers of organic material (arrows). Atomic Force Microscopy (AFM) Phase image. (h) Detail of the same; arrows: layers of organic material

formation. Enameloid is the 'enamel' of fishes (Figure 8(a)), but there is a confusing variety of names (enamel, enameloid, collar ganoine, etc.), all of which lack adequate chemical or structural definitions. Another structure type present in fish teeth has been described: acrodin is composed of interwoven fibers (Figure 8(b)).[10] The main part of the enamel of mammal teeth is organized in 'prisms' or 'rods'. A prism is composed of parallel acicular crystals of enamel, and the arrangements of the prisms are variable (Figure 8(c), (d)). The tooth enamel has the most unusual morphology of the apatite biocrystals: mature enamel contains crystals that are tens of microns long with an aspect ratio (length/width) of at least 1000. The reptilian enamel is usually without prisms (Figure 8(e)), and is composed of parallel acicular crystals (Figure 8(f), (g)). In recent crocodile teeth, waves of an organic matrix are present between the crystals (Figure 8(g), (h)). Their shape and location are similar to the small droplets and the rows of nanospheres of amelogenins observed in mammal enamel.[11]

The tooth enamel has the most unusual morphology of the carbonate-apatite (dahllite) crystals. In mature enamel, the mineral part may reach 98% by weight (=90% by volume). Mammal enamel has a low Mg and S content compared with the bone and dentine (Figure 5). There is no difference in Mg contents of ever growing and brachyodont teeth (Figures 5, 7). The low S content is probably related to the low organic contents of the tissue. Unlike bone, the enamel organic matrix does not contain collagen. Enameloid is usually rich in F. There are distinct differences in the composition and distribution of sulfated glycoconjugates in enameloid and enamel. The fish enameloid contains chondroitin sulfate associated with collagen fibrils. The reptile aprismatic enamel has no sulfated glycoconjugates, whereas in the mammal prismatic enamel sulfated glycoconjugates are detected preferentially in the surface layer.[12]

2.3 Carbonates

2.3.1 Structure

Calcium carbonate minerals ($CaCO_3$) are ubiquitous in biomineralizing systems, since they are in the skeletons of organisms ranging from bacteria and algae to humans, most commonly as calcite (rhomboedral) or aragonite (orthorhombic). Thus, their structures and compositions are highly diversified. Here, only some examples are discussed.

The most studied taxa is the Mollusks, since the pioneering work of Boggild on the microstructure and mineralogy of modern and fossil shells.[13] Mollusk shells are composed of calcite and/or aragonite, usually separated in different layers. Boggild has classified the structures, has shown that the mollusk shell is layered, and that the spatial distribution of the shell layers is characteristic of the taxa at the genus-species level. Moreover, these structures are characteristic of Mollusks and are not found in other taxa. Of these layers, the best known, but not the most common, is the nacreous layer (Figure 9). The wall of bricks where bricks are 'mineral tablets', and mortar is interlamellar and intercrystalline organic membranes, is a common feature of the nacre (Figure 9(a)). However, the shapes and vertical arrangements of the nacreous tablets are different in the Cephalopoda and Gastropoda on one hand (Figure 9(b)), and the Bivalvia on the other

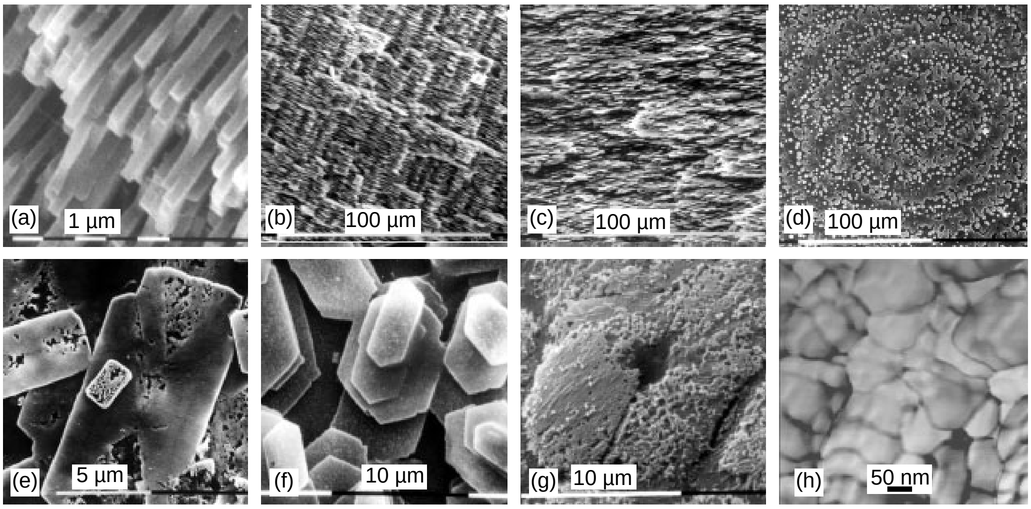

Figure 9 Structure of the aragonitic nacreous layer (mother-of-pearl) in mollusc shells: (a) Typical tablets in *Nautilus* shell (Cephalopod). (b) Vertical section showing the pseudoprismatic pattern of the nacreous layer in Cephalopods and Gastropods.(c) Vertical section showing the lenticular pattern in Bivalves.(d) Tangential section showing the nonsuperposition of the successive tablets in Bivalves and the resulting spiral pattern.(e) Detail of the structure of a tablet of *Pinna* (Bivalve) showing the twin and symmetrical more or less soluble sectors after an enzymatic etching. (f) Tangential section showing the superposition and the hexagonal shape of the successive tablets in a cephalopod shell. (g) Etched tablet of a cephalopod shell showing the 'central hole' and the radial sectors. (h) Rounded granules in a tablet of *Nautilus*. Each granule is surrounded with a thin layer, probably composed of organic materials

hand (Figure 9(c), (d)).[14] This taxonomic dependence and the different growth modes in the two sets were confirmed.[15] Using elaborate preparative processes, Mutvei has shown that the inner structures (= ultrastructures) of the tablets are different in the three main classes of Mollusks: Bivalvia (Figure 9(e)), Gastropoda, and Cephalopoda (Figure 9(f), (g)).[16] Again, the ultrastructures in the two sister groups (Gastropoda and Cephalopoda) are more similar than that of the Bivalvia. The ultrastructures, now called *nanostructures*, are not yet well known and only some samples have been studied. However, the acicular crystallites of the nacreous tablets of cephalopod shells are composed of granules (diameter about 40–50 nm), surrounded with a thin organic envelope (Figure 9(h)). The arrangement of the granules seems dependent on the taxa. Thus, from this example, it appears that the structures, the spatial distribution, and the ultrastructures are strongly dependant on the taxonomy of the organisms, that is, the organisms fully control the minerals they produce.

Another example is given by the calcitic prismatic layer of Pteriomorphid bivalves (Figure 10). The remarkable form and size of these crystals have been recognized for many years.[17] According to Taylor *et al.*, the prisms of *Pinna* and *Pinctada* are similar and called '*simple prisms*': simple prisms are aragonitic or calcitic, their crystallographic *c* axes normal to the layer surfaces, with each prism separated by a thick conchiolin wall.[18] Calcitic prisms have transverse striations, whereas aragonitic prisms have longitudinal and fewer developed transverse striations. The thickness of the organic wall varies from 1 to 8 µm. Nevertheless, repeated observations have shown some differences between the two shells. In *Pinctada*, thin sections observed in polarized light show that each prism extinguishes in several smaller blocks, whereas the individual prism of *Pinna* exhibits a monocrystalline extinction.[13,19,20] Untreated fractures of *Pinna* show long straight parallel prisms with a more or less smooth surface (Figure 10(a)). Occasionally, the surface shows a transverse lineation (Figure 10(b)). Etched transverse sections show the thick organic interprismatic walls and the polygonal shape of the prisms (diameter 70 µm) (Figure 10(c)). These prisms are composite units: on longitudinal sections, transverse synchronous growth lines cross the adjacent prisms (Figure 10(d)). They are composed of aligned oblique and elongated crystallites, the width of which varies from 150 to 180 nm (Figure 10(e), (f)). These crystallites are subdivided into smaller rounded units with distinct boundaries, suggesting that they are surrounded by organic envelopes. The etched longitudinal sections of *Pinctada* also show transverse growth lines (Figure 10(g)). Nevertheless, in transverse sections, enzymatic hydrolyzes reveal intraprismatic sinuous lacunae that are the remains of intraprismatic organic membranes (Figure 10(h)). The orientations of crystallites on both sides of these intraprismatic membranes within a prism are not similar.

Despite their monocrystalline habit, the nacreous tablets and the prismatic units of Mollusks shells are composite structures. We do note that these complex structures are rarely visible on simple fractures of the shells, but enzymatic hydrolyzes or/and acidic etchings are effective from this point of view.

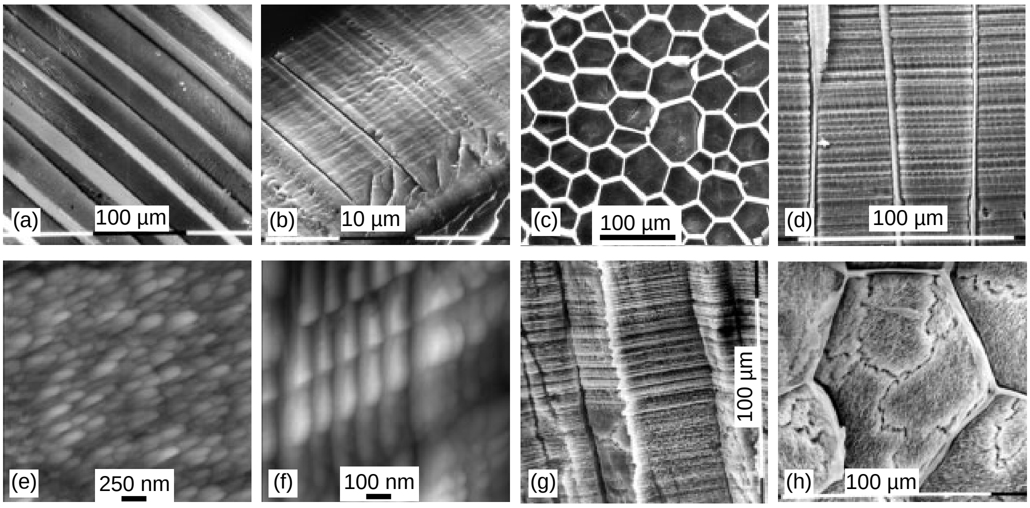

Figure 10 Structure of the outer calcitic prismatic layers of two Bivalve shells: (a) Fracture showing the parallel and straight prisms in *Pinna*. (b) Detail of the same, showing fragments of the interprismatic organic wall and a transverse growth striation in *Pinna*. (f) Fixed and etched prism of *Pinna*, showing the regular arrangement of the longitudinal face. (g) Enzymatic hydrolysis of a fracture of the prisms of *Pinctada*, showing the thin transverse growth lines. (h) Transverse section of the same sample, showing the preserved organic interprismatic wall and the inner prismatic membranes destroyed by the enzymatic hydrolysis

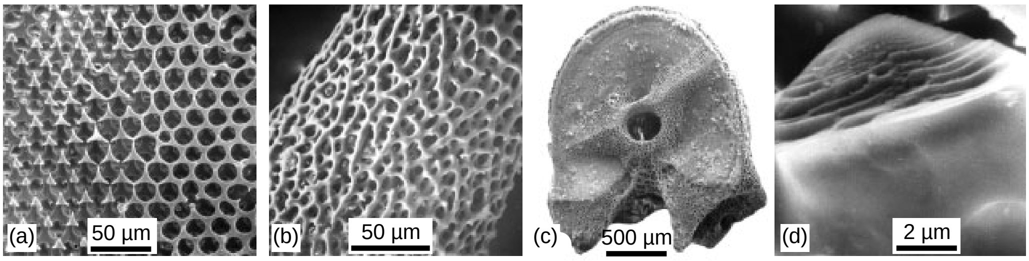

Figure 11 Spongy stereom of Echinoderms: (a) Sea urchin plate showing the various stages of the spongy stereom. (b) Starfish: in this article, the stereom is less regular. (c) Ophiurid vertebrae. The whole structure is a single crystal of calcite. (d) Conchoidal fracture of a sea urchin spine

Opposite to the mineralogical and structural varieties of the mollusk shells are the echinoderm skeletons. All of them show the same microstructural pattern: a calcitic spongy stereom (Figure 11(a)–(c)). Urchin spines and plates are composed of one single crystal of calcite, according to polarized light and X-ray diffraction. However, the fracture surfaces are conchoidal and do not show the cleavage planes of inorganic calcite (Figure 11(d)).

2.3.2 *Composition*

The organisms strongly control not only the shapes of the biominerals, but also their chemical compositions. Within an uniform 'mineralogy' (calcite or aragonite), the contents in minor and trace elements are strongly dependent on the taxa. Many skeletons are composed of Mg calcite, with Mg contents greater than 10 mol% (the maximum content of thermodynamically stable magnesium calcite) and some as high as 40 mol%.[21] Echinoderm tests are composed of high Mg calcite, whereas mollusk shells have low Mg calcite shells; brachiopod shell Mg contents are between them.[22,23] Chemical contents of aragonitic sponge, coral, and mollusk skeletons are also easily recognized with their Mg, Sr, and S contents (Figure 12(a)). The Sr/Mg substitution ratio or L coefficient is discriminant for the sedimentary aragonite, sponges, and corals and mollusk shells (Figure 12(b)).[24] Within a single taxa, within a single mineralogy, some chemical element contents differ. The coral skeleton is aragonitic, and composed of two parts: the centers of calcification and the fibers

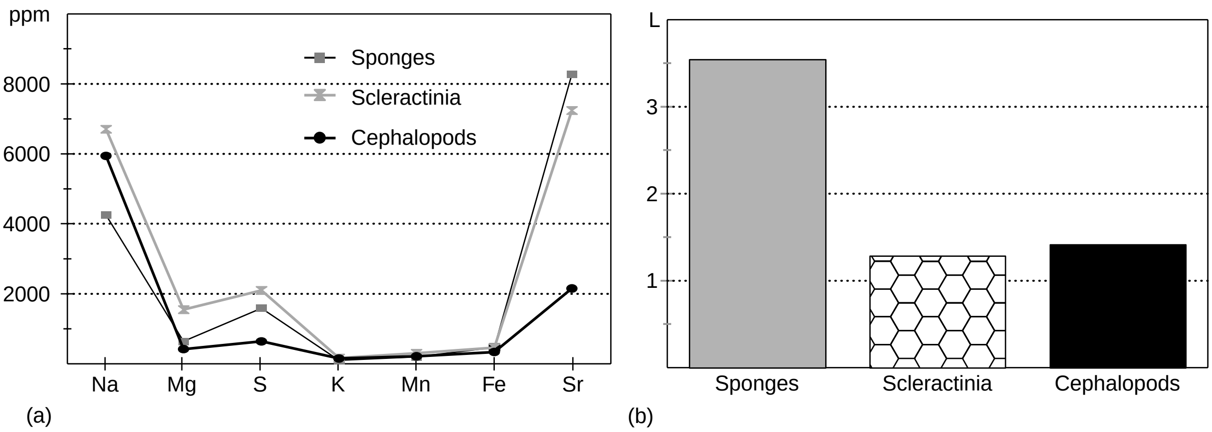

Figure 12 Chemical composition of biogenic aragonites: (a) Chemical composition of the biogenic aragonite of three taxa, showing the strong differences in Sr, Mg, and S contents. (b) Sr/Mg substitution ratio or L coefficient in the three taxa

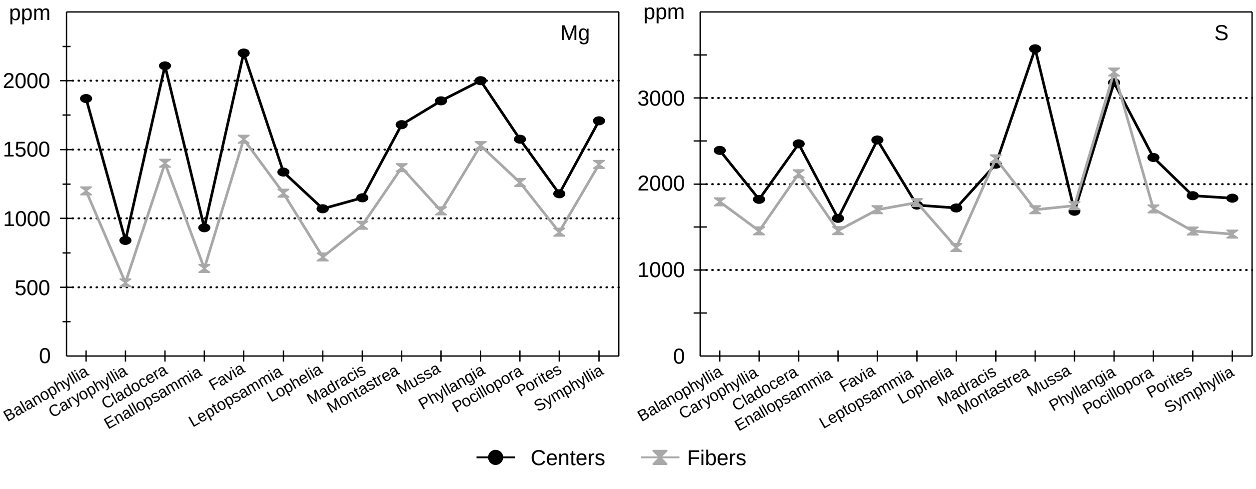

Figure 14 Chemical composition of the centers and fibers in various Scleractinia species

(Figure 13). It has been shown that the 'centers of calcification' are the first zones to mineralize in the septa.[25] According to the species, Mg, Sr, and S contents are significantly different in the centers and fibers (Figure 14).[26] Raman and XANES spectra have shown the absence of $CaSO_4$ in these samples, whereas XANES spectra and electrophoretic data have shown that S is associated with acidic sulfated sugars.[27] Similar results have been obtained in some Mollusk shells, in which the main component of S is related to organic sulfates.[28]

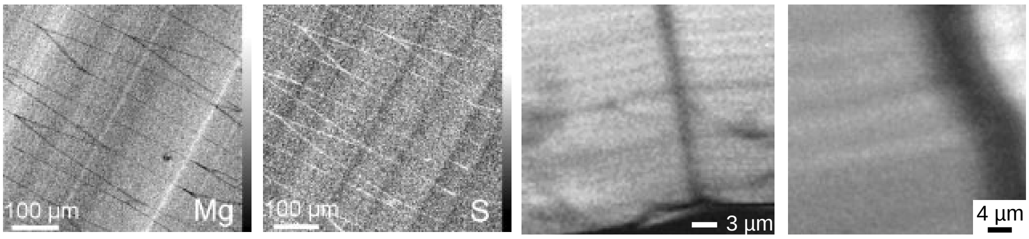

Figure 15 Qualitative chemical maps of the calcitic prisms of *Pinna* (1–3) and *Pinctada* (4): (a), (b) Electron probe maps showing the difference in the zonation in Mg and S, and the high S content of the organic interprismatic walls (C.T. Williams, Department of mineralogy, NHM, London); *Pinna*: average S content 5600 ppm, average Mg content 4600 ppm. *Pinctada*: average S content 3100 ppm, average Mg content 5800 ppm. (d) Organic sulfate map showing the low content of the interprismatic wall and the high content of the intraprismatic matrix. A growth zonation is also visible (M. Salomé, ID21, ESRF, Grenoble)

A growth zonation is usually observed in mineralized skeletons. Different chemical mappings show that this zonation is also compositional. Electron probe maps of Mg and S of longitudinal sections of the calcitic prismatic layer of *Pinna* clearly show the organic composition of the thick walls, lacking Mg and rich in S (Figure 15(a), (b)). It must be noted that the inner part of the prisms show in both maps a different growth zonation. SO_4 maps of the prisms show that the interprismatic wall has a low sulfate content (Figure 15(c)), whereas the inner part has a high sulfate content. Moreover, there is a sulfate growth zonation. Similar results were obtained on *Pinctada* prisms (Figure 15(d)). As for Scleractinia, sulfate is associated with the sugars of the organic matrix.[28,29]

Most shells or exoskeletons are made of crystalline minerals, but amorphous calcium carbonate (ACC) is also present. These biological ACC contain significant amounts of Mg, P and rich glutamic acid proteins.[30]

Mollusk shells are much tougher than inorganic calcium carbonate minerals, and it is still unclear exactly how the growth of these structures is controlled. It is known that the organic macromolecules released by the dissolution of biocrystals are key participants in the control processes of shape and structure in mineralized tissues. But chemical elements also regulate the biomineral properties and formation rates, and provide critical information on crystal growth history. The influences of biological processes on the elemental composition of biominerals, called '*vital effects*', seriously impede efforts to unambiguously interpret biogenic mineral compositions in terms of environmental reconstruction.

3 MODES OF BIOMINERALIZATION

Biomineralization involves the formation of minerals by organisms, and two different modes are summarized by Lowenstam and Weiner.[1] In the *biologically induced mineralization*, an organism modifies its local microenvironment to create conditions suitable for the chemical precipitation of extracellular mineral phases. It is the dominant process in fungi and bacteria.

The second mode is called *biologically controlled* or *organic-matrix-mediated biomineralization*, in which inorganic particles are grown within or on some organic matrix produced by the organism. It is the process in sponges, corals, echinoderms, and so on, in which the mineral units are aligned in a preferred direction. The unique structure and orientation of crystals, the morphology, and composition of these biominerals are clear indications that the processes of crystal nucleation and growth are highly controlled by the organisms. Organisms use macromolecules such as proteins and glycoproteins to control these molecular processes.

3.1 Silica

Biosilicate formation occurs at ambient temperature. Biosilicates grow in closed spaces, and the organic components influence the size and the shape of skeletal parts. In diatoms, the valve formation occurs within the cell. However, the mature mineralized wall is outside the cell. During the first stages of the cell wall development, small vesicles fuse to form the deposition silica vesicle, delimited by a membrane (silicalemna). This membrane is probably integrated in the diatom wall in the adult diatom. The mature diatom wall is composed of amorphous silica, but different forms of silica have been observed at different stages of growth: fibrils, spheres, hexagonal columns.[30] The transport form of intracellular Si is still very poorly understood. Silaffins (polycationic peptides), silicateins and frustulins have been identified as constituents of biosilica. In sponges, a protein (silicatein) is probably implied in the mineralizing process.[31] Silaffins are strongly basic low-molecular weight polypeptides. *In vitro*, silica formation at a pH > 7 is a very slow process. However, in diatoms the same process takes less than one hour.

3.2 Phosphates

The three main structural tissues of vertebrates, bone, dentine, and enamel, have different origin and behavior during the growth of the animal. Most teeth do not change once they are erupted, whereas the bone is continuously modified.

From a biological point of view, bone is a true tissue because it contains cells. Specialized cells are responsible for the replacement of preexisting bone, or remodeling, that takes place both in compact and trabecular bone. Bone remodeling involves the dual processes of bone resorption and redeposition. From TEM observations, it appears that the first step of formation is an ionic adsorption on a substrate, leading to nanoparticle nucleation. The size and orientation of the nanoparticles depend on the substrate.

Dentine is the first calcified tissue to be deposited during tooth embryogenesis by the odontoblasts lining the inner pulp chamber. Odontoblasts lay down the dentinal organic matrix, and the dentine formation proceeds inwards. The mineralization begins when an organic layer of about 10–20 μm thick was deposited, and only cells process encased in the dentinal tubules are present in dentine.

Enameloid and enamel have different structures and compositions, and differ in their genesis: enameloid is produced by both odontoblasts and inner dental epithelial cells; it is deposited before true dentine is formed, and usually includes collagen, epithelial derived proteins, and chondroitin sulfate; enamel is produced by ameloblasts after dentine was deposited; it grows centrifugally, and contains ectoderm-derived proteins (amelogenins and enamelins) but no collagen proteins. These components are almost fully removed throughout the maturation stage. Amelogenins, secreted by the ameloblasts, are believed to function as the scaffold for the initiation and growth of apatite crystals. Amelogenin molecules self assemble to generate nanosphere structures of 1–20 nm in diameter.[11]

In mammals, the eruption of the tooth occurs after the crown is formed, but the tooth gradually moves toward the surface during its development. Nevertheless, all the teeth are not similar and three categories can be recognized. Mammals that feed on abrasive substances have especially high-crowned teeth. These teeth are called *hypsodont*. The teeth of cows and deer are hypsodont. In some species, hypsodont teeth continue to grow throughout an animal's life (e.g. mouse, rabbit). The opposite condition, with a low-crowned tooth, is termed *brachyodont*. These teeth have closed roots and grow to a fixed length and stop erupting (e.g. human teeth).

3.3 Carbonates

From a biological point of view, calcareous shells and tests are not tissues: they do not contain cells, and are not directly produced by cells. For example, neither the calcitic prismatic unit of the *Pinna* shell nor the aragonitic nacreous tablet is the result of the secretion of a mantle cell. Crystals are generally formed in predefined closed spaces, delimited by extracellular macromolecular matrices. Again, the nacreous layer of the mollusk shell is the structure from which some models have been elaborated.

Transmission electron microscope studies have shown that the organic interlamellar membranes have a lamellar structure (Figure 16(a), (b)).[32,33] This structure varies according to the taxa. Some fenestrations or holes have been described, and they have been considered to favor the passage of fluid substances needed for the mineralizing process. The decalcification process of the nacreous layer, and later all the mollusc layers and 'invertebrate' tests, has shown

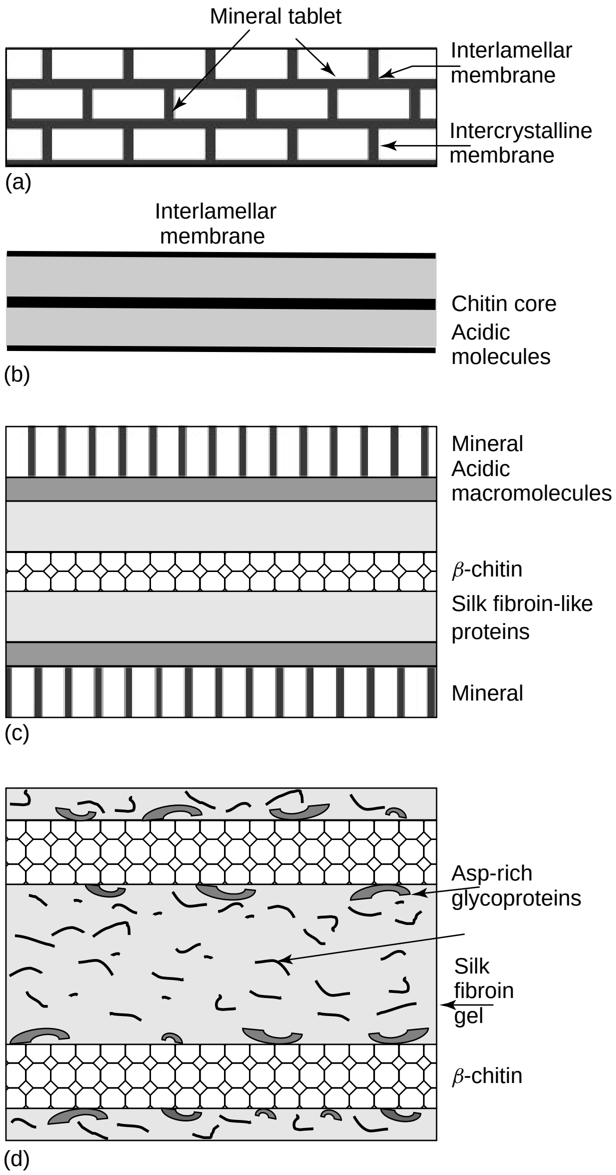

Figure 16 Successive models of the nacreous layer of mollusk shells

that soluble and insoluble organic matrices are present. From the composition of these matrices, and from the ultrastructures, Weiner and Traub have proposed a model (Figure 16(c)).[34] More recently, this model was improved, based on the study of a bivalve shell (Figure 16(d)).[35] Thanks to a fixative-decalcification process, the holes in the interlamellar membranes were not observed. However, the relationships between crystal morphology and surface interactions with the reactive groups of the organic molecules are unclear.

Besides organic growth modifiers, Mg and Sr play a primary role: the incorporation of Mg^{2+} has been shown to modify the morphology, solubility, and polymorphic expression of $CaCO_3$ biominerals. Furthermore, Mg is the principal inhibitor of calcite growth in natural waters. However, the fundamental mechanistic interactions of Mg with the calcite surface remain controversial. *In vitro* experiments show that Mg contents of ACC depend on the Mg/Ca ratio solution, and that Mg stabilizes ACC.[36]

3.4 Magnetite and Ferritin

Among other biominerals, magnetite crystals have a peculiar status. Magnetite biomineralization is a genetically controlled biochemical process having evolved about 2 billion years ago in the magnetotactic bacteria. Magnetite crystals (between 20 and 100 nm) have been extracted from bacteria and some mollusks (chitons).[1] They are arranged in a chain with gaps between the crystals. All the magnetite crystals that have been examined to date are single magnetic domains, and it has been suggested that hydrated iron oxide in ferritin (the major iron storage protein in living organisms) would be the precursor of biological magnetite.[37,38]

4 APPLICATIONS

Studies of biominerals and biomineralization have various applications, from biology to biomimetics.

4.1 Biology

The strict control of the organism on its skeletal units and their arrangement allows us to use the microstructure and composition as taxonomical and phylogenetical criteria. The example of the nacreous layer of the mollusk shells has been described, and reflects the phylogenetic data: similarities of structures (columnar pattern and radial sectors) between the two sister groups, cephalopods and gastropods, differences with the bivalves (noncolumnar pattern, four twinned sectors). Another example is found in scleractinia corals. There is a strong relationship between the spatial arrangement of the septal centers of calcification and the 28 S rRNA phylogeny.[39]

Minor element contents and isotopic ratios are used for physiological purposes. Sr/Ca ratios in bone and teeth are said to reflect the diet of the animal (herbivores versus carnivores). Stable isotope analysis of teeth and bones provides direct information on the lifetime diets: the nitrogen isotopes reflect the trophic level of the protein that has been consumed. Within an ecosystem, they can identify herbivores and carnivores, while the carbon isotopes tell mainly about the amount of protein in the diets from terrestrial *versus* marine ecosystems.

Another unexpected role of some skeletal pieces has been described.[40] Ophiuroids are a large group of Echinoderms that includes the brittlestars. They have five arms, superficially resembling true starfishes (Asteroidea), and can catch fast motile prey. Aizenberg and coworkers have found that calcite crystals in their skeletons act as optical receptors or lenses. However, it is not known whether the system of lenses and nerves is actually an 'eye'. However, these structures are absent in closely related but not light sensitive species of brittlestars.

Growth lines are a general feature of fossil and modern mineralized tissues: they are present in the enamel of a dinosaur tooth (Figure 17(a)), the calcitic dinosaur eggshell (Figure 17(b)), or the aragonitic fish otolith (Figure 17(c)). Otolith growth rings record daily age and growth patterns.[41] But the growth of all the calcified skeletons is not so easy to decipher (Figure 17(d)).

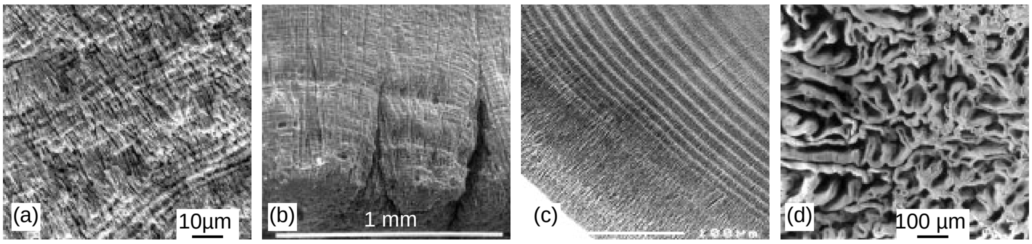

Figure 17 Growth lines: (a) Enamel of a dinosaur tooth. (b) Vertical section in a Dinosaur eggshell. (c) Polished and etched section of a fish otolith. (d) Complex structure of a fossil cephalopod shell (*Belopterina*)

4.2 Geology

Biominerals are strongly dependent on the taxonomy of the organisms, and they are also dependent on the environment. So, modern skeletons can be used as 'proxies' because they record the environmental conditions. Still, the biominerals have another advantage: they have a geological history. Carbonate and phosphate skeletons are known from 540 my, and they can be used as 'paleoproxies'.

Urey *et al*. have shown that the $^{18}O/^{16}O$ ratios in marine carbonates depend on the temperature and on the $^{18}O/^{16}O$ ratios in seawater.[42] Subsequently, they established an isotopic temperature scale based on marine biogenic carbonates. This first 'stable oxygen isotope' study shows the climatic changes during the Cretaceous from belemnitid rostra (Mollusks, Cephalopoda). However, Urey and coworkers were already aware of the physiological factor, so that the $^{18}O/^{16}O$ ratios in biogenic carbonates are not fully dependent on the temperature. This disequilibrium phenomenon was called 'vital effect'. The importance of the 'vital effect' differs according to the taxa. The aragonite deposited by corals is usually depleted in ^{18}O relative to values of isotopic equilibrium with ambient seawater.[43] Moreover, the amplitude of the disequilibrium is different in each coral genus. Recently, the study of *Lophelia*, a deep-sea coral, has shown that the $\delta^{18}O$ in the centers of calcification and in the surrounding fibers are clearly different.[44] Moreover, there is a strong contrast between the homogenous $\delta^{18}O$ values of the centers of calcification and the variable $\delta^{18}O$ values in the fibers. Explaining several per mil variations in a few microns between the centers of calcification and the adjacent fibers is difficult, as both grow from the same fluid simultaneously. In the same species, XANES mapping has shown an exact correspondence between concentration of sulfated polysaccharides and centers of calcification.[27] This result suggests that heterogeneity in isotopic fractionation could be due to the influence of specifically secreted organic mineralizing matrices known to control both crystallization patterns and minor element concentrations.

The presence of the organic matrices included in biominerals must be taken into account in another phenomenon: fossilization. This is well evidenced in bone: as soon as the animal is dead, bone cells release proteases that hydrolyze the organic matrices. DeNiro and Weiner have shown that the $\delta^{13}C$ of fossil and archaeological bones greatly varies according to the preservation of the organic matrices.[45] The diagenetic changes induced in nitrogen isotopic ratios, used for paleophysiology reconstruction (diets) are not yet known. Thus, the usual control of the mineralogy performed on carbonates, bones, and teeth is not sufficient to assert the absence of diagenetic changes. The loss of the organic matrix is not correlative of mineralogical or minor element content changes.

The chemical element compositions of biogenic carbonates reflect the environments in which they formed, resulting in their use as paleoclimate indicators. In aragonite, the Sr contents and the temperature have a negative correlation, and *in vitro* experiments have shown that in calcite, Mg and Sr contents and temperatures have a positive correlation.[46,47] Thus, the Mg/Ca and Sr/Ca ratios have emerged as temperature proxies due to their reduced susceptibility to changes in salinity. But, again, fossil carbonates are altered by diagenetic processes, even if the mineralogy and structure do not seem modified.

4.3 Aquaculture

Otoliths ('earstones') are small calcified structures found in the head of bony fishes. They are an important tool for understanding the life of fish populations. The growth lines and isotopic ratios of otoliths are used to know the migrations of marine fishes, because they are sensitive to salinity and temperature. Then, the obtained results are helpful to control these parameters in cultivated fishes. In mollusk shells, diseases are usually early diagnosed thanks to shell abnormalities and malformations. These data are then used for fossils and paleoenvironmental reconstructions.

4.4 Medical Uses

For hundreds of years, natural and synthetic materials have been used as substitutes for damaged bones and teeth. Among these materials, some corals have been successfully used to replaced pieces of bones. The porous microstructure of these corals, and the abundance of the acidic sulfated sugars in the organic matrices of their skeletons is probably the main favorable factor. The coral micropores favor the settlement of bone cells which produce bone (osteoblasts), and cells which resorb bone (osteoclasts). Thus the coral skeleton is progressively resorbed and replaced by the bone, according to the usual bone remodeling process. Depending on the size of the coral graft, in some months or some years, all the coral is removed and replaced by the new bone. Now, powder or liquid composites containing coral skeletons are used. At last, there is a demand for low-temperature processing techniques with environmentally friendly materials.

Glossary

Cubane: a common geometry adopted by many inorganic cluster complexes of formula A_4B_4 where A and B represent two atom types which occupy alternating vertices of a cube. These atoms may have ligands or other functionalities attached

Stereochemcially active lone pair of electrons: a complex whose observed structure includes a coordination site which is occupied by a lone pair of electrons. Conversely, a complex which contains a stereochemically inactive lone pair of electrons is one in which the geometry does not show a specific vacant site where the electron pair should reside

Abbreviations

Me = Methyl; Et = Ethyl; Ph = Phenyl; hmpa = Hexamethylphosphoramide [$OP(NMe_2)_3$]; THF = tetrahydrofuran; DME = dimethoxyethane.

1 INTRODUCTION

Bismuth, element 83, is a soft gray naturally occurring metal. It is most commonly found as bismite (Bi_2O_3), bismutite ($(BiO)_2CO_3$), or bismuthinite (Bi_2S_3). Bismuth is produced as a by-product of copper and lead smelting. It is the heaviest member of group 15 and the heaviest stable element. While there are many isotopes known, it is found naturally only as $^{209}_{83}Bi$ with a nuclear spin of 9/2. A number of physical properties are summarized in Table 1. Because of its low-melting point, high boiling point, and low neutron absorption cross section, it has found application as a coolant in nuclear reactors. Among metals bismuth is unique: it is the most diamagnetic, has the lowest thermal conductivity, and exhibits the highest Hall effect. The element expands upon solidifying, a property that has been used in the printing industry to produce type with clear well-defined edges.

Bismuth crystallizes as rhombohedral crystals with lattice constants $a = 4.5495$ Å and $c = 11.86225$ Å for space group $R\bar{3}m$ (hexagonal setting). The density of the metal is 9.747 $g{\cdot}cm^{-3}$. When crystallized from molten salt fluxes, elemental bismuth forms highly intricate crystals clearly showing step dislocations (an attractive collector's item often found at commercial gem and mineral shows). The surface of the element is usually tarnished by air oxidation, giving it an appealing multicolored sheen. The chemistry of bismuth may be compared to that of phosphorus, arsenic, and antimony, the lighter members of group 15 (*see* ***Phosphorus: Inorganic Chemistry***; ***Arsenic: Inorganic Chemistry***; ***Antimony: Inorganic Chemistry***). While there are numerous similarities, there are also important differences, many of which arise due to the increasing diffuseness of the s^2 electrons. This means that the +5 oxidation state is found less often and is less stable for bismuth than for phosphorus, arsenic, and antimony. Very few inorganic complexes are known in which bismuth is in the +5 oxidation state. Exceptions include $NaBiO_3$, BiF_5, and salts of the complex ion $BiF_6{}^-$. An extensive series of organobismuth(V) compounds based on the formula $BiAr_3X_2$ (Ar = aryl) are known (discussed in *Bismuth: Organometallic Chemistry*). Bismuth is, on the other hand, easily oxidized to Bi^{III}, which is its most common oxidation state. The element reacts with dilute nitric acid, hot sulfuric acid, and concentrated hydrochloric acid, giving bismuth(III) salts. Bi^+ has been observed in solid-state phases and molten salts, but is rare. This formal oxidation state is also found in the unstable R_2Bi^- generated as intermediates in the reduction of R_2BiX. Other formal oxidation states which have been reported include Bi^{2+} in tetraorganodibismuthines and Bi^{3-} in BiH_3 and in the alkali metal phases M_3Bi (M–Li, Na, K, Rb, Cs). As will be detailed below compounds of bismuth are important for their biological activity, as high T_C superconductors, and as oxidation catalysts. Bismuth chemistry has been compiled in the Gmelin series[1] and in *Comprehensive Inorganic Chemistry*.[2] Some aspects of the structural chemistry of bismuth are also treated in *Structural Inorganic Chemistry*.[3]

2 COMPOUNDS OF BISMUTH

2.1 Intermetallic Compounds

2.1.1 Antimony Compounds

Not surprisingly, bismuth forms solid solutions with antimony. Recent work has shown that $Bi_{1-x}Sb_x$ nanowires and films can be deposited electrochemically.[4]

Table 1 Physical properties of elemental Bi

Atomic weight	208.98 amu
Melting point	271 °C
Boiling point	1560 °C
ΔH fusion	10.48 kJ mol^{-1}
ΔH vaporization	179.1 kJ mol^{-1}
Density	9.747 g cm^{-3}
$S°$ (298.15 K)	56.74 J K^{-1} mol^{-1}
C_p	25.22 J K^{-1}mol^{-1}
Electrical resistivity	106.8×10^{-8} Ωm (273 K)
Thermal conductivity	7.87 W m^{-1} K^{-1}
Mass magnetic susceptibility	-1.684×10^{-8} kg^{-1} m^3 (s)
Coefficient of linear thermal expansion	13.4×10^{-6} K^{-1}
Electronegativity	2.02 (Pauling)
	1.67 (Allred)
Radii: ionic Bi^{5+}	0.74 Å
Bi^{3+}	0.96 Å
atomic	1.55 Å
covalent	1.52 Å
van der Waals	2.40 Å
Ionization potentials:	
1st	703 kJ mol^{-1}
2nd	1609 kJ mol^{-1}
3rd	2466 kJ mol^{-1}
4th	4370 kJ mol^{-1}
5th	5403 kJ mol^{-1}

2.1.2 Alkali Metal and Alkaline-earth Metal Compounds

Bismuth with a formal oxidation state of −3 is found in solid-state phases M_3Bi (M = alkali metal) and M'_3Bi_2 (M′ = alkaline-earth metal). The compound Na_3Bi is metallic. Less reduced intermetallic phases with the alkali metals and alkaline-earth metals are also known. Examples include MBi (M = Li, Na), MBi_2 (M = K, Rb, Cs), and $M'Bi_3$ (M = Mg, Ca, Sr, Ba). The compounds $M'Bi_3$ (M′ = Ca, Sr, or Ba) superconduct at low temperatures. Some of these intermetallic phases have been extracted with amine solvents to yield anionic bismuth clusters in solution (see Section 2.8.2).

2.1.3 Transition Metal–Bismuth Intermetallic Compounds

A number of bismuth–transition metal phases have been tabulated.[2] Bi_2Ag, BiCu, BiCo (high-temperature, high-pressure phase), Bi_2Ir, Bi_4Mg to Bi_9Mg, Bi_3Mo, $BiRe_2$, BiRu, Bi_3Sn, Bi_3Te, Bi_3Zn, and $BiZr_3$ are reported to be superconducting at low temperatures.[5] The near stoichiometric BiMn compound known as Bismanol is a very strong permanent magnet material.[6] Bismuth does not form stable binary compounds with iron, chromium, or cobalt under ordinary conditions. The adsorption of Bi on to Au electrodes has been noted to activate the surface to electrocatalytic activity.[7] Ternary phases have also been examined. Direct fusion of alkali metals, indium, and bismuth leads to several alkali metal–indium–bismuth phases showing In-centered tetrahedra of bismuth that are corner- and/or edge-shared. These include $Na_3In_2Bi_3$, Na_3InBi_2, $K_7In_4Bi_6$, $K_{11}In_6Bi_9$, and $Rb_7In_4Bi_6$.[8]

2.1.3 Posttransition Metal Compounds of Bismuth

Bismuth is not miscible with cadmium. It is miscible with mercury but does not form any discrete compound. A simple eutectic system is observed with bismuth and zinc. A number of low-melting alloys are known such as Wood's metal (50% Bi, 25% Pb, 12.5% Cd, 12.5% Sn; mp 70 °C).[1,2] These alloys are often used as heating bath materials, in automatic sprinkler systems, fire detection devices, safety plugs in compressed gas cylinders, and so on. Alloys which contain more than 55% Bi expand on freezing and are used in the production of castings, type metal, and accurate dies. Bismuth and antimony are completely miscible and alloys with a small percentage of antimony show large galvanothermomagnetic effects. Bismuth forms compounds of formula MBi with M = In or Tl. In addition, In also forms the compounds In_5Bi_3 and In_2Bi, which are superconducting at low temperature.[9] Bismuth phosphide has been prepared by reaction of $BiCl_3$ and $P(SiMe_3)_3$.[10]

2.2 Bismuth Hydride

Bismuthine, BiH_3, a thermally unstable compound which decomposes above −45 °C, was first prepared in 1961.[11,12] More recently, the compound has been reexamined in order to confirm its existence and physical properties, both experimentally and computationally.[12,13] It is best prepared at −45 °C by the disproportionation of $MeBiH_2$ or Me_2BiH, which are formed from the reaction of the appropriate organobismuth halides with reducing agents such as $NaBH_4$ or $LiAlH_4$. It may also be prepared by the reaction of a Mg/Bi alloy with HCl or of $BiCl_3$ with $LiAlH_4$ at low temperature. The boiling point has been estimated to be 16.8 °C and the heat of formation 277 kJ mol^{-1}. The compound (2,6-$C_6H_2(CH_3)_2H_3C_6)_2BiH$ was recently been isolated as the first example of a stable bismuth hydride.[14] It derives its stability from the bulky organic protecting groups. Bismuthine has been used in the manufacture of silicon and germanium semiconductors. Because of its instability the chemistry of BiH_3 has not been extensively investigated.

2.3 Bismuth Halides, Pseudohalides, and Complex Halo Ions

Reaction of elemental bismuth with the halogens at elevated temperatures leads to the production of BiX_3. Properties of the trihalides are summarized in Table 2. Bismuth is first oxidized by F_2(g) to BiF_3, with conversion to BiF_5 occuring above 600 °C. The latter is the only known homoleptic bismuth(V) halide, although organic derivatives of the form

Table 2 Physical properties of bismuth halides

	Mp (°C)	Bp (°C)	$\Delta G°_f$ (298 K, kJ mol^{-1})	Density (g cm^{-3})	$d_{Bi–X}$ (Å)	$\nu_{Bi–X}$ (a_1) (cm^{-1})
BiF_3	725					
$BiCl_3$	233	441	−314.6	4.750	2.50	280
$BiBr_3$	219	462	−247.7	5.720	2.63	196
BiI_3	409	542	−148.7	5.640	3.07	145

Ar_3BiX_2 (Ar = aryl; X = F, Cl, Br) are well known. BiF_5 is a very powerful oxidizing and fluorinating agent.

The bismuth(III) halides are moisture sensitive and are readily converted into the oxyhalides BiOX (equation 1). Addition of acid to aqueous suspensions of the oxyhalides will regenerate BiX_3, which exist as complex halo anions in solution. Addition of ammonium hydroxide to such solutions results in the formation of insoluble $Bi(OH)_3$, which is easily dehydrated to the oxide.

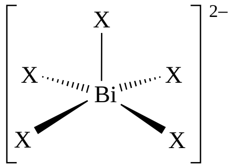
$$BiX_3 + H_2O \longrightarrow BiOX + 2HX \qquad (1)$$

$BiCl_3$ is very easily hydrated and commercial samples may need to be dried or sublimed if anhydrous material for use in sensitive reactions (e.g. with Grignard reactions) is required. Refluxing a thionyl chloride suspension of $BiCl_3$ is an effective method for dehydrating the solid. Anhydrous $BiCl_3$ is soluble in aromatic hydrocarbons and donor solvents such as ethers where complexes are formed. Bismuth(III) halides are useful starting compounds for the production of many other bismuth(III) compounds.[1,2] (*see also* ***Bismuth: Organometallic Chemistry***).

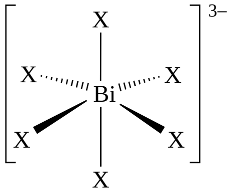
A feature commonly found among bismuth(III) complexes is their ability to function as Lewis acids and expand the octet of the bismuth atom (*see* ***Hypervalent Compounds***). This leads to a number of adducts between the bismuth halides and common donor molecules such as ethers, amines, phosphines, and organosulfur compounds.[15,16] Simple bismuth–arene complexes (*see Arene Complexes*) in which the aromatic ring is π-bonded to the bismuth atom have been structurally characterized.[17] A similar bonding mode has been found when $AlCl_3$ is added to $BiCl_3$ in arene solvents.[18] Bismuth–arene complexation is also observed for the bismuth alkoxides such as $[Bi(OC_6F_5)_3(toluene)]_2$ and $Bi_4(\mu_4\text{-}O)(\mu\text{-}OC_6F_5)_6\{\mu_3\text{-}OBi(\mu\text{-}OC_6F_5)_3\}\cdot 2(C_6H_5CH_3)$.[19–21] The ability to form complexes with arenes is probably dependent on the electronegativity of the groups attached to bismuth.

Ether–bismuth halide adducts also exist. Structural work on bismuth chloride–diethyl ether or THF complexes show that, at low temperature, polymeric chains of BiX_3 linked by halide bridges exist and that the bismuth atoms may be coordinated by one or two ether molecules.[22,23] Bismuth(III) bromide coordinates three THF molecules.[23] These solvent molecules are readily removed under vacuum. The polyethers diglyme and diethylcarbitol give dimeric adducts with $BiCl_3$.[21] In the presence of cyclic polyethers, simple coordination, or formation of polyether-coordinated bismuth cations occurs. Examples include $[BiCl_2(15\text{-crown-}5)(MeCN)]SbCl_6$, $[BiCl(18\text{-crown-}6)(MeCN)_2][SbCl_6]_2$,[24] $BiCl_3(12\text{-crown-}4)$, and $[BiCl_2(18\text{-crown-}6)]_2[Bi_2Cl_8]$.[25] Hexamethylphosphoramide (hmpa, $OP(NMe_2)_3$) also binds to bismuth halides yielding complex halo-hmpa bismuth cations: $[Bi_2I_6(hmpa)_2]$, $[BiI_2(hmpa)_4][I_3]$, and $[BiI_2(hmpa)_4][I_5]$.[26]

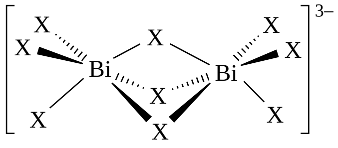
Halide ions form adducts with Bi^V or Bi^{III} halides, leading to complex ions. $[BiF_6]^-$ is formed upon reaction of NiF_2 with BiF_5 in anhydrous HF.[27] The resultant $Ni[BiF_6]_2$ compound dissolves readily in MeCN giving $[Ni(NCMe)_6][BiF_6]_2$. The alkali metal/BiF_6^- complexes have been prepared by the reaction of elemental fluorine with various salts.[28] For example, $LiBiO_2$, $NaBiO_2$, and $NaBiS_2$ are converted into the corresponding $MBiF_6$ at 450–500 °C. The K^+ compound was prepared from either $KBiS_2$ or a mixture of KCl and Bi_2O_3 at 360–450 °C, while the Rb^+ and Cs^+ salts arose from fluorination of mixtures of the alkali metal carbonates and Bi_2O_3 at 400–450 °C. XeF_4 reacts with BiF_5 in anhydrous liquid HF to give $[XeF_3^+][BiF_6^-]$, in which there is a tight association between one of the F atoms on the bismuth and the Xe. The Bi–F bond distance is substantially lengthened by this interaction (2.1 Å as against ca. 1.9 Å).[29]



(**1**)

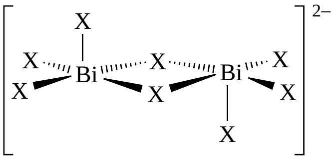


(**2**)

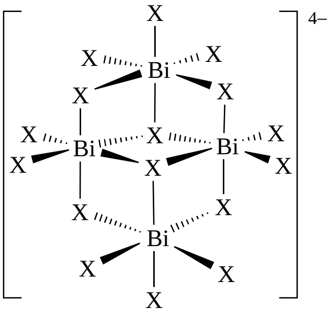


(**3**)

For Bi^{III} halides and pseudohalides, a wide range of complex anion structures has been observed, including $[BiX_5]^{2-}$ (**1**), $[BiX_6]^{3-}$ (**2**), $[Bi_2X_9]^{3-}$ (**3**), $[Bi_2X_8]^{2-}$ (**4**), $[Bi_3I_{12}]^{3-}$, $[Bi_4X_{16}]^{4-}$ (**5**), $[Bi_2Cl_{10}]^{4-}$, $[Bi_4Cl_{20}]^{8-}$ and $[Bi_8X_{28}]^{4-}$.[30–32] In addition to discrete ions such as (**1**)–(**5**), polymeric species may result. Thus $[BiX_4]_n^{\,n-}$ adopt edge-sharing (**6**) and $[BiX_5]_n^{\,2n-}$ vertex-sharing (**7**) octahedral

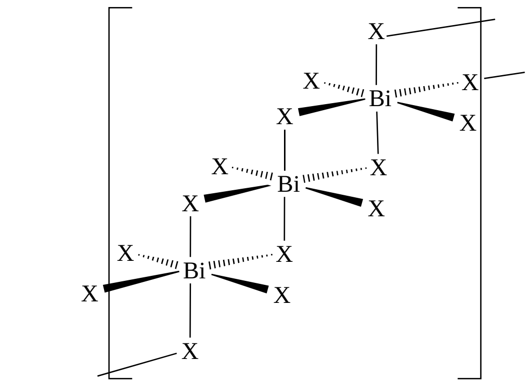


(**4**)

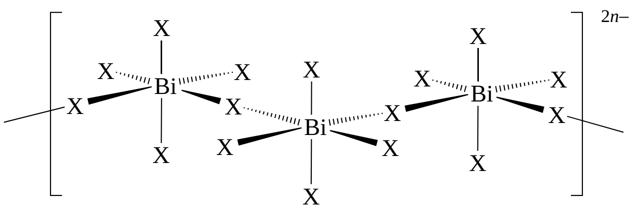


(**5**)

BiX_6 configurations. The polymeric anion $\{Bi_2I_7^-\}_n$ is also known.[31] HCl reacts with $BiCl_3$ in ether solution to produce the acid $H[BiCl_4]\cdot(solvent)_x$, in which a complex anion (**5**) exists. As seen in the structures, the bismuth atoms which are hypervalent may or may not show stereochemically active lone pairs of electrons.



(**6**)



(**7**)

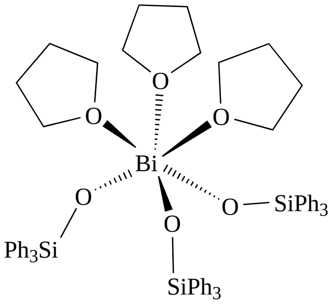
Related complexes with halide ligands and other donors such as THF, pyridine, picoline, or phosphines have been reported. These include the netural molecules $BiCl_3$(pyridine)$_4$ and BiI_3(pyridine)$_3$ and the anions $[BiBr_5(picoline)]^{2-}$, $[BiCl_5(pyridine)]^{2-}$, and $[Bi_2Cl_8(THF)_2]^{2-}$.[33,34] Phosphine adducts include $Bi_2Br_6(PME_3)_4$, $Bi_2Br_6(dmpe)_2$ [dmpe = 1, 2-bis(dimethylphinoethane)], $Bi_4Br_{12}(PEt_3)_4$, and $[BiI_4(PMe_2Ph)_2]^-$.[16,35,36] Some mixed halide-aryloxide complexes are also known.[37] Formulations include $Bi_2Cl_4(THF)_2(\mu\text{-}OR)_2$ (R = $OC_6H_3Me_2$-2,6, $OC_6H_2Me_3$-2,4,6), $[Bi_2(OC_6H_2Me_3\text{-}2,4,6)_6(\mu\text{-}Cl)_2]^{2-}$, $[BiBr_3(OC_6H_2Me_3\text{-}2,4,6)_2]^{2-}$.

2.4 Bismuth Compounds with Oxygen-based Ligands

2.4.1 *Alkoxides*

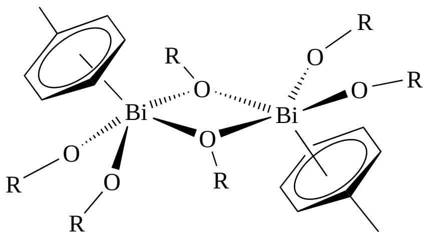
Because of the interest in a variety of heterometallic oxides with potentially valuable applications such as high T_C superconductivity, oxide ion conductivity, piezoelectric properties, and ferroelectric properties, bismuth alkoxides have been prepared for use as sol–gel and vapor deposition precursor compounds.[38] Mehrotra and coworkers found that $Bi(OR)_3$ (R = Me, Et, Pr) were insoluble and probably polymeric.[39] No structural information is available for these simple compounds. The *t*-butoxide complex is soluble, as is the compound for which R = 2,6-$Me_2C_6H_3$.[40] These are monomeric as determined by electron or X-ray diffraction. For the case where R = $CH(CF_3)_2$, the compound is a centrosymmetric dimer which also has coordinated THF.[21] These compounds were prepared by the reaction of $BiCl_3$ and an appropriate alkali metal alkoxide. The mixed halide–methoxide $BiCl(OMe)_2$ has also been prepared by this method or by pyrolysis of $BiCl(O_2COMe)_2$.[41] $Bi(OSiPh_3)_3$ is prepared by this salt metathesis method and has low solubility, except as the THF adduct $Bi(OSiPh_3)_3(THF)_3$ (**8**), which is monomeric and very soluble.[42] $\{BiOSi(O^tBu)_2Ph\}_3$ has also been prepared.[43] The related complex $Bi(OCPh_3)_3$ does not show the solvent coordination but the electron demand at the bismuth center is satisfied by π-interactions between the bismuth and one phenyl ring of each alkoxide ligand.[44] Dimeric monoalkoxide complexes of the type $[Bi(NO_3)_2$(triethylene glycolate)$]_2$ have been synthesized by Rogers and coworkers.[45] Higher order oligomerization is hindered by the chelation by the triethylene glycolate ligand. $Bi(OH)_3$ reacts with triethanolamine to give $Bi(OCH_2CH_2)_3N$.[46] The compound is composed of chains of alkoxo-bridged bismuth units.[47] The chains are aligned in pairs with weak Bi–O interactions between them. Structural features are similar to those found in many of the bismuth complexes with naturally occurring multidentate carboxylate and alkoxide ligands.

Another synthetic method to produce alkoxide complexes of bismuth employs the solvolysis of $\{BiN(SiMe_3)_2\}_3$[48] by alcohols. $Bi(OCH_2CH_2OMe)_3$ has been prepared in this fashion and is dimeric in the solid state.[42,48] The similar complex with $OCMe_2CH_2OMe$ is also known.[49] These complexes are volatile and may be used for chemical



(**8**)

vapor deposition methods. Solvolysis of organobismuth compounds may also be accomplished using acidic alcohols. $BiPh_3$ has also been shown to react with C_6F_5OH to give $[Bi(OC_6F_5)_3(toluene)]_2$ (**9**).[21] The toluene ligands of (**9**) are labile and are replaced with two THF ligands when dissolved in that solvent.



(**9**)

Organobismuth alkoxides have been prepared: Et_2BiOEt and $MeBi(OEt)_2$ are formed from the reaction of Et_2BiBr[50] or $MeBiBr_2$[51] with NaOEt. Siloxy derivatives are also known.[52] $BiEt_3$ undergoes partial solvolysis by phenol or C_6F_5OH, producing $[BiEt_2(OAr)]_\infty$ which is a chain polymer with the alkoxide function bridging between bismuth atoms.[53]

Bismuth alkoxide complexes are easily hydrolyzed and complex bismuth oxo-alkoxide compounds may result as intermediates to full hydrolysis. A number of examples of these are known for the pentafluorophenoxide system and include $Bi_4(\mu_4\text{-}O)(\mu\text{-}OC_6F_5)_6\{\mu_3\text{-}OBi(\mu\text{-}OC_6F_5)_3\}_2\cdot 2(C_6H_5CH_3)$, $Bi_8(\mu_4\text{-}O)_2(\mu_3\text{-}O)_2(\mu\text{-}OC_6F_5)_{16}$, $Bi_6(\mu_3\text{-}O)_4(\mu_3\text{-}OC_6F_5)\{\mu_3\text{-}OBi(OC_6F_5)_4\}_3$, $NaBi_4(\mu_3\text{-}O)_2(OC_6F_5)_9(THF)_2$, $Na_2Bi_4(\mu_3\text{-}O)_2(OC_6F_5)_{10}(THF)_2$, $[NaBi(OC_6F_5)_4(THF)]_\infty$, and $Na_4Bi_2(\mu_6\text{-}O)(OC_6F_5)_8(THF)_4$.[20,54] A hexanuclear compound $Bi_6(\mu_3\text{-}O)_3(\mu\text{-}OR)_7(OR)_5$ has also been observed where $R = C_6H_3Cl_2$-2,6.[55] The formation of oxide ligands can arise not only from hydrolysis but also from condensation of two phenoxide ligands to produce bis(pentafluorophenyl)ether. For example, careful addition of one equivalent of $NaOC_6F_5$ to $[Bi(OC_6F_5)_3(toluene)]_2$ yields first the adduct $[NaBi(OC_6F_5)_4(THF)]_\infty$ as an infinite chain polymer in which there are alternating Bi^{3+} and Na^+ ions with two phenoxides bridging between each metal, but if more phenoxide is added, the ether is eliminated and $Na_4Bi_2(\mu_6\text{-}O)(OC_6F_5)_8(THF)_4$ results.[54] This molecule has an oxide ion sitting in the center of the six metal ions. In addition to the sodium salts, other heterometallic alkoxides have also been prepared. These include $Bi\{Al(O^iPr)_4\}_3$, $Bi\{Al(O^iPr)_4\}_2(O^iPr)$, $CpMo(\mu\text{-}OEt)_2Bi(OEt)_2Cl$, $\{MeC(CH_2)_2\}Mo(CO)_2(\mu_3\text{-}OEt)_3Bi(\mu_3\text{-}OEt)_2Bi((\mu_3\text{-}OEt)_3Mo(CO)_2\{MeC(CH_2)_2\}$, $\{MeC(CH_2)_2\}Mo(CO)_2(OCH_2CH_2OMe)_2(\mu\text{-}Cl)BiCl$, and $[\{MeC(CH_2)_2\}Mo(CO)_2(OCH_2CH_2OMe)_2(\mu\text{-}Cl)Bi(THF)][BF_4]$.[56]

2.4.2 *Carboxylate Complexes*

Bismuth readily forms complexes with organic carboxylates. These compounds are easily prepared from bismuth(III) halides and the alkali metal or silver carboxylates or by reaction of bismuth oxides or bismuth oxycarbonate $(BiO)_2CO_3$ with carboxylic acids or the acid anhydrides. Bismuth acetate is commercially available and has been used to effect addition of acetate to organic substrates. For example, cyclohexenes react with bismuth acetate in the presence of I_2 giving the 1,2-diacetatocyclohexanes. If the reaction is conducted in the absence of water, *trans*-1,2-diacetates are obtained, but if water is present, cis compounds result.[57] Carboxylate linkages from naturally occuring organic acids form the basis for many biologically active bismuth compounds (discussed in the next section). In addition to $Bi(OAc)_3$, bismuth formate[58] and bismuth trifluoroacetate[59] have been studied. Bismuth trifluoroacetate crystallizes with coordinated trifluoroacetic acid when prepared from reaction of Bi_2O_3 with a mixture of trifluoroacetic acid and trifluoracetic anhydride.[60] The adduct $NaBi(O_2CCF_3)_4$ is formed when $NaBiO_3$ is treated with trifluoroacetic acid.[59] Pyrolysis of the formate leads first to $BiO(O_2CH)$ and ultimately to $(BiO)_2CO_3$.

The bismuth(II) compound $[Bi_2(O_2CCF_3)_4]\cdot C_6Me_6$ compound has been prepared in low yield by the pyrolysis of bismuth(III) trifluoroacetate in hexamethylbenzene. It possesses a Bi–Bi bond that is bridged by four bridging carboxylate ligands in a fashion similar to the tetracarboxylate complexes of the metal–metal bonded transition metal dimers.[61] Salicylic acid, o-$HOC_6H_4CO_2H$, has proven useful for linking bismuth to other metals such as Ti, Ta, or Nb owing to the presence of both the phenol and carboxylic acid functions.[62] The salicylate ligand can be found in either the monodeprotonated form o-$HOC_6H_4CO_2^-$ and in the dideprotonated version o-$OC_6H_4CO_2^{2-}$ giving flexibility in both charge and coordination mode. These complexes serve as useful precursors to heterometallic oxides.

2.4.3 *Biologically Active Bismuth(III) Complexes*

Bismuth compounds have long been known for their biological function,[63–65] primarily for treating gastrointestinal disorders.[64,66] Generally bismuth compounds are not very

toxic owing to low solubility of bismuth salts in solution and have potential for a variety of medicinal applications.[63,67] Bismuth chloride reacts rapidly with water to form the insoluble subhalide BiOCl and other salts behave similarly. However, bismuth oxalate is reported to be poisonous. Bismuth aluminate, bismuth phosphate, bismuth subgallate, and bismuth subnitrate have antacid properties. Several compounds have been used as antisyphilitics, including bismuth butylthiolaurate, bismuth oxychloride, bismuth tris(ethyl camphorate), bismuth potassium tartrate, bismuth sodium iodide (Na_2BiI_5), and bismuth sodium tartrate. Bismuth oxide, bismuth subgallate, and bismuth tannate have found uses as astringents, and bismuth subnitrate has been used in cosmetics. Gastritis and duodenal ulcers may be treated with bismuth subcitrate, while bismuth iodide oxide, bismuth iodosubgallate, and bismuth tribromophenate find uses as anti-infective agents. Bismuth sodium triglycollamate and bismuth subsalicylate function as suppressants of *lupus erythematosus*.

Complexes of bismuth(III) with naturally occurring organic acids have been synthesized and studied for potential biological activity.[68–71] Citric acid complexes have long been known to have biological activity and a number have been recently synthesized and characterized in solid state and solution.[71,72] Synthetic methods to these compounds are straightforward, as exemplified by the reaction of bismuth nitrate with L-(−)-malic acid and L-(+)-tartaric acid to give bismuth(III) malate monohydrate and tartrate trihydrate,[69] or reaction of $Bi(OH)_3$ with (*S*)-lactic acid to produce bismuth(III) lactate.[70] Bismuth salicylate is conveniently prepared by the reaction of $BiPh_3$ with salicylic acid in refluxing toluene. From this preparation, the structures the bipyridine and phenanthroline adducts of bismuth salicylate have been reported.[73] While the bipyridine simply adds to $Bi(HOC_6H_4CO_2)_3$, the addition of phenanthroline results in the elimination of salicylic acid and the deprotonation of one of the other salicylate ligands. In both cases, the high Lewis acidity of the bismuth center gives rise to dimer formation: $[Bi(HOC_6H_4CO_2)_3(bipyridine)]_2$ and $[Bi(HOC_6H_4CO_2)(HOC_6H_4CO_2)(phenanthroline)]_2$.

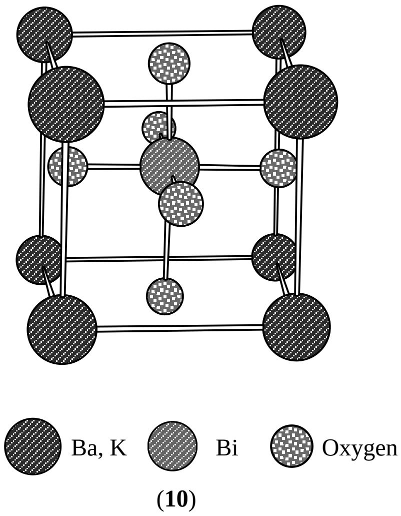
While the mechanism of the interaction of these carboxylate complexes with the biological molecules that leads to their activity is not well understood, there is some evidence that the molecules can bind to N-donor and S-donor molecules in proteins. Bismuth(III) has been shown to bind most strongly to the thiolates in glutathione.[74] There is some evidence that Bi(III) can replace metals such as Fe(III) in lactoferrin and transferrin or Zn(II) in metallothionein.[75]

2.4.4 Bismuth Oxides

The common oxide of bismuth is Bi_2O_3, which is found in nature as the mineral bismite, has a variety of uses including the making of enamels for cast iron, in the manufacture of glass and ceramic products, in disinfectants, magnets, catalysts, and rubber vulcanization. It readily dissolves in acidic solution yielding complex halide species. High purity material may be prepared by igniting bismuth nitrate. Four crystalline modifications α, β, γ, and δ are known, which are monoclinic (pseudoorthorhombic), tetragonal, body-centered cubic, and cubic, respectively. The thermodynamically stable α phase converts to the δ phase at 729 °C. Upon cooling to 650 °C the β phase is produced and at 629 °C the γ phase is obtained. Bismuth oxide has been reported to be an oxygen ion conductor at high temperatures and this conductivity varies with the phase in the order $\alpha < \beta < \gamma \ll \delta$.[76] The δ phase is highly disordered and reportedly has about 75% of the disorder of the molten compound. The oxide is very easily contaminated, forming compounds which have the same crystal system and similar lattice parameters to the body-centered cubic γ form. These compounds are based upon a formulation of $[Bi_{24}O_{40}]^{8-}$ in which contaminant cations complete the charge balance. Simple compounds with the formula $EBi_{12}O_{20}$ (E = Si, Ge) are examples. Silicon can be incorporated by leaching of that element from porcelain crucibles during high-temperature reactions.

The pentavalent oxide Bi_2O_5 is reportedly prepared by oxidation of Bi_2O_3 in solution or by fusion of Bi_2O_3 with $KClO_3$.[77] The compound is very unstable and has not been isolated in pure form.

Bismuth oxide forms a number of complex mixed-metal phases with the divalent metal oxides of calcium, strontium, barium, lead, and cadmium, and these show a wide variety in composition. With transition metal oxides, mixed-metal oxide phases have been observed which are based upon a Perovskite-type lattice (**10**) containing layers of Bi_2O_2.[78] It is notable that the high T_c superconducting materials which include bismuth[40] also have this Perovskite-type of lattice with layers of copper oxide interleaved with bismuth oxide layers.

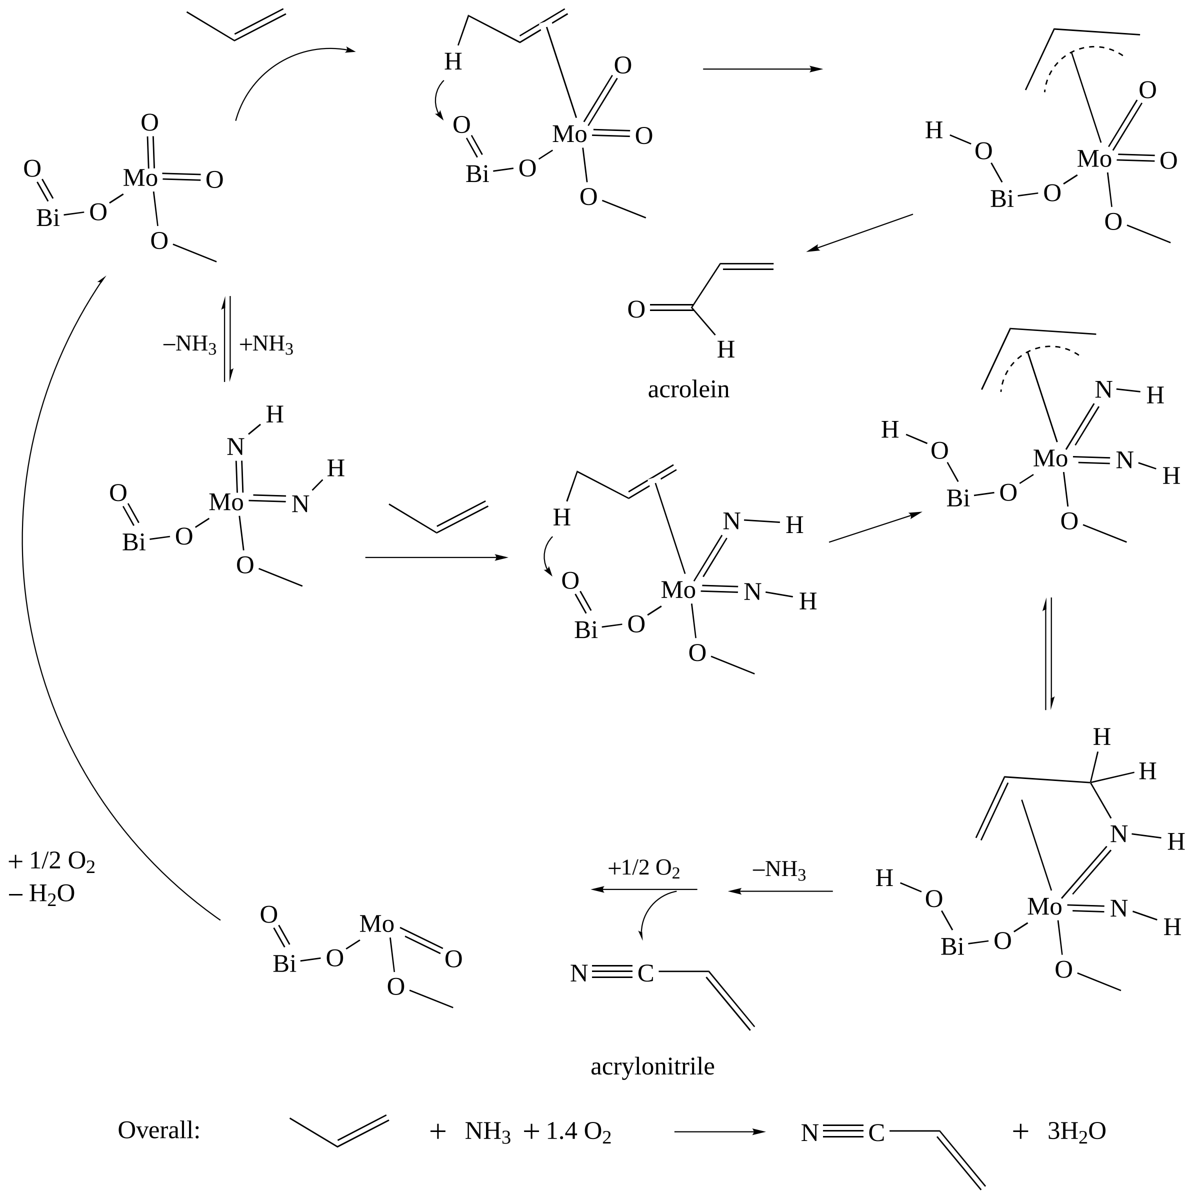


(**10**)

The alkali metal oxides $MBiO_2$ (M = Na, K, Rb, Cs) have been prepared and structurally characterized.[79] The bismuth has a +5 oxidation state in sodium bismuthate ($NaBiO_3$), a well-known but ill-defined substance which has been used as an analytical reagent capable of oxidizing Mn^{2+} to Mn^{7+}. The solid has the ilmenite structure ($FeTiO_3$). It dissolves in strong acid solutions to give an as yet uncharacterized bismuth(V) complex which is stable for a few days in solution. Other phases containing Bi^V have recently been reported.[80] These include $LiSr_3BiO_6$, $NaSr_3BiO_6$, $NaBa_3BiO_6$, Li_6KBiO_6, Li_6RbBiO_6, and $Li_2Ba_5Bi_2O_{11}$ produced in molten salt reactions.

The importance of bismuth oxide species in oxidation of organic molecules is illustrated in Scheme 1, which shows a proposed mechanism for the SOHIO process for the oxidation and ammoxidation of propene using a molybdenum bismuthate catalyst.[81] The intermediates proposed in Scheme 1 have not been observed in discrete molecular systems. Indeed, no molecular molybdenum–bismuth oxide species is known. The reaction of $BiPh_3Cl_2$ with $[Bu_4N]_2[MoO_4]$ has been examined[82] and the products identified as $(BiPh_3MoO_4)_x$ and $[BiPh_3(MoO_4)_2]^{2-}$, but these compounds may be more appropriately considered organobismuth derivatives than bismuth oxide models.

Saturated hydrocarbons may also be oxidized by bismuth oxide catalysts. For example, methane is converted to CO_2 and a mixture of higher hydrocarbons over bismuth oxide catalysts that also contain sodium, calcium, cesium, and/or halide

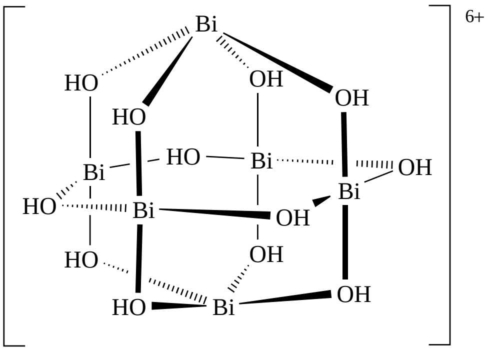


Scheme 1

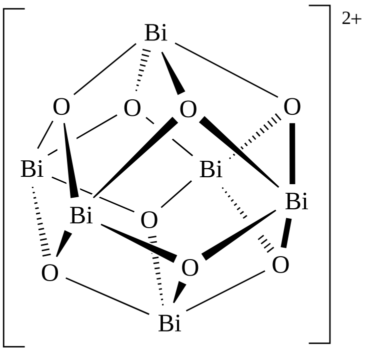
ions.[83] Propane has been oxidized to acrolein over a silver-doped bismuth–vanadomolybdate catalyst.[84] Heterometallic bismuth oxides containing vanadium, titanium, niobium, or tantalum have also been shown to serve as photocatalysts for a variety of reactions including the splitting of water.[85]

2.4.5 Bismuth Oxo Cluster Complexes and Related Compounds

In very acidic solutions, bismuth(III) exists in the form of the nonaaquo ion $[Bi(H_2O)_9]^{3+}$, which is similar to the aquo complexes of the lanthanide ions,[86] but partial hydrolysis of bismuth(III) salts leads to the formation of bismuth oxo clusters. The core structure of these complexes is often based upon a Bi_6 octahedral core with oxide, hydroxide, or alkoxide functions bridging the edges and/or faces of the octahedron. The $[Bi_6(OH)_{12}]^{6+}$ ion (**11**) has been studied spectroscopically.[87] In oxo clusters, the octahedron is face-bridged by eight oxo or alkoxide functions (**12**). Such core structures have been found in the hydrolysis of bismuth nitrate or perchlorate.[88]



(**11**)



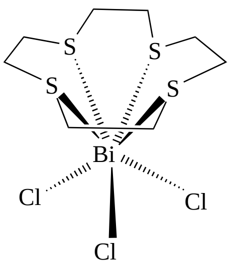
(**12**)

A number of bismuth alkoxo-oxo cluster complexes have been observed in the C_6F_5OH system.[19–21,54,89] These compounds include $NaBi_3(\mu_3\text{-}O)(OR)_8(THF)$, $NaBi_4(\mu_3\text{-}O)_2(OR)_9(THF)_2$, $Na_2Bi_4(\mu_3\text{-}O)_2(OR)_{10}$, and $Bi_6(\mu_3\text{-}OR)(\mu_3\text{-}O)_4[\mu_3\text{-}OBi(OR)_4]_3$, which have been obtained from the reaction of $BiCl_3$ and $NaOC_6F_5$. The reaction of $[Bi(OC_6F_5)_3(toluene)]_2$ with $NaOC_6F_5$ led to the production of $Bi_6(\mu_3\text{-}O)_2(\mu_4\text{-}O)(OR)_{12}$ and $NaBi_3(\mu_3\text{-}O)(OR)_8(THF)_3$. Reaction of $BiPh_3$ with HOC_6F_5 in THF led to the formation of $Bi_6(\mu_3\text{-}OR)(\mu_3\text{-}O)_4[\mu_3\text{-}OBi(OR)_4]_3(THF)_2$. $Bi_6(\mu_3\text{-}OR)(\mu_3\text{-}O)_4[\mu_3\text{-}OBi(OR)_4]_3$ and $Bi_6(\mu_3\text{-}OR)(\mu_3\text{-}O)_4[\mu_3\text{-}OBi(OR)_4]_3(THF)_2$ possess the core geometry in (**12**).[54]

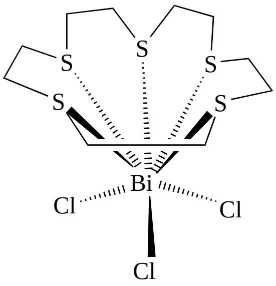
2.5 Bismuth Chalcogenide-based Ligands

2.5.1 Compounds with Organochalcogenide Ligands

Bismuth very readily forms complexes with sulfide and sulfur-containing ligands, and this ability may be important in understanding the biological activity of colloidal bismuth carboxylate complexes. The crown thioether compounds $[9]aneS_3$, $[12]aneS_4$, $[15]aneS_5$, $[18]aneS_6$ and $[24]aneS_8$ add to $BiCl_3$.[90] The bismuth is bonded to each sulfur and the Bi–Cl bonds are retained, as has been established for the $[12]aneS_4$ and $[15]aneS_5$ complexes, (**13**) and (**14**). The Bi–Cl distances are on the order of 2.57 Å and the Bi–S distances range from 2.98 to 3.25 Å. The compound $[SMe_3]_2[Bi_2I_8(SMe_2)_2]$ has dimethylsulfide bonded to bismuth,[91] and the tridentate $MeSi(CH_2SMe)_3$ reacts with BiX_3 (X = Cl, Br) to displace the halide ions forming $[Bi(MeSCH_2)_3SiMe)]X_3$ which is polymeric in the solid state.[92]



(**13**)



(**14**)

$BiEt_3$ reacts with thiols and the likely product is $Bi(SR)_3$, which has not yet been fully characterized;[93] however, such complexes have been synthesized via other methods.[94] The organic thiolates RS^- examined include those with R = C_6F_5, 4-MeC_6H_4, 2,6-$Me_2C_6H_3$ or 3,5-$Me_2C_6H_3$. The structure of $BiSC_6H_2$-2,4,6-$\{(CMe_3)_3\}_3$ from the reaction of $BiCl_3$ with the lithium salt of the thiolate has been reported.[95] Bismuth nitrate reacts with 3 equivalents of (3-trimethylsilyl)pyridine-2-thiol to yield the tris{(3-trimethylsilyl)pyridine-2-thiolato}Bi complex[96] which, by comparison with the antimony analog, should have the three ligands chelating the bismuth atom

bonded through both the S and N atoms. Cyclic complexes of the formula $BiCl\{(SCH_2CH_2)_2E\}$ (E = O, S) are obtained from the reaction of $BiCl_3$ with the appropriate thiol.[97] While the structures of these compounds have not been reported, that of the compound $PhBi\{(SCH_2CH_2)_2O\}$, prepared from $PhBi(OEt)_2$ and the thiol, is known. The ether oxygen is coordinated to the bismuth atom and one may expect a similar situation in the halide complexes.[98] Similarly, BiX_3 ($X = Cl^-$, Br^-, NO_3^-) form complexes with thiolates that also have amine, alcohol, and ester functions.[99,100] Electrospray mass spectrometry has proven useful for identifying species in solution that are otherwise difficult to characterize.[100,101]

Dithiocarbamate, a popular ligand for bismuth(III), is formed easily in the reaction of an amine, CS_2, and $BiCl_3$. A number of complexes have been reported in which the bidentate ligand is chelating.[102] The coordination geometry about bismuth is similar to that found in the complex halide ions described above. Selenocarbamates of bismuth have been prepared by the same route.[103] Ligands such as hexamethylphosphoramide, Ph_3PO, Ph_3PS, *N*,*N*′-dimethylthiourea, and *N*,*N*′-dimethylpropyleneurea have been shown to complex to $Bi(SC_6F_5)_3$ giving 1:2 adducts,[104] while addition of excess $C_6F_5S^-$ leads to the formation of $[Bi(SC_6F_5)_5]^{2-}$ and SCN^- to $[Bi(SC_6F_5)_4(SCN)]^-$.[104,105]

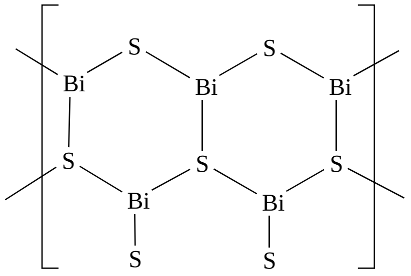
2.5.2 Compounds with Inorganic Chalcogenide Ligands

In addition to the chalcogenides of the general formula Bi_2E_3, BiS_2 (high-pressure phase), BiSe, and Bi_3Se_4 are known. The sulfur complex crystallizes in an orthorhombic lattice isostructural to that found for Sb_2S_3. This structure is based upon double chains with two unique types of Bi atoms. One of the chain units is shown in (**15**). In the selenide, telluride, Bi_2Te_2S, and Bi_3Se_4 compounds the anions form close-packed layers with bismuth atoms occupying octahedral holes. The close-packed layer structure in these phases is complex, having regions of ABA and ABC anion alternations. Both the selenide and telluride are semiconductors. The compound $NaBiS_2$ has the rock salt structure. BiEX (E = S, Se; X = Cl, Br, I) are all known and all are isostructural, except BiSeCl. The predominant structure is made up of bromide ions lying between pleated chains of $(BiE)_n^{n+}$ (**16**). Bismuth chalcogenides have received attention owing to their thermoelectric properties. Nanowires and thin films of Bi_2Te_3 can be prepared and show enhanced thermoelectric properties.[106]

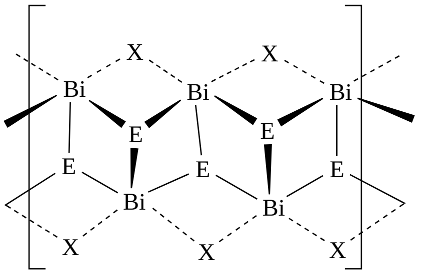
2.6 Bismuth Complexes with Group 15-based Ligands

Simple amine adducts of the bismuth halides have been prepared, although many have not been structurally characterized.[107] Adducts between amines and organobismuth complexes have been better defined (*see* ***Bismuth: Organometallic Chemistry***). Amido complexes of bismuth are conveniently synthesized by the reaction of $BiCl_3$ with the appropriate lithium dialkyl amide, $LiNR_2$ (R = Me, Ph, $SiMe_3$).[108] The R = Me and Ph compounds have been structurally characterized. For R = Me the bismuth atom is pyramidal (sum of angles about bismuth = 292.8°) with Bi–N bond distances averaging 2.184 Å and unique N–Bi–N bond angles on the order of 98.3 and 96.2°. The structure of the R = Ph compound shows it to be slightly more planar (sum of angles about bismuth = 296°) with Bi–N distances ranging from 2.12 to 2.18 Å. The compound $Bi(NMe_2)_3$ is light sensitive and volatile, making it potentially useful for chemical vapor deposition of bismuth for production of thin films. If the amide Li[NHR] ($R = C_6H_3Me_2$-2,6) is employed, the trinuclear complex $Bi_3(\mu\text{-NR})_4(NHR)$ results.[55] Coordination of a cyclic bismuth diamide, $Cp(OC)_3\,W[BiN_2(t\text{-Bu})_2SiMe_2]$, has been confirmed by X-ray diffraction.[109] The compound $Bi(N_3)_3$ has been prepared and examined by Hartree-Fock ab initio calculations.[110]

The chemistry of bismuth with macrocyclic N-donor ligands is not extensive but some reports have appeared. Bismuth octaethylporphyrin nitrate,[111] bismuth tetratolylporphyrin nitrate[112] and $[bismuth(cyclen)(H_2O)](ClO_4)_3$ (cyclen = 1, 4,7,10-tetrazacyclododecane)[113] have been prepared, as has the tetrakis(cumylphenoxy)phthalocyaninebismuth.[114] Reaction of 1,2-dicyanobenzene with bismuth and I_2 at 200 °C yielded mixed valent $[Bi(phthalocyanine)_2]I_{1.5}$ in which there are columnar stacks of $[Bi(phthalocyanine)_2]$ and linear chains of iodine atoms. A similar reaction between Bi_2Se_3 and 1,2-dicyanobenzene yielded the triple-decker $Bi_2(phthalocyanine)_3$.[115]



(**15**)



(**16**)

Triphenylbismuth undergoes complete ammonolysis with KNH_2 in liquid ammonia to yield the binary bismuth nitride BiN, which is explosive.[116] $Bi(NH_2)_3$ is believed to be an intermediate, though it was not detected in this reaction.

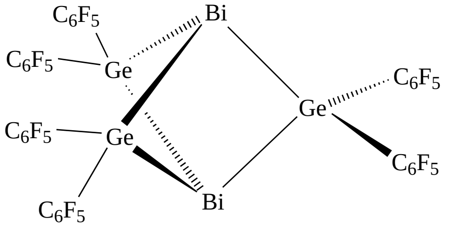
Similar to a number of other main group element complexes,[16] phosphines can complex to bismuth halides to form simple adducts such as $Bi_2Br_6(PMe_3)_4$, $Bi_2Br_6(dmpe)_2$, $Bi_4Br_{12}(PEt_3)_4$, and $Bi_2Br_6(PMe_2Ph)_2(OPMe_2Ph)_2$.[35,36,117] In the presence of added halide ions, complex anions such as $[PPh_4][BiI_4(PMe_2Ph)_2]$ containing an octahedral Bi center bonded to four iodide ions and two cis phosphine ligands can be obtained.[36]

2.7 Bismuth Complexes with Si, Ge, and Sn Based Ligands

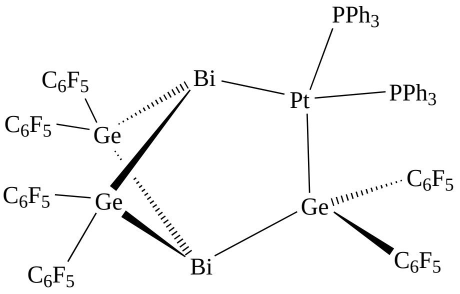
$Bi(SiMe_3)_3$, a highly air and moisture sensitive colorless liquid, is prepared via the reaction of Me_3SiCl with M_3Bi (M = alkali metal) in DME.[118] The Me_3Sn and Me_3Ge analogs have also been prepared.[119] Bismuth atoms react with SiF_3 radicals generated from Si_2F_6 to yield the volatile and unstable $Bi(SiF_3)_3$ in low yield.[120]

The silyl compound $Bi(SiMe_3)_3$ is cleaved to give $LiBi(SiMe_3)_2{\cdot}DME$ upon reaction with lithium alkyls and subsequent reaction with 1,2-dibromoethane yields the tetrakis(trimethylsilyl)dibismuthine, $(Me_3Si)_2Bi–Bi(SiMe_3)_2$. Both $LiBi(SiMe_3)_2{\cdot}DME$ and $(Me_3Si)_2Bi–Bi(SiMe_3)_2$ have been structurally characterized.[121] The chemistry of these compounds is related to that of a number of organobismuthine complexes. The structure of $LiBi(SiMe_3)_2{\cdot}DME$ is composed of $-(-Bi–Li-)_n-$chains with a Li–Bi distance of 2.92(3) Å. The bismuth–silicon distance is 2.633(14) Å in $LiBi(SiMe_3)_2{\cdot}DME$ and 2.683(av) Å in the dibismuthine. The Bi–Bi distance in the dibismuthine is 3.035(3) Å, in agreement with distances found for tetraphenyldibismuthine.

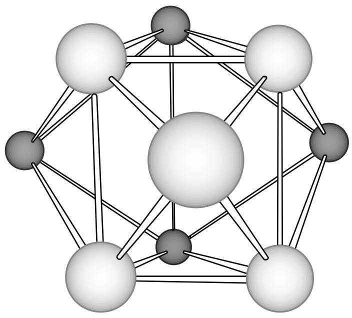
Triethylbismuthine reacts with $(C_6F_5)_3GeH$ and $(C_6F_5)_2GeH_2$ to give compounds containing Bi–Ge bonds.[122] These include $(C_6F_5)_3GeBiEt_2$, $[(C_6F_5)_3Ge]_2BiEt$, and the triply bridged compound $Bi_2\{\mu\text{-}Ge(C_6F_5)_2\}_3$ (**17**). The last compound reacts with $Pt(PPh_3)_3$, undergoing a platinum insertion into a Bi–Ge bond to give (**18**). The Bi–Ge bond distances in these compounds are on the order of 2.73 Å.



(**17**)



(**18**)



(**19**)

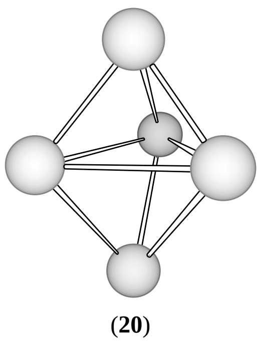
2.8 Bismuth Compounds with Metal–Metal Bonds

2.8.1 *Cationic 'Naked' Clusters of Bismuth: Reduced Bismuth Halide Phases*

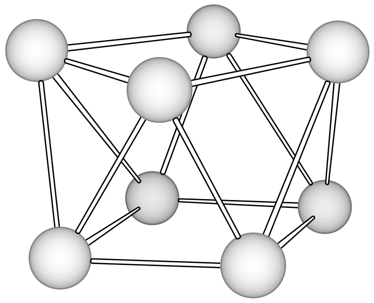
Bismuth chloride reacts with elemental bismuth at elevated temperatures to give a subhalide phase which contains clusters of Bi atoms linked by halide bridges. The overall stoichiometry of this phase is $Bi_{24}Cl_{28}$ with a complicated structure best described as $[Bi_9^{5+}]_2[BiCl_5^{2-}]_4[Bi_2Cl_8^{2-}]$.[123] The Bi_9^{5+} cluster has a tricapped trigonal prismatic geometry (**19**). The Bi–Bi distance within the triangular faces is 3.241(3) Å, while the distances from these atoms to the capping Bi atoms are shorter at 3.086(3) and 3.103(3) Å. The Bi–Bi distances between the two triangular faces is quite long at 3.737(4) Å and probably does not represent a direct bonding interaction. The Bi_9^{5+} cluster has also been found, along with a rare example of Bi^+ ions, in $(Bi^+)(Bi_9^{5+})(HfCl_6^{2-})_3$.[124] These phases are generated by the reaction of Bi with $BiCl_3$ in the presence of Lewis acids such as $HfCl_4$.[125] Reactions involving $AlCl_3$ give $Bi_5[AlCl_4]_3$ with a trigonal bipyramidal cluster (**20**), or $Bi_8[AlCl_4]_2$ in which a square antiprismatic Bi_8^{2+} has been found (**21**).[126] The average Bi–Bi distance in (**21**) is 3.100 Å. Reaction of Bi with AsF_5 in SO_2 also produces the Bi_8^{2+} and Bi_5^{3+} clusters with AsF_6^- as the counterion.[127]

2.8.2 *Anionic 'Naked' Clusters of Bismuth: Zintl Ions*

Zintl reported early in this century that reactions of the heavier main group elements with Na or K in liquid ammonia

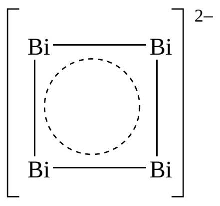


(**20**)

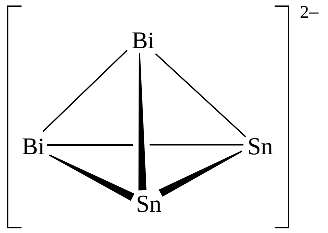


(**21**)

result in highly colored solutions of complex cluster ions (*see* ***Zintl Compounds***).[128] This reaction is general for many main group elements and the naked clusters which result have come to be known as Zintl ions. For bismuth, Zintl's work proposed clusters with compositions $[Bi_3]^{3-}$, $[Bi_5]^{3-}$, and $[Bi_9]^{3-}$, but these have not been structurally confirmed. Often these clusters revert to alloy phases when the solvent is removed, but, in an elegant series of experiments, Corbett has shown that in higher boiling amine solvents such as ethylenediamine the reversion to the alloy phase can be inhibited by the addition of an appropriate encapsulating ligand.[128] The ligand sequesters the alkali metal cation, preventing reversion to the alloy phase. Using this strategy, the planar, six π-electron cluster anion $[Bi_4]^{2-}$ (**22**) was crystallized.[129] The bismuth distances of 2.936(2) and 2.941(2) Å, which are shorter than other Bi–Bi distances, support the contention that there is significant Bi–Bi multiple bonding. The complicated alloy phase $Ca_{11}Bi_{10}$ also contains the $[Bi_4]^{2-}$ unit,[130] while the phases A_5Pn_4 (A = K, Rb or Cs; Pn = As, Sb, Bi) are reported to have isolated and flat zig-zag chains of the $Pn_4{}^{4-}$ ions with delocalized π-electrons.[131] The $Bi_2{}^{2-}$ ion exhibits a Bi–Bi bond distance of 2.8377(7) Å, consistent with a Bi–Bi double bond.[132] The $Bi_3{}^{3-}$ unit has been stabilized by metal-carbonyl fragments in the trigonal bipyramidal anions $[Bi_3M_2(CO)_6]^{3-}$M = Cr or Mo (2).[133] The intermetallic ions $[Bi_2Sn_2]^{2-}$ (**23**), $[In_4Bi_5]^{3-}$, $[InBi_3]^{2-}$, and $[GaBi_3]^{2-}$ are also known.[134]



(**22**)



(**23**)

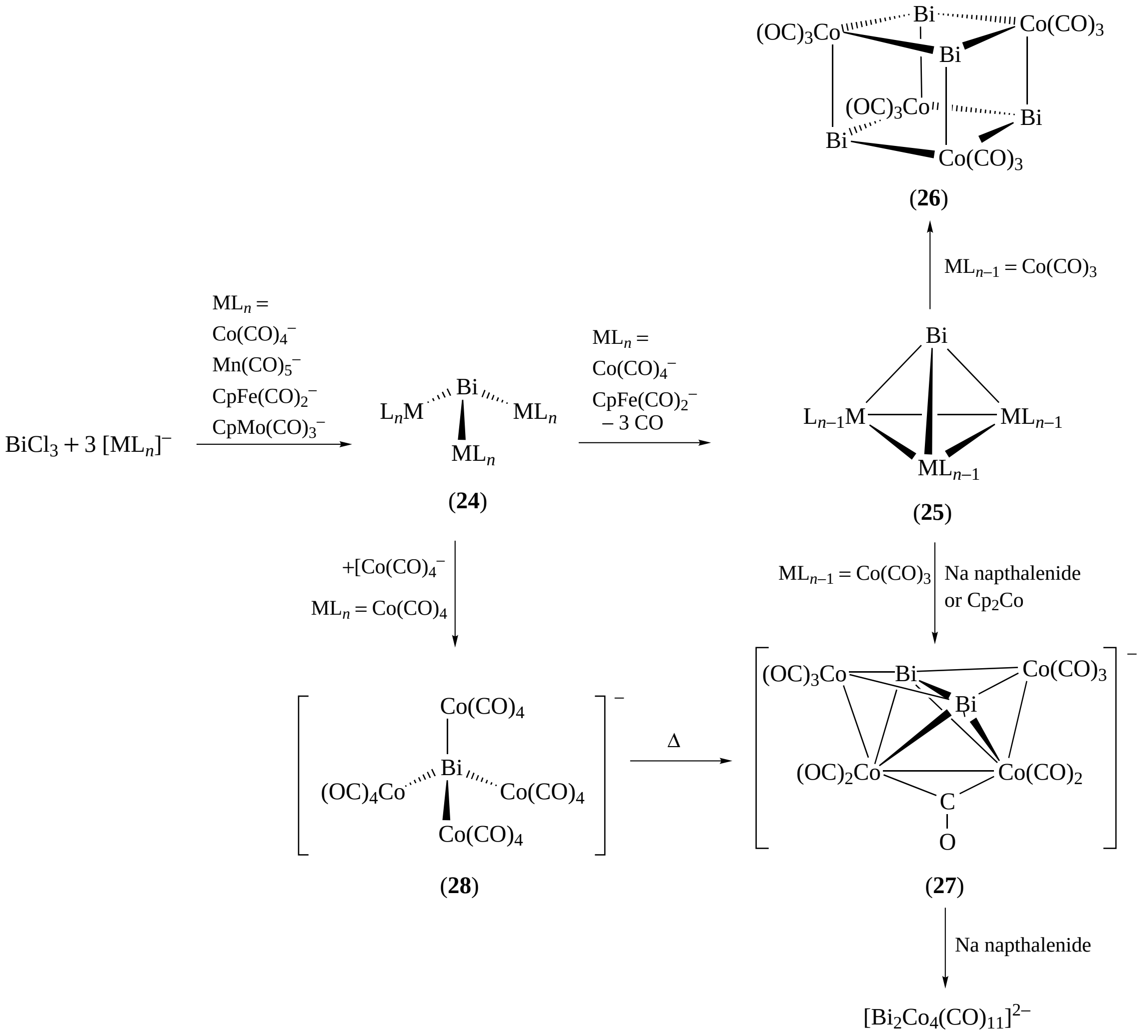
2.8.3 *Transition Metal–Bismuth Clusters*

Several reviews have appeared describing metal-carbonyl complexes incorporating bismuth and the other heavy main group elements (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***).[135,136] Transition metal complexes which incorporate organobismuth functions are also described in (*see* ***Bismuth: Organometallic Chemistry***).

Bismuth readily forms bonds to many metals. The most direct route to transition metal–bismuth complexes is the reaction of metal-carbonyl anions with bismuth halides. The complexes $Bi\{Mn(CO)_5\}_3$, $Bi\{CpMo(CO)_3\}_3$, $Bi\{Fe(CO)_2Cp\}_3$, $Bi\{Co(CO)_4\}_3$, $Bi\{Ru(CO)_2Cp\}_3$, and $Bi\{Ni(CO)C_5Me_5\}_3$ (Scheme 2, (**24**)) are obtained by this method.[137–142] A heterometallic compound, $Bi\{Co(CO)_4\}_2\{Fe(CO)_2Cp\}$, is known.[34] Derivatives with one or two metal fragments, for example, $X_2Bi\{ML_n\}$ and $XBi\{ML_n\}_2$ [X = Cl^-, $NO_3{}^-$, SCN^-, $SeCN^-$; ML_n = $CpMo(CO)_3$, $CpW(CO)_3$, $(C_5H_4Me)Fe(CO)_2$, $CpRu(CO)_2$, $CpMn(CO)_2$, $(C_5Me_5)Ni(CO)$] have been prepared.[32,34,137,140,142,143] The Mo and W compounds are discrete but the Fe and Mn complexes are oligomeric, being based upon rings of alternating Bi and Cl atoms. The Fe compound is a cyclic trimer, while the Mn compound exists as a dimer. There appear to be similar Bi···X interactions in the solid state for $BrBi\{CpMo(CO)_3\}_2$ and $IBi\{CpMo(CO)_3\}_2$.[144] $ClBi\{MnCp(CO)_2\}_2$ is also interesting in that the Bi is formally in the +1 oxidation state and Mn–Bi multiple bonding is proposed.[145] This is supported by the very short Bi–Mn distances (2.469 Å av). $Bi\{C_5H_4MeM(CO)_3\}_3$ (M = Mo, W) convert to tetrahedral clusters $Bi_2M_2(CO)_4(C_5H_4Me)_2$ upon thermolysis in solution.[146] One compound with a bismuth–copper bond is known: $(Me_3Si)_2Bi–Cu(PMe_3)_3$.[147] Its formation is driven by removal of ^{t}BuOSiMe$_3$ upon reaction of CuO^{t}Bu with $Bi(SiMe_3)_3$.

Compounds with open framework structures may be induced to lose CO and form metal–metal bonds (**25**). At one time it was believed that the heavy main group elements would not allow the formation of closo configurations in combination with the first-row transition metals because of steric strain imposed by the size of the main group atom. This does not appear to be the case and a number of *closo* species have now been reported. $BiIr_3(CO)_9$ is prepared by addition of $[Ir(CO)_4]^-$ to $BiCl_3$, but the open dodecacarbonyl compound is not observed as an intermediate.[148] The structure is similar to that found for $BiCo_3(CO)_9$ except that it has no bridging CO ligands.[149,150] Compound (**25**) readily adds ligands such as phosphines, arsines, and stibines to give open $Bi\{Co(CO)_3L\}_3$ compounds.[139] $BiNi_3(CO)_3(C_5Me_5)_3$ has also been reported[142] In some cases, closed, tetrahedral compounds are obtained directly as in the reaction of $NaBiO_3$ with $Mo(CO)_6$ to give $[Et_4N]_2[BiMo_4(CO)_{12}(\mu_3\text{-}OMe)_3]$.[151] This interesting compound shows a bismuth atom capping a triangle of Mo atoms with an additional $Mo(CO)_3(OMe)_3{}^{3-}$ fragment bonded to the tetrahedral $BiMo_3{}^+$ unit. It is part of a family of complexes that may also have As or Sb in place of Bi.[152]

Metallated bismuth atoms function as Lewis acids, as exemplified by the addition of $[Co(CO)_4]^-$ to $Bi\{Co(CO)_4\}_3$ to form the hypervalent complex $[Bi\{Co(CO)_4\}_4]^-$ (**28**)



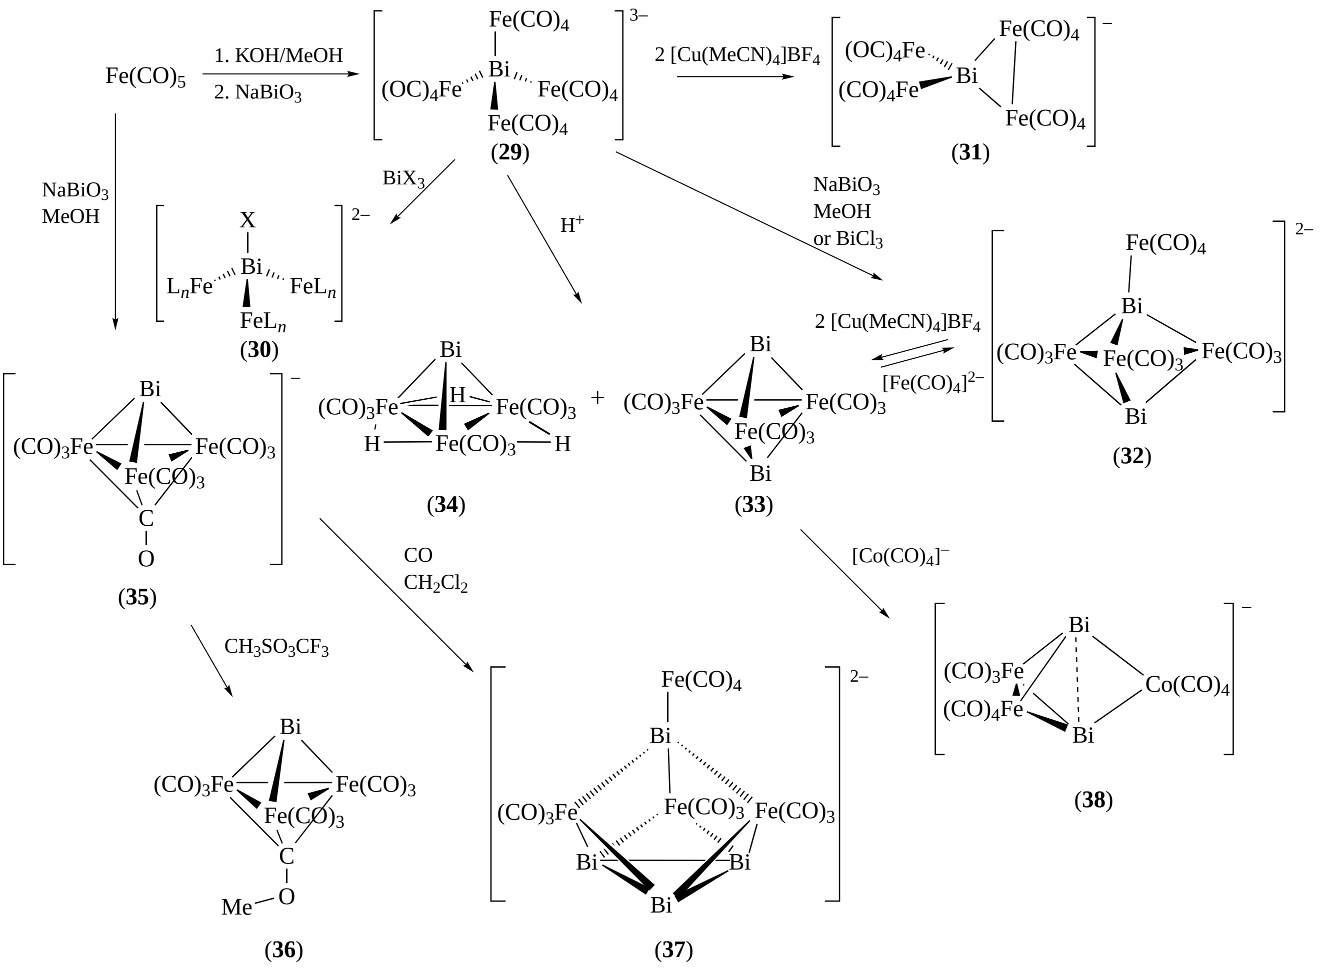
Scheme 2

(*see* ***Hypervalent Compounds***).[153] The Bi–Co distances in this molecule are very long (ca. 2.9 Å) and the lone pair is stereochemically inactive. The ability of the bismuth atom to act as an acceptor may be key in reactions of clusters with nucleophiles. The bismuth centers in these molecules can also act as Lewis acids toward halide ions or other donor ligands as exemplified by the formation of $[Cl_2Bi\{Fe(CO)_2Cp\}_2]^-$, $\{[OP(NMe_2)_3\}_2Bi\{Fe(CO)_2Cp\}_2]^+$, $[Fe(CO)_4Bi_2Cl_4(\mu\text{-}Cl)_2]^{2-}$, $[Bi_3Cl_4(\mu\text{-}Cl)_4\{Fe(CO)_3\}]^{3-}$, and $[(\mu\text{-}H)Fe_2(CO)_6Bi_2\{(\mu\text{-}Cl)_2\}^-]_n$.[154,155]

The cubane cluster $Bi_4Co_4(CO)_{12}$ (**26**) is a thermodynamic sink in a number of reactions of the other Bi–Co carbonyl compounds.[149] It does not appear to be stable to substitution or to reduction, but detailed chemistry of this compound has not been reported.

Electrochemical reduction of $BiCo_3(CO)_9$ (**25**) or pyrolysis of (**28**) produces the unusual cluster compound $[Bi_2Co_4(CO)_{11}]^-$ (**27**) (Scheme 2).[156] This compound is reduced to a dianion that is believed to have essentially the same structure as (**27**) based upon the structures of $[Sb_2Co_4(CO)_{11}]^{n-}$ ($n = 1$ or 2) which have both been reported.[157] For that redox pair the major change upon reduction is lengthening of the CO-bridged Co–Co bond by about 0.135 Å. The bismuth compounds are more sensitive to oxidation and fragmentation than are the antimony analogs.

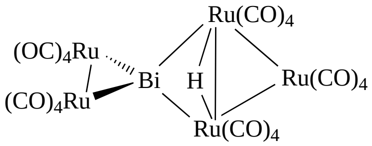
$NaBiO_3$ may also be used to introduce Bi atoms into metal clusters, as has been demonstrated in the case of iron (Scheme 3), osmium, ruthenium, chromium, and molybdenum carbonyls. This reaction works best for $Fe(CO)_5$ in methanolic KOH, where $[Bi\{Fe(CO)_4\}_4]^{3-}$ (**29**) is produced cleanly and in high yield.[158] Similarly, reaction of $Cr(CO)_6$ with $NaBiO_3$ at room temperature in methanol leads to $[Bi\{Cr(CO)_5\}_4]^{3-}$ or to $[MeBi\{Cr(CO)_5\}_3]^{2-}$ at 80 °C.[159] If the $NaBiO_3/Fe(CO)_5$ reaction is carried out with heating in the absence of KOH, the cluster product is $[BiFe_3(CO)_{10}]^-$ (**35**).[160] Alkylation of (**35**) occurs at the μ_3-CO rather than at Bi, giving (**36**), illustrating the low basicity of the main group atom.[161] Compound (**31**) is the starting point for a wide number



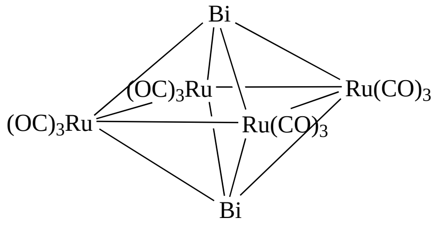
Scheme 3

of Bi–Fe carbonyl complexes. Addition of $BiCl_3$ to (**31**) results in the formation of $[XBi\{Fe(CO)_4\}_3]^{2-}$ (**30**), which appears to be a simple substitution of X^- for $[Fe(CO)_4]^{2-}$, but this exchange does not occur with $[Et_4N]X$ and probably is initiated by initial oxidation of (**31**). The structurally related $[RBi\{Fe(CO)_4\}_3]^{2-}$ ($R = Bu$, $PhCH_2$) are obtained when $[Bi\{Fe(CO)_4\}_4]^{3-}$ is treated with the organic halides, although cyclic $[RBiFe(CO)_4]_2$ compounds may also be obtained.[162] The latter complexes show Bi_2Fe_2 ring structures, but the R = butyl compound has also been crystallized in a polymeric form.[163] Reaction of (**32**) generated in situ with $Cr(CO)_5(THF)$ produces the mixed-metal compound $[Bi\{Fe_2(CO)_8\}\{Fe(CO)_4\}\{Cr(CO)_5\}]^-$. Compound (**31**) is protonated to yield a mixture of $Bi_2Fe_3(CO)_9$ (**35**) and $H_3BiFe_3(CO)_9$ (**34**). The first can be viewed as arising via an oxidation of (**31**), while the second as a protonation reaction with subsequent loss of CO and a metal fragment. Compound (**29**) is also oxidized by $[Cu(NCMe)_4]BF_4$ to give a monoanion with an Fe–Fe bond (**31**). This compound is unstable and decomposes to $[Bi_4Fe_4(CO)_{13}]^{2-}$ (**37**) upon standing in solution.[164,165] This product is a very interesting compound based upon a tetrahedral array of Bi atoms with $Fe(CO)_3$ groups capping three of the triangular faces (it is discussed further below). Compound (**29**) will react further with $NaBiO_3$ to form $[Bi_2Fe_4(CO)_{13}]^{2-}$ (**32**),[166] which is based upon a square pyramidal Bi_2Fe_3 arrangement of metal atoms. Compound (**32**) also arises when $[Fe(CO)_4]^{2-}$ adds to (**33**). This can be viewed as formally adding two electrons to the Bi_2Fe_3 cluster core, giving rise to Fe–Fe bond cleavage as predicted from simply electron counting considerations. Oxidation of (**32**) regenerates (**33**). A series of compounds of the general form $[\{Fe_3(CO)_9EML_n\}_2]$ have been examined and the structural parameters associated with the main group atom can be interpreted in terms of the hybridization at that atom.[167] The compound $Fe_3(CO)_9[BiFe(CO)_2\{Fe(CO)_2C_5H_3{}^tBu_2\}_2]$, another square pyramidal cluster, is obtained when $\{(CO)_2C_5H_3{}^tBu_2\}(CO)_2FeBiCl_2$ is treated with $[Fe(CO)_4]^{2-}$,[34] and the isoelectronic asymmetric species $Fe_3(CO)_9\{SeBiFe(CO)_2C_5H_4{}^tBu\}$ is formed when $[Fe_3(CO)_9Se_2]^{2-}$ is treated with $(C_5H_4{}^tBu)Fe(CO)_2BiCl_2$.[168] Addition of $[Co(CO)_4]^-$ to (**33**) leads instead to vertex replacement and the formation of $[Fe_2(CO)_6Bi_2(\mu\text{-}Co(CO))_4]^-$ (**38**).[169]

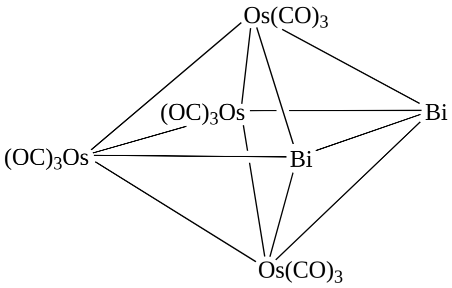
This molecule as well as the $[(\mu\text{-H})Fe_2(CO)_6Bi_2\{\mu\text{-Fe(CO)}_4\}]^-$ and $[Fe_2(CO)_6\{BiMo(CO)_3(C_5H_3{}^tBu_2)\}_2\{\mu\text{-Fe(CO)}_4\}]^-$ have tetrahedral Bi_2Fe_2 cores with the Bi–Bi vector bridged by the third transition metal fragment.[155] There appears to be a substantial bonding interaction between the bismuth atoms even though none would be predicted by normal electron counting formalisms. Main group element-main group element bonding of this sort is a hallmark of clusters molecules in this class.[170] Interestingly, when $[W_2(CO)_{10}]^{2-}$ is treated with $(C_5H_4{}^tBu)Fe(CO)_2BiCl_2$ another edge-bridged tetrahedral cluster is obtained. It has the formula $Bi_2W_2(CO)_8\{\mu\text{-BiFe(CO)}_2(C_5H_4{}^tBu)\}$. It is also based upon a M_2Bi_2 tetrahedron, but in this case it is the M–M bond that is bridged.[34]



(**39**)

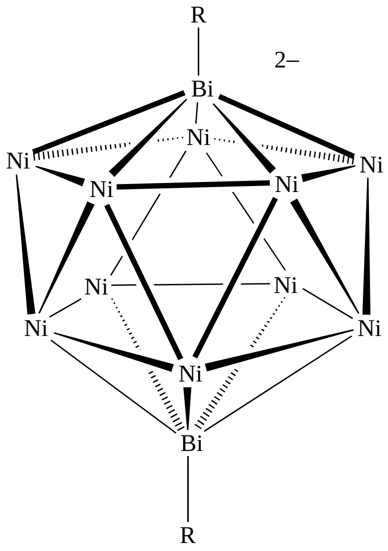


(**40**)



(**41**)

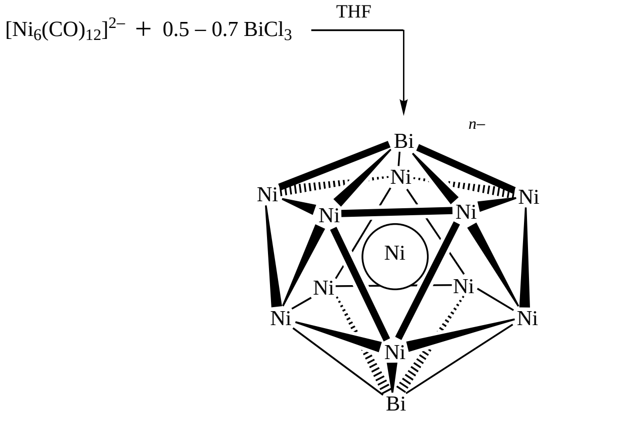
Some analogous ruthenium- and osmium-bismuth clusters have been found.[171] Examples include $Bi_2M_3(CO)_9$ and $H_3BiM_3(CO)_9$ (M = Ru, Os). The structures of the hydride compounds have both been determined and they are isostructural with the iron complexes as is $Bi_2Ru_3(CO)_9$ with $Bi_2Fe_3(CO)_9$. The structure of $Bi_2Os_3(CO)_9$, on the other hand, has not been determined and its IR spectrum indicates that it probably has a different structure. A spirocyclic cluster $[Ru_2(CO)_8(\mu_4\text{-Bi})Ru_3(CO)_{10}(\mu\text{-H})]$ (**39**) has been reported.



(**42**)

Of particular interest is the observation of different isomers for $Bi_2Ru_4(CO)_{12}$ (**40**) and $Bi_2Os_4(CO)_{12}$ (**41**).

Antimony–iron carbonyl clusters show similarities to the bismuth–iron compounds as well.[172] A key difference between the antimony- and bismuth-containing complexes is that the bismuth atom is generally less basic and more Lewis acidic than the antimony atoms in corresponding compounds. Reaction of $[Ni_6(CO)_{12}]^{2-}$ (1) with $RBiCl_2$ gave icosahedral $[Ni_{10}(CO)_{18}(BiR)_2]^{2-}$ (R = Me, Et; (**42**)) as the major product. These molecules possess noncentered 1,12-$Ni_{10}Bi_2$ icosahedral cages as do the other members of the homologous series $[Ni_{10}(CO)_{18}(EMe)_2]^{2-}$ (E = P, As, Sb).[173] Metal-centered versions of these cluster geometries are also known from the reaction of $BiCl_3$ with $[Ni_6(CO)_{12}]^{2-}$ (equation 2, (**43**)).[174]

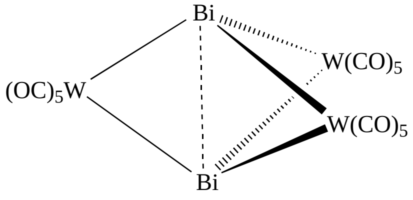


(**43**)

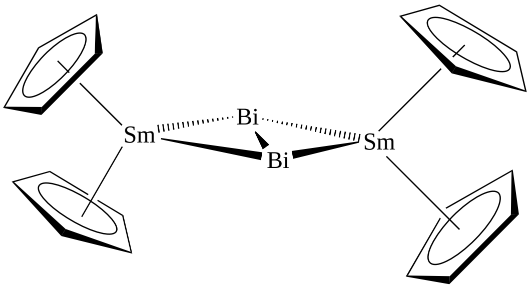
Cluster core structure of $[Bi_2Ni_{10}(\mu_{12}\text{-Ni})(CO)_{18}]^{n-}$

(2)

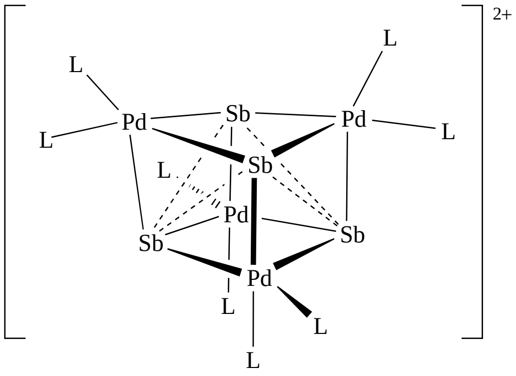
The reaction of $[W_2(CO)_{10}]^{2-}$ with $BiCl_3$ gives rise to a neutral compound $Bi_2\{\mu\text{-W(CO)}_5\}_3$ (**44**), in which the Bi–Bi



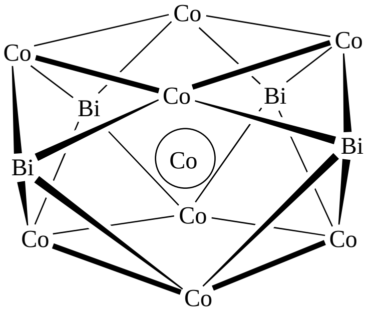
(**44**)



(**45**)

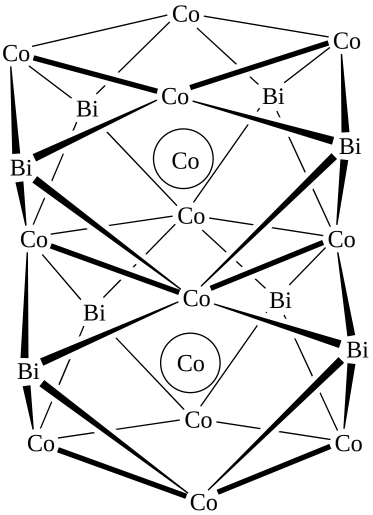


(**46**)



Cluster core structure of $[Bi_4Co_9(CO)_{16}]^{2-}$

(**47**)



Cluster core structure of $[Bi_8Co_{14}(CO)_{20}]^2$

(**48**)

distance is very short (2.8183(3) Å).[136,175] The molecule is proposed to be based on a Bi–Bi triple-bonded fragment. Reaction of $Me_3SiCH_2BiCl_2$ with $[W(CO)_5]^{2-}$ yields this compound as well as $[Bi_2W_2(CO)_8(\mu\text{-BiMeW(CO)}_5)]$.[176]

Only one early transition metal complex has been reported. That compound is $[(Me_5C_5)_2SmBi_2Sm(C_5Me_5)_2]$ (**45**), which arises from the reaction of $Sm(C_5Me_5)_2$ with $BiPh_3$. The compound is unique in that it contains a planar Sm_2Bi_2 core in which there is a Bi–Bi bond of 2.851(1) Å, a value substantially shorter than most observed Bi–Bi single bonds.[177] Similarly the late transition metal complex PdL_4 ($L = Ph_2Me$), which is known to lose phosphine ligands readily, reacts with Ph_2BiBr to give the cationic cluster $[Bi_4Pd_4L_8]^{2+}$ (**46**) with $Ph_2BiBr_2{}^-$ as the counterion.[178] That reaction proceeds presumably by initial oxidative addition of the Bi–Br bond to the Pd^0 center.

Electron counting rules have been developed to explain the observed geometries of many cluster compounds (*see* ***Electronic Structure of Clusters***). Interesting, heavy main group element-transition metal complexes tend to violate these rules. In simple cluster compounds the bismuth atom will function as a three-electron donor to the skeletal electron count. The bismuth atom retains a lone pair of electrons which, except in the more negatively charged compounds, is not used for further bonding. This is in contrast to antimony-containing cluster compounds where the lone pair is usually donated to some appended metal fragment. But higher nuclearity compounds begin to exhibit unusual electron counts. Bismuth–transition metal clusters which do not obey the simple electron counting rules include $[Bi_4Fe_4(CO)_{13}]^{2-}$ (**37**) (Scheme 3), $[Bi_4\{Fe(CO)_3\}_3\{Fe(CO)_2(C_5H_3{}^tBu_2)\}_2]^{2-}$, and $[Bi_2Co_4(CO)_{11}]^{x-}$ ($x = 1$ or 2) (**27**) (Scheme 2).[34,157,164] These clusters are formally electron-rich and molecular orbital calculations show that the interaction of the bismuth atoms and the transition metals gives rise to additional nonbonding orbitals which can accommodate extra electrons. Both of these compounds show direct Bi–Bi bonding. These compounds can be viewed as Zintl ions being stabilized by coordinated metal fragments, and so direct reaction of Zintl ions with metal fragments would be expected

to lead to interesting products. Thus, when the Zintl phase K_5Bi_4 is treated with 4,7,13,16,21,24-hexaoxa-1,10-diazabicylco[8.8.8]hexacosane (crypt) and $Cr(CO)_3$(mesitylene) or $Mo(CO)_3$(cycloheptatriene), the trigonal bipyramidal $[Bi_3M_2(CO)_6]^{3-}$ (M = Cr, Mo) complexes are formed.[133] The two transition metal atoms are located in equatorial positions, leading to the analysis of the bismuth fragment as a bent $Bi_3{}^{3-}$, which is isoelectronic and isostructural with ozone. Further exceptions to the cluster-electron counting rules are $[Bi_4Co_9(CO)_{16}]^{2-}$ (**47**) and $[Bi_8Co_{14}(CO)_{20}]^{2-}$ (**48**), which arise upon oxidation of the reaction product of $[Bi_2Co_4(CO)_{11}]^-$ and $Mo(CO)_3$(toluene). These compounds are based upon close-packing of metal atoms and do not have closed-shell electronic configurations.[179]

1 INTRODUCTION

Triethylbismuth, the first known organobismuth compound, was prepared in 1850 by Löwig and Schweizer[1] from iodoethane and a potassium–bismuth alloy. As with most trialkylbismuth compounds, $BiEt_3$ has an extremely pungent and unpleasant odor, and is spontaneously oxidized in air. The development of organobismuth chemistry was, therefore, delayed until better techniques for the handling of air sensitive materials were developed in 20th century. The chemistry of these complexes first began to receive significant attention when Grignard reagents and organolithium compounds became available. These reagents greatly expanded the synthetic capabilities for preparing organobismuth compounds. An excellent book[2] and several detailed reviews of organobismuth chemistry have appeared.[3–6] In addition, the *Journal of Organometallic Chemistry* has published periodic reviews of organobismuth chemistry.[7] Part of the current interest in organobismuth compounds can be attributed to their biological activity/pharmaceutical applications and to their application as precursor compounds to important electronic and/or magnetic materials such as the high T_c superconductors.

2 TRIVALENT ORGANOBISMUTH COMPOUNDS

2.1 Syntheses of Homoleptic Organobismuth Compounds

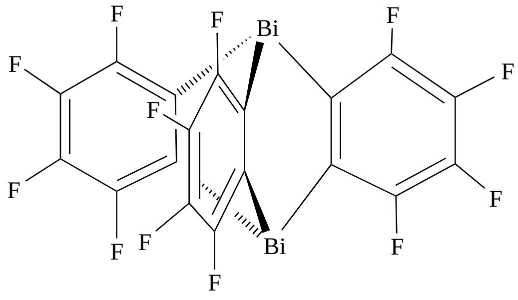
The most general and widely used methodology for the synthesis of homoleptic trialkyl- and triarylbismuth complexes (**1**) is the reaction of a bismuth trihalide with organolithium or magnesium reagents (equation 1). Besides alkyl and aryl groups, alkynyl, alkenyl, and allyl functions have also been introduced into organobismuth molecules by this method. Fluorinated aryl groups have also been introduced using organolithium reagents.[8] This is a particularly important methodology for creating asymmetric bismuth compounds, as described below. Organomercury compounds also may be used. Perfluoroalkylbismuth compounds have been prepared from an appropriate organo-cadmium or -zinc reagent and BiX_3.[9–12] The reaction of K_3Bi with organic halides (equation 2) was, as mentioned above, the first method used to prepare triorganobismuth compounds. This method is generally more difficult, not as clean, and produces a lower yield. In some cases, however, such as the synthesis of $(Me_3Si)_3Bi$, it is the only available method.[13] Other more esoteric methods have been used to produce trivalent organobismuth compounds, such as the reaction of bismuth atoms from a metal atom reactor with in situ generated organic radicals, but these have limited synthetic utility.[14] Direct reaction of bismuth metal usually produces mixed halo/organobismuth complexes and not homoleptic compounds.

$BiCl_3 + 3LiR \longrightarrow$  $+\ 3LiCl$ (1)

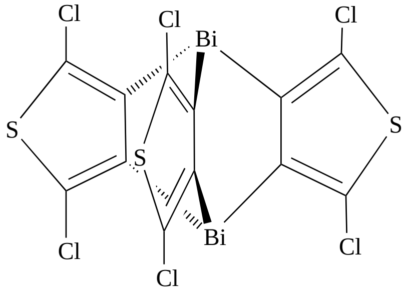
(**1**)

$$K_3Bi + 3RX \longrightarrow BiR_3 + 3KX \quad (2)$$

A novel variation on the synthesis of triarylbismuth compounds is the formation of complexes containing two bismuth atoms as shown in (**2**)[15] and (**3**).[16] The triptycene compound (**2**) was prepared via the reaction of 1,2-diiodotetrafluorobenzene with bismuth powder in a sealed tube. The related compound (**3**) was prepared via the reaction of 2,5-dichloro-3,4-dilithiothiophene with $BiCl_3$. Difunctional alkyl reagents such as $X(CH_2)_nX$ are also observed to react with R_2BiNa. Long-chain compounds form the expected dibismuth compounds, but for $n = 4$ or 5, dismutation occurs to give the heterocyclic compounds *cyclo*-$MeBi(CH_2)_n$ and $BiMe_3$.[17] Both cyclic compounds were obtainable directly via the reaction of the Grignard reagents $BrMg(CH_2)_nMgBr$ with Me_2BiBr. Phenylene bridges have been used to connect organic bismuth functions with the goal of creating bismuth-containing polymers and dendrimers.[18]



(**2**)



(**3**)

2.2 Syntheses of Asymmetric Organobismuth Complexes

Asymmetric organobismuth compounds are those in which there is more than one type of organic group attached to the bismuth atom. The syntheses of these compounds proceed naturally and most conveniently from the organobismuth halides $RBiX_2$ and R_2BiX. In this fashion, a wide variety of organic functions have been introduced, usually via reaction with an organolithium or organomagnesium reagent. The nature of the end product may be controlled by redistribution reactions, however, as discussed by Gilman and Yale.[4] An alternate route to asymmetric organobismuth complexes is addition of organic halides to R_2BiM. The latter is prepared by reduction of R_2BiX in anhydrous liquid ammonia with active metals such as sodium or potassium. Complexes with three different groups attached are chiral and some examples have been prepared, but they undergo inversion when heated in solution.[19] So far, there are no reports of resolution of organobismuth enantiomers.

2.3 Properties and Structure

Physical properties of a number of organobismuth complexes have been compiled.[3,4] The trialkylbismuth compounds are generally very oxygen sensitive, though stable to moisture. Many triarylbismuth compounds are air stable as well as stable to moisture. The trialkyls with small R groups are colorless liquids, which may be distilled under vacuum. Triphenylbismuth is a commercially available, air stable, white crystalline solid.

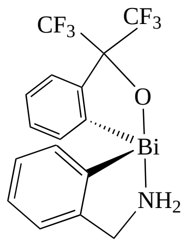
The compound $R_2Bi–O–BiR_2$ has been found as an intermediate in the oxidation of trialkylbismuth compounds.[20] Unlike $BiPh_3$, the compound $Bi(R_f)_3$ [R_f = 2,4,6-$(CF_3)_3C_6H_2$] is air sensitive and slowly evolves R_fOR_f and R_fOH upon standing in air.[21] These findings are consistent with the intermediacy of an $O{=}Bi(R_f)_3$ complex followed by the insertion of O into a Bi−C bond. Reductive elimination from such an intermediate would generate the ether, while hydrolysis would produce the phenol.

Simple trialkyl- and triarylbismuth compounds are pyramidal molecules as expected from simple Valence Shell Electron Pair Repulsion Model (VSEPR) considerations. The degree of pyramidality has been shown to correlate with the charge on the bismuth atom, with barriers to inversion calculated to be in the range of 30−70 kcal mol^{-1}.[22] Structures of several BiR_3 (R = Ph, 4-tolyl, CH_2SiMe_3, $C_6H_2Me_3$, 2,4,6-$C_6H_2(CF_3)_3$) compounds are known from single-crystal X-ray diffraction data[21,23,24] and bond parameters for Me_3Bi are available from electron diffraction.[25] Bismuth−carbon bond distances range from 2.24 Å for small R groups to 2.38 Å where the organic group is sterically demanding. Values for Bi–C bond strengths range from 33−44 kcal mol^{-1} for $BiMe_3$, and from 42−47 kcal mol^{-1} for Ph_3Bi. In spite of the fact that these numbers cover quite a range of values and that it is difficult to compare quantitatively the relative Bi–C bond strengths, it appears that bonds to aryl functions are generally stronger than those to alkyl groups. BiR_3 compounds are much less basic and the lone pair is much more diffuse than the lighter group V analogs.

Bismuth, the heaviest member of group 15, has a strong tendency to form hypervalent complexes. A common structural feature in alkyl- and arylbismuth compounds is the interaction of the bismuth atom with the appended donor functionality (e.g. NH_2, carbonyl, etc.) present in the organic fragment. Specific examples will be seen in subsequent discussions.

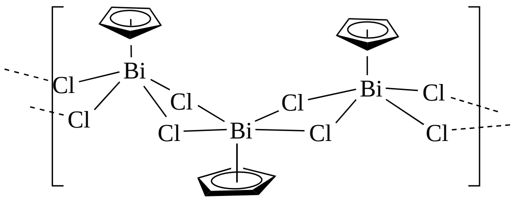
The pyramidal bismuth atom may undergo inversion and this has been studied for several chelating ligands, as in (**4**). The findings were consistent with an edge inversion mechanism rather than a vertex inversion process.[26] The edge inversion mechanism proceeds through a T-shaped transition state. This mechanism predicts that the inversion barrier will decrease with an increasing atomic number, and that σ-acceptors will stabilize the transition state as will coordination of nucleophiles to an empty p orbital that appears in the transition state.[27] The chiral bismuth complexes BiBr(4-tolyl)($C_6H_4CH_2NMe_2$) and BiBr(4-tolyl)($C_6H_4CH_2OMe$) have been prepared and studied by NMR.[28] On the NMR timescale, the diastereotopic methylene protons for the NMe_2 compound can be resolved, but in strongly donating solvents, such as DMSO, inversion occurs readily.

Cyclopentadienylbismuth compounds have been prepared and Cp_3Bi exists in two crystalline forms: a



(**4**)

red and a black modification.[29] This has been commonly found for cyclopentadienyl derivatives of bismuth: tris(pentamethylcyclopentadienyl)bismuth and $CpBiCl_2$ also exhibit red/black isomerism. The Cp rings are π-bound in $CpBiCl_2$,[30,31] but the π-interaction is asymmetric and involves η^2- and η^3-coordination to the bismuth atom. $CpBiCl_2$ is polymeric, being held together by intermolecular Cl−Bi bridges (**5**), which further illustrates the ability of the bismuth atom to function as a Lewis acid. π-Bonding may be involved in the tris(allyl) complex, but its structure is not yet known.



(**5**)

Simple arene solvates of bismuth(III) halides and pseudohalides have been structurally characterized, as have adducts prepared in the presence of $AlCl_3$.[32–34] The solid-state structures of these compounds show π-coordination of the arenes to the bismuth centers, as well as intermolecular Bi···X bonding that produces dimers or polymeric structures. Arene complexes that have been structurally characterized include those of benzene, *o*-, *m*- and *p*-xylene, mesitylene, and hexamethylbenzene.[32] π-Coordination of arenes has also been seen in $[Bi(OC_6F_5)_3(toluene)]_2$ and $Bi_4(\mu_4\text{-}O)(\mu\text{-}OC_6F_5)_6\{\mu_3\text{-}OBi(\mu\text{-}OC_6F_5)_3\}\cdot 2(C_6H_5CH_3)$.[34,35]

2.4 Trialkyl- and Triarylbismuth Compounds as Donors to Transition Metals

R_3Bi compounds possess lone pairs of electrons but, compared to phosphines, very few metal complexes with R_3Bi ligands are known. Exceptions are $M(CO)_5BiPh_3$ (M = Cr, Mo, W),[36] $[CpFe(CO)_2BiPh_3]BF_4$,[37] and $[Ir(BiPh_3)(PPh_3)_2(CO)]ClO_4$.[38] Trialkylbismuth compounds are more basic than the triaryl compounds, as may be expected, and should form more stable donor adducts with transition metals. Trialkylbismuth complexes, which have been reported, include $Ni(CO)_3BiR_3$, $M(CO)_5BiR_3$ (R = Et, *t*-Bu), $[Et_4N][CpV(CO)_5BiEt_3]$, $CpV(CO)_3BiEt_3$, and $CpV(CO)_2(BiEt_3)_2$.[38,39] The complex $Fe(CO)_4(BiPh_3)_2$ was reported a number of years ago[40] but attempts to repeat that preparation have not been successful. Instead, the cluster complex $Bi_2Fe_3(CO)_9$ is obtained, pointing up a complication in the formation of triorganobismuth-metal complexes: the weakness of the Bi–C bond. This property results in facile redistribution reactions or the loss of organic functions from bismuth with the building of higher nuclearity metal complexes. Thus, reactions between $BiPh_3$ and metal halides often give Ph_2BiX and not Ph_3Bi−metal complexes. In contrast to these findings, $BiPh_3$ reportedly forms 1:2 adducts with UCl_5, and 1:1 and 1:2 adducts with $NbCl_5$.[41] These formulations have not, however, been confirmed by X-ray diffraction and in light of the other reports may be questioned.

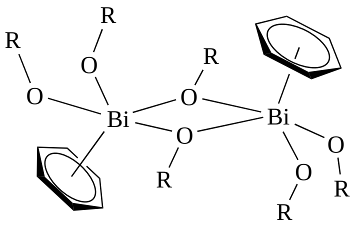
2.5 Uses of BiR_3 Compounds

BiR_3 compounds have a number of uses. They are effective cocatalysts for the polymerization of substituted acetylenes by $MoCl_5$ or WCl_6.[42] $BiPh_3$ can act as a radiopacifying additive for polymeric materials such as polystyrene, poly(vinyl chloride), polyacrylates, and polyethylenes, with which it forms homogeneous mixtures. Leaching from the polymer can be prevented by using styryldiphenylbismuth, which copolymerizes. BiR_3 compounds have been used for preparing thin films of bismuth or bismuth oxide, and for incorporating bismuth into thin films of high T_c superconductors.

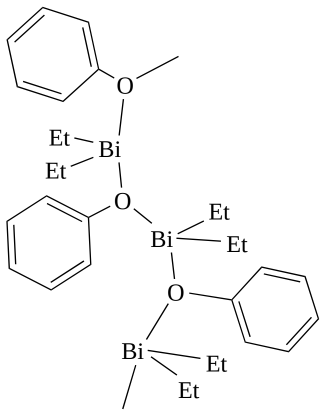
Organobismuth derivatives may undergo solvolysis with compounds that have acidic protons to replace one or more of the organic functions. The production of bismuth alkoxides and biologically relevant bismuth complexes has been accomplished in this way (*see* ***Bismuth: Inorganic Chemistry***). $BiPh_3$ reacts with HOC_6F_5 in toluene to give the dimeric alkoxide complex $[Bi(OC_6F_5)_2(\mu\text{-}OC_6F_5)(toluene)]_2$ (**6**),[34] while $BiEt_3$ reacts with HOPh or HOC_6F_5 to give the polymeric $[Et_2BiOAr]_\infty$ (**7**).[43] Two phenyl groups are displaced when $BiPh_3$ is treated with maleic acid to give $PhBi(O_2CCH{=}CHCO_2H)_2$. The maleic acid functions are themselves displaced when the complex is treated with Na[dtc].[44]

2.6 Organobismuth Halides

Redistribution reactions (equation 3) are a facile method of synthesizing organobismuth halides.[11,45] As an example, when stoichiometric amounts of $BiCl_3$ and $BiPh_3$ (each dissolved in Et_2O) are mixed, an essentially quantitative precipitation of Ph_2BiCl is achieved. Stoichiometric reactions of the appropriate organolithium, -magnesium, or -mercury compounds with bismuth halides may also be used. For example, 2-(2′-pyridyl)phenylmercury chloride reacts with $BiBr_3$ to give dibromo-2-(2′-pyridyl)phenylbismuth.[31] This



(**6**)



(**7**)

method has been used for preparing other alkylbismuth halides.

$$BiCl_3 + 2BiPh_3 \longrightarrow 3BiPh_2Cl \qquad (3)$$

Organobismuth(III) halides may be prepared by elimination of aryl halide from triarylbismuth(V) dichlorides or dibromides upon heating (equation 4). Presumably, a bismuth(V) compound is the intermediate when triarylbismuth compounds are treated with iodine or when trialkylbismuth complexes are treated with chlorine, bromine, or iodine, but the intermediates have not been isolated and organobismuth halides are obtained directly (equation 5). The tris(trifluoromethyl)bismuth behaves like the trialkyl compounds without the observation of a bismuth(V) intermediate.[9]

$$BiAr_3X_2 \xrightarrow{\Delta} BiAr_2X + ArX \qquad (4)$$

$$BiAr_3 + I_2 \longrightarrow Ar_2BiI + ArI \qquad (5)$$

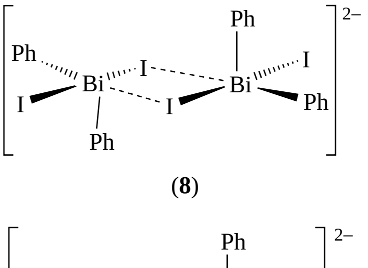
Aryl groups appear to be preferentially cleaved with acids, so that addition of HX (X = Cl, Br) to Ph_2BiMe leads to $MeBiX_2$.[46]

Cyclopentadienyl halide complexes have been prepared from the reaction of NaCp or LiC_5Me_5 and $BiCl_3$.[47] As described earlier, $CpBiCl_2$, in its red crystal morphology, has been structurally characterized (**5**) and shows a chain polymeric structure containing both η^2- and η^3-coordination of the Cp ring to bismuth. In $(C_5Me_5)_2BiCl$, the cyclopentadienyl rings are pentahapto.[30] The pentamethylcyclopentadienyl complex $(C_5Me_5)BiBr_2$ was prepared via the reaction of bismuth powder with 5-bromopentamethyl-1,3-cyclopentadiene.[48]

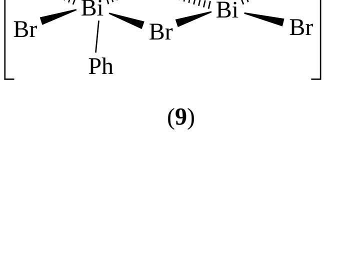
For decades, it has been known that reaction of organobismuth halides with hydride reducing agents often results in intractable products presumably via the intermediacy of highly reactive bismuth hydrides. The use of the bulky organic function 2,4,6-$C_6H_2(^tBu)_3$ allows the isolation of the stable R_2BiH species.[49] When R = $(Me_3Si)_2CH$, the hydride intermediate can be detected but decomposes at room temperature to give the dibismuthine R_2BiBiR_2.[50]

2.7 Lewis Acidity of Organobismuth Compounds

Just as bismuth complexes with inorganic substituents are Lewis acids, so are their organobismuth analogs (*see* ***Bismuth: Inorganic Chemistry***). Lewis acidity is enhanced by the presence of the electronegative ligands, which tend to make the bismuth centers more electropositive. This feature can reduce the solubility of the aryl bismuth halides through intermolecular halide bridges as observed for Ph_2BiCl, $PhBiBr_2$, and $MeBiCl_2$.[51] Not surprisingly then, $RBiX_2$ (R = Me, Ph) can be isolated as THF, bipyridine, or phenanthroline adducts in which there are also Bi···X intermolecular contacts.[46,52] In some cases, weak π interactions are seen between the bismuth atom and the aryl rings of an adjacent molecule. In addition to solvent adducts, organobismuth halides also form complexes with added halide ions. Structurally characterized examples include $[Et_4N][Ph_2BiI_2]$ (**8**) and $[Et_4N]_2[Ph_2Bi_2Br_6]$ (**9**).[33] In the iodide complex, the bismuth has a distorted square-pyramidal geometry in which one phenyl group is in the axial position. The square base is defined by the second phenyl group, two iodide ligands at 3.0517(8) and 3.1415(8) Å, and a close contact to an iodide ligand in an adjacent molecule at 4.0850(11) Å, giving the compound an asymmetric, dimeric nature. In (**9**), the phenyl group in the square base has been



(**8**)



(**9**)

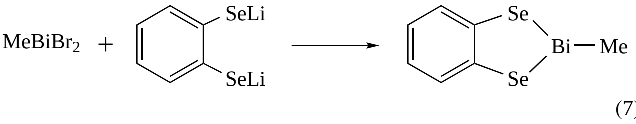
replaced by a Br^- ion and is similarly dimeric, although more symmetrical. The terminal Bi–Br distances are 2.7417(14) and 2.7559(14) Å, while the bridge distances are significantly longer at 3.0072(14) and 3.0545(14) Å. These complex halo aryl bismuth anions can also be found coordinated by other neutral ligands such as triphenylphosphine oxide and *N*,*N'*-dimethylpropylene urea.[53] Observed structures include those of $Bi_2Ph_2Br_4L_2$ (L = $OPPh_3$ and *N*,*N'*-dimethyl urea), $PhBi_2X(4\text{-}RC_6H_4N)_2$ (X = Cl, Br, I; R = H, Me, ^{t}Bu) and $(Mes)_2Bi(L)Br$ (L = hexamethylphosphoramide or $OSPh_2$). Dibromo-2-(2′-pyridyl)phenylbismuth forms 1:1 adducts with $[Et_4N]I$ and $Na[O_2CEt]$, but reacts with Na[dtc] to displace both of the Br^- ions giving bis(dithiocarbamato){2-(2′-pyridyl)phenyl}bismuth.[44] It is possible to promote displacement of the halides in R_2BiX with halide-abstracting reagents such as $TlPF_6$.[54] In this way, $[BiPh_2L_2][PF_6]$ (L = $OP(NMe_2)_3$ or pyridine) and $[BiPh\{OP(NMe_2)_3\}_4][PF_6]_2$ have been produced. In addition to coordination by external ligands, organic groups that contain donor functionality can form Lewis acid-base adducts intramolecularly as in the case of $[(2\text{-}Me_2NCH_2C_6H_4)_2Bi]^+$, where the amine functions coordinate to bismuth.[55] The bismuth biphenylene complex $[Bi(2,2'\text{-biphenylene})Cl_2]^-$ is another example of a 10-electron organobismuth center.[56]

A very interesting species is $[Bi(CF_3)_4]^-$, which is formed by reaction of $Bi(CF_3)_3$ with Me_3SiCF_3 in the presence of $[NMe_4]F$.[57] Presumably, the fluoride ion displaces $CF_3{}^-$ from the silyl reagent making it available for reaction with $Bi(CF_3)_3$.

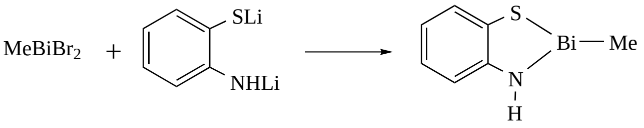
2.8 Organobismuth Compounds with E and ER$_x$ Ligands (E = O, S, Se, Te, x = 1; As, Sb, x = 2; Si, Ge, Sn, x = 3)

Organobismuth complexes that contain other heteroatom ligands are known and generally are prepared by (1) anion metathesis reactions or (2) reaction of HER_x with the organobismuth compound BiR'_3 upon the elimination of HR′. A third route involves the use of dibismuthines, as described in Section 2.11. A few examples of a variety of $RBi(ER_x)_2$ and R_2BiER_x complexes produced by methods (1) or (2) are given in equations (6–9). Alkoxide complexes from method (2) have been described above. Similarly, OH^- reacts with R_2BiX to give R_2BiOH, and with $RBiX_2$ to produce RBiO. Neither of these compound types have been particularly well characterized, but they present some interesting possibilities for future work. The mixed alkyl/alkoxide complexes have been implicated as intermediates in the oxidation of alkylbismuth complexes. $RBi(SR)_2$ complexes have been demonstrated to have antitumor activity.[58]

$$MeBiBr_2 + 2LiSMe \longrightarrow MeBi(SMe)_2 + 2LiBr \quad (6)$$



(7)

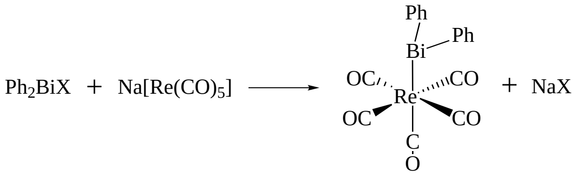


(8)

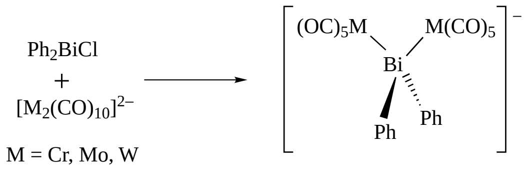
$$BiEt_3 + HGeEt_3 \quad Et_2BiGeEt_3 + EtH \quad (9)$$

2.9 Metallated Organobismuth Fragments

Metallated derivatives of organobismuth fragments may also be prepared. These compounds have synthetic and structural relationships to compounds without organic functionalities attached. These compounds may be prepared via the reaction of the organobismuth mono- and dihalides with a wide variety of metal carbonyl anions in straightforward anion metathesis reactions. For example, Ph_2BiML_n or $PhBi\{ML_n\}_2$ (ML_n = $Mn(CO)_5$, $Re(CO)_5$, $Fe(CO)_4{}^-$, $CpMo(CO)_3$), and $\{Ph_2Bi\}_2Fe(CO)_4$ (**10**) arise from the reaction of Ph_2BiCl and the appropriate metal carbonyl anion (equation 10 and Scheme 1).[59] The mixed species $BiBrPh\{Mo(CO)_3Cp\}$ will act as a Lewis acid toward bromide ions giving $[Br_2Bi(Ph)\{Mo(CO)_3Cp\}]^-$.[60] The latter complex rearranges to give $[Br_2Bi\{Mo(CO)_3Cp\}_2]^-$. Reactions between $[M_2(CO)_{10}]^{2-}$ (M = Cr, Mo, or W) and Ph_2BiCl lead to the production of the dimetallated complex ions $[Ph_2Bi\{M(CO)_5\}_2]^-$ (equation 11). In the case of M = Cr, the monometallated species $[Ph_2BiCr(CO)_5]^-$ has also been obtained. In the iron system, the products may also be accessed via the reaction of in situ generated Ph_2Bi^- with $Fe(CO)_5$.[61]

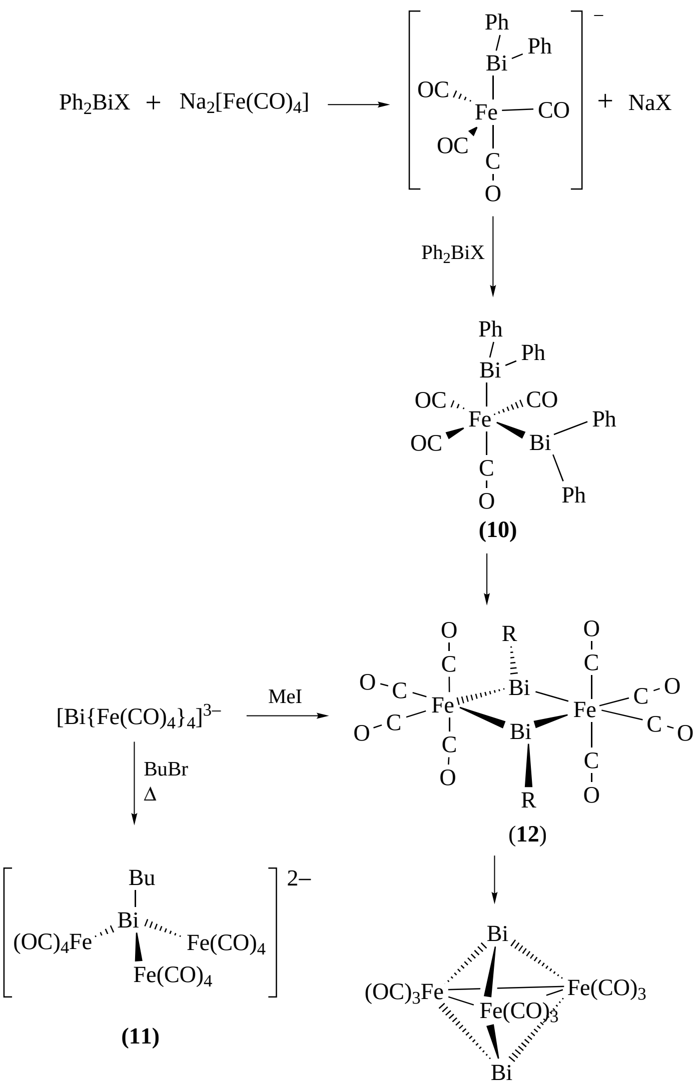


(10)



(11)

Organobismuth dihalides ($RBiX_2$) are useful starting materials, as has been demonstrated in the reactions of $PhBiBr_2$ with $Na[CpMo(CO)_3]$ and $Na[Co(CO)_3PPh_3]$ to give the corresponding $PhBi[ML_n]_2$ compounds.[62] The compound $EtBi[CpMo(CO)_3]_2$ can be prepared from the reaction of $ClBi[CoMo(CO)_3]_2$ with $K[HBEt_3]$ (equation 12), and $ClBi[CpFe(CO)_2]_2$ similarly reacts with $AlMe_3$ to give $MeBi[CpFe(CO)_2]_2$.[62] In a number of cases, metallated compounds readily lose one or more organic groups from the bismuth atom or undergo redistribution reactions. An example is the reaction of $BiBrMe_2$ with $[CpM(CO)_x]^-$ (M = Cr,



Scheme 1

Mo, W $x = 3$; M = Fe, $x = 2$), giving $MeBi[CpM(CO)_x]_2$ instead of the expected $Me_2Bi[CpM(CO)_x]$.[63] Reaction of $[Bi\{Fe(CO)_4\}_4]^{3-}$ with alkyl halides leads to $[RBi\{Fe(CO)_4\}_3]^{2-}$ (**11**) or $[RBiFe(CO)_4]_2$ (**12**).[64] For R = Bu, two forms are observed. One is the usual cyclic Bi_2Fe_2 core, while the other shows a polymeric chain of BiFe units.[65]

$$ClBi[CpMo(CO)_3]_2 + K[HBEt_3] \longrightarrow EtBi[CpMo(CO)_3]_2 \qquad (12)$$

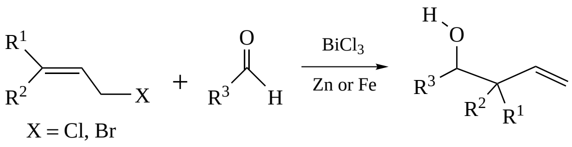
Tetraorganodibismuthines and cyclic bismuthines are useful for the preparation of metallated diorganobismuth complexes, as described in Section 2.11.

2.10 Organic Transformations Involving Bi^{III} Complexes

Bismuth salts are known for promoting a variety of organic reactions, and may have considerable advantages in replacing other metals that are toxic. For example, bismuth metal catalyzes the addition of allyl halides to ketones in the absence of a solvent, and presumably proceeds via Bi(III) intermediates.[66] Bismuth triflate has proven particularly useful and has been widely examined recently.[67–69] Reactions catalyzed by this salt include Diels–Alder reactions, acylations, allylations, and Michael additions among many others. Bismuth chloride has also been used for these same catalytic organic transformations,[68,70,71] but it is sensitive to hydrolysis, producing the insoluble BiOCl. Bismuth triflate, on the other hand, has been used successfully in the presence of water.[69]

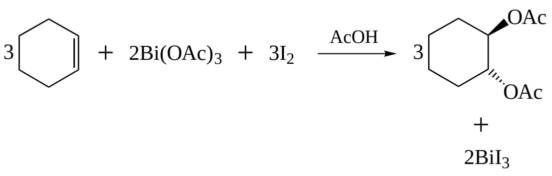
Organobismuth(III) complexes may mediate a number of reactions involving allylic compounds and aldehydes. In these reactions, an allyl halide is treated with a bismuth(III) salt such as $BiCl_3$ and a reducing agent (Zn, Fe, or Al) in the presence of an aldehyde (equation 13).[71,72] A likely reaction

mechanism involves the reduction of the bismuth halide to an activated metal powder, which can then oxidatively add the organic halide. In cases reported to date, these intermediates have not been isolated or characterized. Some substantiation for this comes from the fact that aldehydes can be allylated in the presence of bismuth powder.

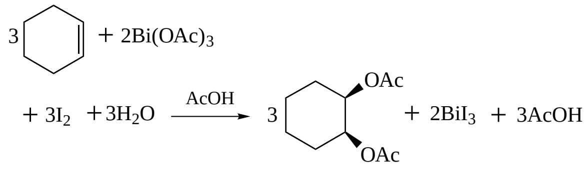


(13)

Bismuth(III) acetate reacts with cyclohexene to produce 1,2-diacetatocyclohexane. If conditions exclude water, a trans configuration arrangement of the two acetate groups is obtained, while the configuration is cis if water is included in the reaction (equations 14 and 15).[73]

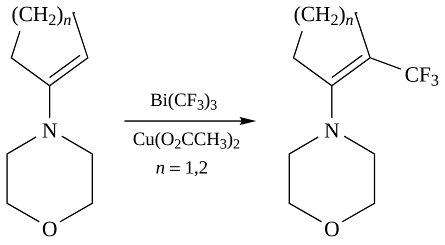


(14)

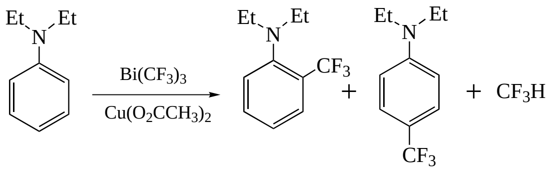


(15)

Copper acetate catalyzes the transfer of CF_3 groups from $Bi(CF_3)_3$ as shown in equations (16) and (17).[12] It is known that $Cu(O_2CCH_3)_2$ and $Bi(CF_3)_3$ undergo redistribution reactions to produce $Bi(CF_3)_2(O_2CCH_3)$ and $Bi(CF_3)(O_2CCH_3)_2$. The bismuth compound is also capable of transferring a methyl group to other metals: with $AgNO_3$ it gives $Ag[Ag(CF_3)_4]$, and with $TeCl_4$ the product is $Te(CF_3)_2Cl_2$.



(16)

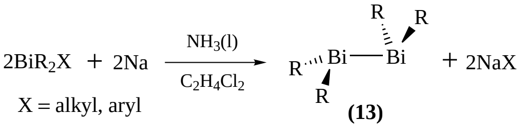


(17)

A number of bismuth/metal oxides are used in the catalytic oxidation of hydrocarbons, and in the oxidation and ammoxidation of alkenes. These transformations are described briefly in ***Bismuth: Inorganic Chemistry***.

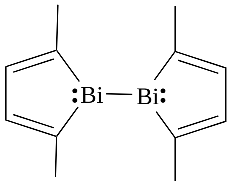
2.11 Molecules with Bi–Bi Bonds: Dibismuthines, Dibismuthenes, and Cyclobismuth

Reactions of R_2BiX (X = halide or R) with two equivalents of sodium in liquid ammonia followed by treatment with a dihaloethane results in the formation of the dibismuthines R_2BiBiR_2 (**13**, R = Ph, Me, Et, Pr, *i*-Pr, Bu, Mes; equation 18).[74–76] The heterocyclic derivative 2,2′,5,5′-tetramethylbibismole (**14**) has been similarly prepared from 1-phenyl-2,5-dimethylbismole (see Section 2.12).[77] Presumably $Na^+R_2Bi^-$ is an intermediate, but it has not been isolated. The related $LiBi(SiMe_3)_2{\cdot}DME$ complex has, however, been structurally characterized and is converted to the tetrakis(trimethylsilyl)dibismuthine upon reaction with 1,2-dihaloethane.[78] Reduction of Ph_2BiI using Cp_2Co produces $Ph_2BiBiPh_2$, with the advantage that the Cp_2CoI can be recycled (equation 19). Some dibismuthines are thermochromic, as are similar diantimonides.[6,79]



(13) (18)

$$2BiPh_2I + 2Cp_2Co \xrightarrow{THF} R_2Bi\text{–}BiR_2 + 2Cp_2CoI \qquad (19)$$



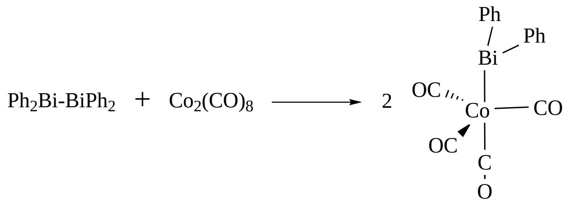
(14)

The dibismuthines with R = phenyl[75,80] and trimethylsilyl[78] have been structurally characterized. Bi–Bi distances are on the order of 3.0 Å. The Bi–Bi bond is reactive and is readily cleaved by a variety of reagents. Chalcogens insert into the Bi–Bi bonds (equation 20).[76] When treated with diarsines, distibines, ditellurides, or diselenides, scrambling of the organo/main group fragments occurs (equation 21), producing $R_2Bi\text{–}E\text{–}BiR_2$, which can also be prepared by direct reaction of R_2BiX with Na_2E.[20,81] A similar scrambling occurs with a variety of transition metal carbonyl dimers such as $Co_2(CO)_8$ (equation 22).[82]

$$Ph_2Bi\text{–}BiPh_2 + E \xrightarrow{E = O, S, Se, Te} Ph_2Bi\text{–}E\text{–}BiPh_2$$
$$\xrightarrow{E = O} Bi_2O_3 + BiPh_3 \qquad (20)$$

$$Ph_2Bi\text{–}BiPh_2 + R_XE\text{–}EiR_X \longrightarrow 2Ph_2Bi\text{–}E\text{–}R_X \quad (21)$$

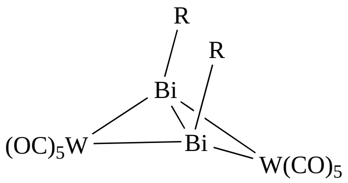
$$E = Sb, X = 2; E = Te, Se, X = 1$$



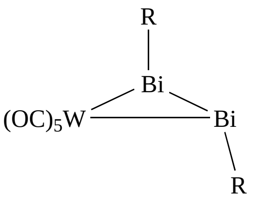
(22)

When extremely bulky aryl groups are attached to bismuth, it has proven possible to isolate dibismuthenes from the reduction of $ArBiX_2$.[83] The aryl groups employed included 2,6-$Mes_2C_6H_3$ and 2,6-$TripC_6H_3$ (Trip = 2,4,6-$^iPr_3C_6H_2$). Analogous complexes of P, As, and Sb were also prepared. Density functional theory calculations on PhBi=BiPh showed good agreement with the experimental X-ray structure and confirmed the presence of a σ and a π bond, both of which are composed almost completely of p orbitals, the s orbitals being used primarily for the nonbonding electron pair.[84]

Cyclic organobismuth compounds of the form $(RBi)_x$ ($x = 3, 4$) result from the reduction of $RBiCl_2$ with Mg [R = $(Me_3Si)_2CH$], $LiAlH_4$ (R = Me_3CCH_2, 2-$Me_2NCH_2C_6H_4$), or Na/NH_3(l) (R = 2-$Me_2NCH_2C_6H_4$).[85,86] These compounds are unstable with respect to disproportionation into BiR_3 and Bi. Metal fragments can be appended to the cyclobismuthines, but the cyclobismuthine structure may not be retained.[50,86,87] For example, reaction of $W(CO)_5(THF)$ with $(RBi)_n$ (R = Me_3CH_2, $n = 3$ or 5) produces $Bi_2R_2\{W(CO)_5\}_2$ (**15**), in which the two tungsten atoms bridge the Bi–Bi bond, and the R groups are cis to each other. Thermal decomposition of $Bi_2R_2\{W(CO)_5\}_2$ (**16**, R = Me_3SiCH_2) results in the elimination of one tungsten carbonyl group, and the R groups end up in a trans configuration.



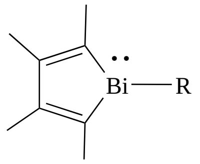
(**15**)



(**16**)

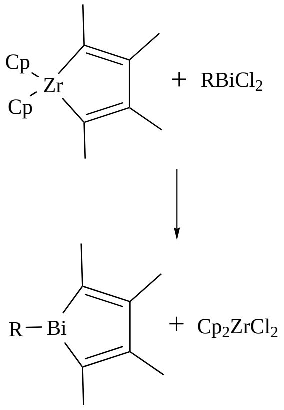
2.12 Heterocyclic Complexes

Inclusion of bismuth atoms in heterocyclic ring complexes has been actively investigated for a number of years. Complexes of the type (**17**), for example, 1-phenyl-2,5-dimethylbismole, have been sought for comparison with pyrrole derivatives and for information about the degree of aromaticity in its heavier analogs. Compound (**17**) is prepared via the addition of 2(*Z*),5(*Z*)-dilithio-3,4-dimethylhexa-2,4-diene to $PhBiI_2$ in 28% yield.[77] This heterocycle is converted to the dibismuthine in the standard fashion: treatment of (**17**) with Na in liquid NH_3 followed by addition of 1,2-dichloroethane.



(**17**)

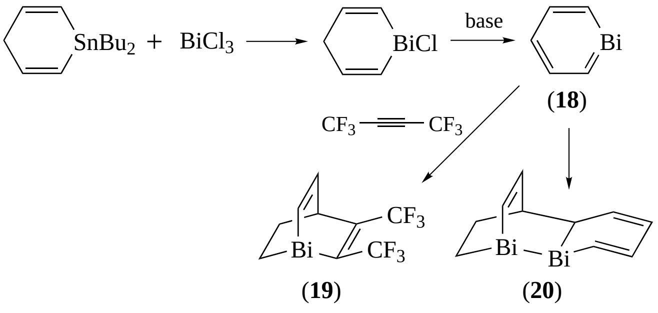
Another method that has been used to prepare bismuth-containing heterocycles is the ligand exchange reaction between $RBiCl_2$ and $Cp_2Zr(C_4Me_4)$ (equation 23).[88] The product where R = Ph can be isolated in 70% yield, but the R = Cl derivative is thermally unstable. Heterocyclobutadienes with one or two bismuth atoms have been studied theoretically.[89]



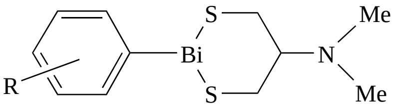
(23)

Bismabenzene (**18**) has been prepared according to Scheme 2.[90] The complex is not stable and will add 1,1,1,4,4,4-hexafluorobutyne to give (**19**). In solution at low temperature, the complex appears to exist as the Diels–Alder dimer (**20**), but raising the temperature gives an NMR spectrum consistent with (**18**).

The heterocyclic complexes incorporating other main group element atoms have been prepared via the reaction of $RBiBr_2$ with an appropriate difunctional salt or chelating ligand (see equations 7 and 8). The compound (**21**) is reported to have anticoccidial and insecticidal properties, as do other $RBi(SR)_2$ compounds.



Scheme 2



(21)

3 PENTAVALENT ORGANOBISMUTH COMPOUNDS

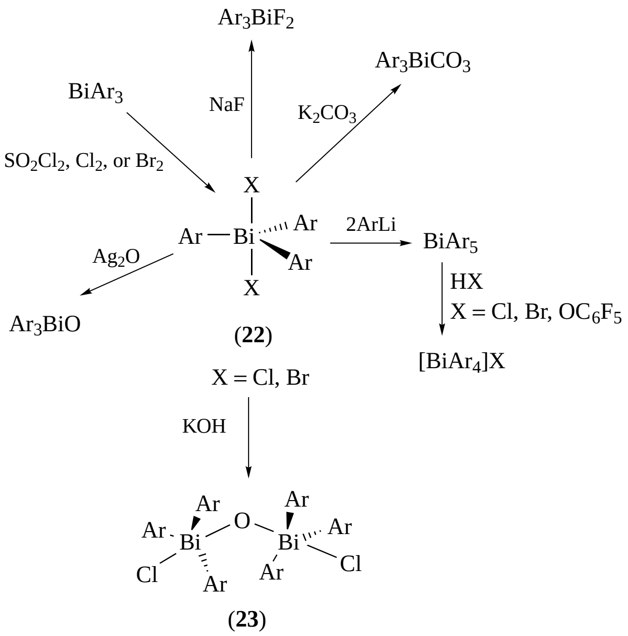
3.1 Syntheses and Structures

Triarylorganobismuth complexes are easily oxidized to bismuth(V) complexes by treatment with chlorine or bromine, giving Ar_3BiX_2 (X = Cl, Br). Reactions with iodine result in elimination to give trivalent $Ar_{3-x}BiI_x$, while reactions with fluorine are too vigorous. Xenon difluoride can be used to prepare Ar_3BiF_2 (Ar = C_6F_5, 2,6-$F_2C_6H_3$).[9,91] Fluoride derivatives are more often prepared by anion metathesis with NaF or $NaBF_4$, but the reaction can be reversed as in the reaction of $(C_6F_5)_3BiF_2$ with Me_3SiCl to form $(C_6F_5)_3BiCl_2$.[92] Substitution of chloride or bromide from Ar_3BiX_2 occurs readily, and has been used to prepare a wide variety of derivatives including the carbonate, the oxide, sulfonates, and carboxylates.[93] Aryloxide complexes of the type $Ph_3Bi(OAr)_2$ may also be prepared by metathesis, while the Ph_4BiOAr complexes are obtained upon alcoholysis of Ph_5Bi.[94] Careful, stoichiometric addition of LiOAr to Ph_3BiX_2 leads to $Ph_3BiX(OAr)$, which undergoes redistribution reactions in solution, presumably through halide- or aryloxide-bridged intermediates.[94] The structure of $(C_6F_5)_3BiF_2$ was shown to have the typical trigonal bipyramidal arrangement with axial fluorine ligands ($d_{Bi\text{–}F} = 2.088(8)$ Å). Each of these fluorine atoms also interacts weakly with the bismuth atoms of the $Bi(C_6F_5)_3$ molecules ($d_{Bi\cdots F} = 2.759(8)$ Å) that cocrystallized with the difluoride.[9] Trimethylbismuthine has been chlorinated with thionyl chloride at low temperatures to give unstable Me_3BiCl_2, which was converted into $BiMe_5$ and $[BiMe_6]^-$.[95,96] $BiMe_3$ reacts with $MeSO_3CF_3$ to give $BiMe_4{}^+$ salts.

3.2 Reactions of Pentavalent Organobismuth Compounds

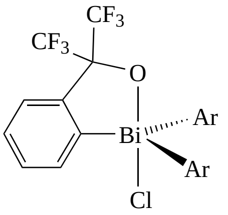
Heating of Ar_3BiX_2 (**22**, X = Br, Cl) eliminates ArX with the production of Ar_2BiX. Reactions with I_2 do not yield tractable Bi^V complexes, but lead directly to Ar_2BiI and/or $ArBiI_2$ at room temperature, presumably through a similar Bi^V intermediate. For the trialkyl species, bismuth(V) compounds are not observed and halogenation leads directly to the formation of either R_2BiX or $RBiX_2$. The formation of Ar_3BiX_2 is the starting point for the production of a wide range of triarylbismuth(V) complexes (Scheme 3). Cl^- and Br^- have been replaced by such anions as F^-, $CO_3{}^{2-}$, $SO_4{}^{2-}$, $ClO_4{}^-$, $ReO_4{}^-$, $MoO_4{}^{2-}$, and so on. The oxide Ph_3BiO, prepared by treating Ph_3BiCl_2 with moist Ag_2O, is reported to be soluble in acetonitrile, but may be polymeric in the solid state. Alkaline hydrolysis of Ph_3BiCl_2 (**22**) gives $[ClPh_3Bi]_2O$ (**23**), whereas with an aqueous solution of $AgClO_4$, this product is $[\{(H_2O)Ph_3Bi\}O][ClO_4]_2$. The water is lost under vacuum and anhydrous material is obtained. The nitrate is prepared similarly using $AgNO_3$.

Structural work on Ph_3BiCl_2, $ClBiPh_3OC_9H_6N$, and $O[BiPh_3OClO_3]_2$ confirms the trigonal bipyramidal coordination geometry about the bismuth atom.[97,98] The hydroxyquinolinate complex $Ph_3BiCl(OC_9H_6N)$ shows a weak Bi–N interaction. The displacement of the halides may also occur intramolecularly, as seen for the ligand $OC(CF_3)_2C_6H_4$ in (**24**)–(**26**).[99] Compound (**24**) can be converted into BiL(4-tolyl)$_3$ (L = $OC(CF_3)_2C_6H_4$). This complex reacts with MeLi to give the anionic, octahedral anion $[BiL(4\text{-tolyl})_3Me]^-$, which subsequently reacts with water to give BiL(4-tolyl)$_2$Me.

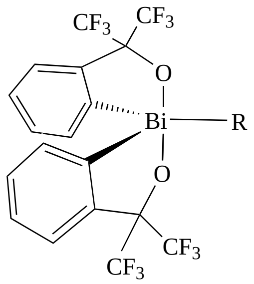


(23)

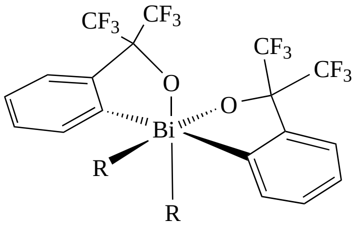
Scheme 3



(**24**)



(**25**)



(**26**)

These two molecules are rare examples of bismuth(V) alkyl complexes.

Reactions of Ar_3BiX_2 with organolithium reagents are common for producing Ar_5Bi complexes. Unstable, purple Ph_5Bi was the first of these to be synthesized.[100] Interesting variations in the structure and color of these complexes as a function of Ar have been reported.[101] The color of $BiPh_5$ has been attributed to relativistic effects.[102] A series of $BiAr_5$ complexes have been structurally characterized. The nature of the aryl ligands is important in determining whether the structure of those complexes is trigonal bipyramidal or square planar, which is also related to their color.[103]

In addition to exchange reactions, a halide ion can be abstracted from the bismuth of Ar_3BiX_2 complexes to give $[Ar_3BiX]^+$ ions. As mentioned before, Ar_3BiI_2 has not been isolated as it apparently undergoes immediate elimination, but at low temperatures, in the presence of $AgAsF_6$ the complex, $[Ar_3BiI][AsF_6]$ has been isolated.[104] This complex has been reported to be a better bactericide than Ph_3Bi. The complex $[Ph_4Bi][MeC_6H_4SO_3]$ is similar, but the tosylate anion is weakly bound to the bismuth atom ($d_{Bi\text{–}O} = 2.77$ Å), giving it a distorted trigonal bipyramidal geometry.[98] There is a similar interaction between $[Ph_4Bi]^+$ and an oxygen atom of an acetate ligand in $[Ph_4Bi][Ph_2Bi(O_2CCF_3)_2]$. Pentaphenyl bismuth is Lewis acidic and will react with pyridine to give the adduct $BiPh_5$·pyridine or with LiPh in diethyl ether or THF to produce unstable $Li[BiPh_6]$.[105]

Organobismuth(V) reagents are useful for a wide variety of organic transformations including transfer reactions, oxidation of primary, secondary, benzylic, and allylic alcohols (equations 24–33). Copper or copper salts promote, and may be required for, the transfer reactions.[106,107] These reagents also cleave glycols (equations 27 and 28), and under the appropriate conditions function as aryl group transfer reagents (equations 29–33). These examples are only a small representation of the work that has been done in this area.[108] Reactions of *cis*-cyclohexane-1,2-diol, *meso*-butane-2,3-diol, and *meso*-cyclopentane-1,2-diol with $Ph_3Bi(OAc)_2$ in the presence of catalytic amounts of $Cu(OAc)_2$ have been studied.[109] In the case of the cyclopentanediol, phenylation occurred giving a racemic mixture of the phenoxycyclopentanol. Optical selection was obtained when the reaction was carried out in the presence of one of the enantiomers of chiral 2-pyridyloxazolines. Alkoxide complexes are implicated as intermediates in some of these reactions, and for one case such a complex, (3,5-(*t*-Bu)$_2C_6H_3OBiPh_3Cl$), has been isolated. The aryl group transfer reaction is thought to proceed via a nonionic, nonradical concerted mechanism.

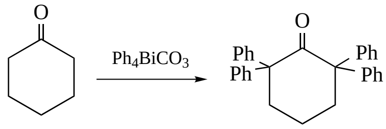
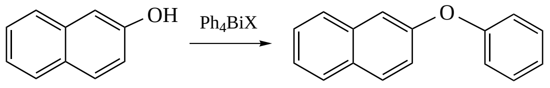
(31)



(32)

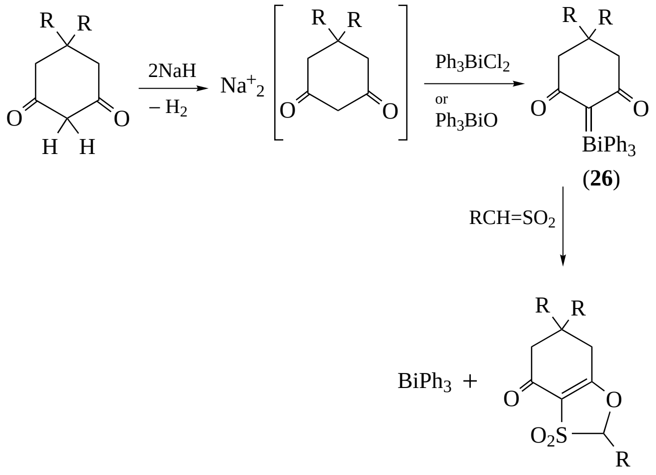


(33)

The compound $Ar_2Bi(O)OMe$, which was prepared via the reaction of Ar_3Bi and 4-$MeC_6H_4SO_2NClNa$, has been reported to acylate amides, thioamides, ureas, and thioureas. The first step of the process is believed to be reaction of the $Ar_2Bi(O)OMe$ compound with acetic acid to replace the methoxide with acetate.[110]

3.3 Bismuth Ylides

Bismuth ylide chemistry is not nearly so well developed compared to the extensive chemistry of phosphorus ylides ($R_3P{=}CR_2$). This is in large part due to the inaccessibility of bismuth alkyl cations R_4Bi^+ for deprotonation to ylides, as is frequently the strategy employed for phosphorus. A theoretical investigation of the group 15 ylides predicted that the formation of $MeBiH_3^+$ from MeCl and BiH_3 is endothermic.[111] Quaternization of bismuth is difficult, but MeO_3SCF_3 will react with $BiMe_3$ to give $BiMe_4^+$.[95] Alternative routes that involve the reaction of sodium salts of methylene compounds with Ph_3BiCl_2 or Ph_3BiO (Schemes 4 and 5) have been developed.[107,112] In many cases, the bismuthonium ylides have not been isolated from solution. Compound (**26**), where R = Me, has yielded to X-ray structural characterization.[113] The Bi–C_{ylide} distance is 2.16 Å, only slightly shorter than the Bi–C_{phenyl} distances, suggesting that there is considerable ionic character in the Bi−ylide bond.



Scheme 5

The ylide function is exchanged upon addition of dimethyl sulfide in the presence of CuCl to give $R^1R^2CSMe_2$ and $BiPh_3$ (Scheme 5). Exchange could also be accomplished to PPh_3 and $AsPh_3$ but not $SbPh_3$. The sodium salt of acetylacetone reacts with Ph_3BiCl_2 to generate an ylide complex that could not be isolated. Attempts at chromatography led to the isolation of the *C*-phenylated acetylacetone instead. This ylide complex, however, reacts with H_2CSO_2 generated in situ to give 1,3-oxathiole-3,3-dioxide.

In related chemistry, $BiPh_3$ is oxidized by anhydrous chloramine-T (RSO_2NClNa, $R = p\text{-}MeC_6H_4$) or with $R_fSO_2NH_2$ ($R = CF_3$, 4-FC_6H_4, $CF_2CF_2CF_2CF_3$) in the presence of NaOMe to give $Ph_3Bi{=}NSO_2R$.[114] This may be compared to the same reaction carried out in the presence of wet methanol, which gives the $Ar_2Bi(O)OMe$ complexes described above.

1 INTRODUCTION

During the last 10 years, significant advances have been made in the area of organometallic bonding energetics. Most data were obtained from solution calorimetric studies. In the present chapter, a compilation of thermochemical data on organometallic systems is presented. This account represents a survey and is by no means exhaustive yet we have endeavored to provide the reader with as much data as possible in an effort to complement the contribution found in the first edition.

2 CASE STUDIES

The case studies below will provide selected examples of calorimetric studies carried out on metal–ligand exchange reactions of phosphorous-based ligands (such as phosphines, phosphite, *N*-pyrrolyl-phosphines) and *N*-heterocyclic carbene ligands (NHCs) as well as addition reactions relevant to catalytic transformations, involving metals such as ruthenium,[1–15] rhodium,[16–23] platinum,[24,25] and molybdenum.[26,27]

2.1 Binding of Monodentate Phosphine Ligands to Cp-ruthenium Systems

Ligand substitution reactions (*see Ligand Substitution*) are at the heart of many catalytic transformations, since creation of vacant coordination sites oftentimes requires liberation of one or more ligands from the coordination sphere of the metal. Important and/or industrially relevant processes using organoruthenium catalysts include the enantioselective reduction of olefins and ketones developed by Noyori *et al.* (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***),[28,29] the ring-opening and closing metatheses of olefins reported by Grubbs *et al.* (*see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***),[30–32] or the recently developed ruthenium-catalyzed synthesis of formic acid and formamides in supercritical CO_2.[33,34]

In order to gain insight into the thermodynamics of phosphine binding to ruthenium systems, the tetrameric complex $(Cp^*RuCl)_4$ was chosen as the starting material (*see* ***Polynuclear Organometallic Cluster Complexes***). Complexes of the type $Cp^*Ru(diene)Cl$ are formed from the tetrameric $(Cp^*RuCl)_4$ compound according to equation (1)[35,36] and provide a thermodynamic entryway into the solution calorimetric studies of ligand substitution in these systems. Table 1 gives an overview of the enthalpies of substitution for the reaction in equation (1) and shows that for subsequent ligand substitution chemistry involving phosphines and arsines, the relatively labile nature of the COD ligand in $Cp^*Ru(COD)Cl$ is ideal.

$$(Cp^*RuCl)_{4(s)} + 4diene_{(soln)} \xrightarrow[30\,^\circ C]{THF} 4Cp^*Ru(diene)Cl_{(soln)} \quad (1)$$

Indeed, reacting this complex with monodentate arsine/phosphine/phosphite ligands provides access into the thermochemistry of the ligand substitution of equation (2). Table 2 gives the respective enthalpies of ligand substitution found by calorimetry for the series of monodentate phosphine ligands.

$$Cp^*Ru(COD)Cl_{(soln)} + 2L_{(soln)} \xrightarrow[30\,^\circ C]{THF} Cp^*Ru(L)_2Cl_{(soln)} + COD_{(soln)} \quad (2)$$

The enthalpy trend can be examined in terms of electronic and steric contributions to the enthalpy of reaction, the relative importance of which can be quantified in terms of the respective A_1/A_2 ratios obtained in a treatment first proposed by Tolman,[37] where enthalpies of reaction are correlated with steric (θ, cone angle, *see Tolman's Cone Angle*) and electronic (ν, carbonyl stretching frequency in $Ni(CO)_3L$, L = tertiary phosphine) factors. A correlation factor of 0.95 is obtained when enthalpic data are fitted to equation (3) and a value of 2.32 is calculated for the A_1/A_2 and quantitatively denotes the overwhelming influence of steric factors. Since the steric factors have such a profound influence on the enthalpy of reaction, a direct relationship between the enthalpy of reaction and the phosphine cone angle can be established as shown in Figure 1.

$$-\Delta H^o = A_o + A_1\theta + A_2\nu \quad (3)$$

These results are not unexpected in view of the cis arrangement of the phosphine ligands and the steric bulk of the Cp^* ligand in these complexes. Therefore, the enthalpies of reaction of $CpRu(COD)Cl$ ($Cp = C_5H_5$) with a series of

monodentate phosphine and arsenic ligands have also been measured in order to examine how the overall steric and electronic variations accompanying this change in ancillary ligation (Cp* versus Cp) influence the thermodynamic stability of Cp′Ru(PR$_3$)$_2$Cl (with Cp′ = Cp or Cp*). Again, the reactions of CpRu(COD)Cl with a series of phosphines have been found to be quantitative and rapid under the experimental

calorimetric conditions. Several trends are observed when looking at the results in Table 3: (1) The arsenic ligand displays enthalpies 15.1 kcal mol^{-1} less exothermic than that of its phosphine relative. (2) Phosphine sterics are the predominant factor influencing the magnitude of the enthalpy of reaction and a direct relationship can be established (Figure 2). (3) The ruthenium complex shows a relatively high affinity for phosphates, which can possibly be explained in terms of back donation (*see Back Bonding*) from the metal into orbitals on the phosphite ligand (phosphorous–oxygen σ^* orbitals).

A comparison between the two Cp′Ru(COD)Cl systems shows the importance of ancillary ligands (*see Ancillary Ligand*). Since Cp is less electron donating than Cp*, the Cp system is able to accommodate greater electron density from the incoming two-electron donor (higher electrophilicity), therefore leading to more exothermic enthalpies of ligand

substitution. One of the best ways to experimentally assess the lack of phosphine electronic factors playing a role in these two systems is to determine the bond dissociation enthalpies of a series of isosteric, para-substituted triphenylphosphine ligands. The enthalpies of reaction of Cp′Ru(COD)Cl (where Cp′ = Cp and Cp*) with several para-substituted monodentate phosphines are listed in Table 4. This study clearly indicates an important lack of sensitivity associated with the enthalpies of ligand substitution reactions as a function of electronic variation and can only be explained in terms of overwhelming steric contribution to the enthalpy of reaction.

Besides the class of traditional phosphines ligands, the related class of phosphite ligands has been utilized as ancillary ligation in various industrially relevant processes such as the hydrocyanation (*see Hydrocyanation*) of dienes or hydroformylation (*see Hydroformylation*) or the copolymerization of CO and olefins.[38,39] The thermochemistry of ligand substitution of a variety of phosphite ligands has therefore been determined by measuring the enthalpies of reaction of Cp′Ru(COD)Cl (where Cp′ = Cp and Cp*) with a series of monodentate phosphite ligands, leading to the formation of $Cp'Ru(P(OR)_3)_2Cl$ complexes. A compilation of phosphine/phosphite ligands with their respective enthalpies of reaction, in solution, is presented in Tables 5 and 6. Not unlike in the case of phosphines discussed above, the tables suggest that the different phosphite reaction enthalpies are overwhelmingly sterically controlled, and a graphical representation of this is shown in Figures 3 and 4 respectively. The increased exothermicity displayed by the $CpRu(PR_3)_2Cl$ system over its Cp* parent can again be taken as a gauge of the increased metal basicity on going from Cp to Cp*.

Another very interesting family of phosphorous ligands is the recently synthesized class of *N*-pyrrolyl phosphine compounds.[40] The pyrrazolyl moiety is known for its π-involvement (back donation from metal to ligand) and should greatly affect the binding ability of the phosphine,

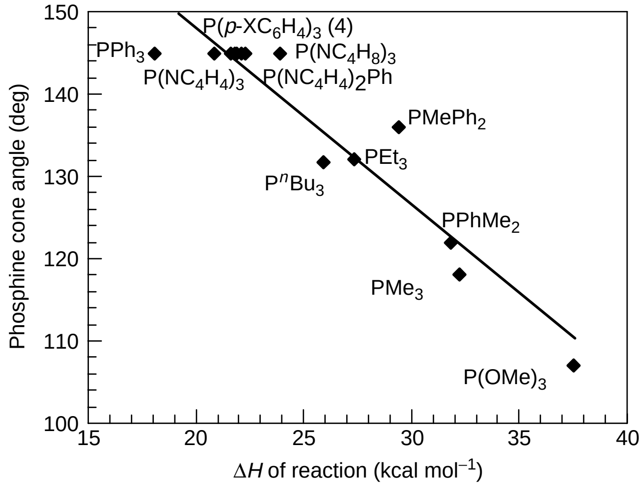

Figure 6 Enthalpies of reaction $(kcal\ mol^{-1})$ for the $Cp^{*}Ru(PR_3)_2Cl$ system vs phosphine cone angle (deg) (*slope* = −2.15; *R* = 0.95)

at least if electronic factors play a major role in the system studied. The enthalpies of reaction of $Cp'Ru(COD)Cl$ ($Cp' = C_5H_5$ and C_5Me_5) with a series of *N*-pyrrazolyl-substituted tertiary phosphine ligands, leading to the formation of $Cp'Ru(PR_3)_2Cl$ complexes, as well as a comparison with previously investigated phosphines, are given in Table 7. Once again, the observed enthalpies underline the validity of previous results insofar as in these ruthenium systems, steric factors seem to be the principal contributor to the magnitude of the reaction enthalpy. This overwhelming steric contribution accounts for the relatively weaker than expected donor ability of the *N*-pyrrolyl ligand family and can be correlated for both Cp- and Cp*-Ru systems as shown in Figures 5 and 6.

From the thermochemical studies on these $Cp'Ru(L)_2Cl$ systems, it was found that the trends can be analyzed in terms of a predominant contribution from the Tolman cone angle (*see Tolman's Cone Angle*) of the incoming ligand. An interesting question would therefore be whether the same trends are present in the metrical parameters obtained from single-crystal X-ray diffraction analysis of the compounds formed (of the general formula $CpRu(PR_3)_2Cl$) in the prior investigations. With five X-ray structures of complexes of the type $CpRu(ER_3)_2Cl$ at hand, a closer examination of the Ru–P bond lengths of the ligands indeed shows that a quantitative relationship between structural and thermodynamic parameters can be established. In fact, there appears to exist a direct correlation between Ru–E bond lengths and the magnitude of the enthalpies of substitution. As shown in Figure 8, an even higher degree of correlation exists between the reaction enthalpies and the Ru–P bond distances in the related $Cp^{*}Ru(ER_3)_2Cl$ system. The reaction

Table 7 Enthalpies of substitution (kcal mol^{-1}) in the reaction:

[a]Enthalpy values are reported with 95% confidence limits.

enthalpies involved in this correlation are directly related to Ru–P bond dissociation enthalpies, Figure 7 is in fact a bond length-relative bond dissociation enthalpy correlation. The correlation between crystalline Ru–P distances and solution thermochemical measurements suggests that longer bonds are associated with less exothermic reactions (dmpm > PMe_3 > $PPhMe_2$ > PPh_2Me > PEt_3 > P^nBu_3 > PPh_3).

As mentioned above, the ancillary Cp (*see Cyclopentadienyl*) ligands (Cp versus Cp*) can influence the enthalpies of reaction of Cp′RuCl systems with phosphorous ligands. The availability of $[Cp^*Ru(OCH_2CF_3)]_2$,[41,42] permits therefore a direct comparison of alkoxide vs chloride ancillary ligands in this system. The enthalpies of reaction of $[Cp^*Ru(OCH_2CF_3)]_2$ with PR_3 ($PR_3 = PCy_3$, P^iPr_3) have been measured by solution calorimetry giving complexes $[Cp^*Ru(PR_3)(OCH_2CF_3)]$ and in order to test the internal consistency of the approach, a thermochemical cycle, shown in Scheme 1, was constructed leading to the formation of $Cp^*Ru(PR_3)_2(OCH_2CF_3)$. This reactivity is analogous to the one involving chloride ligation and a comparison of the results is shown in Table 8.

Important comparisons can be made between the Cp*RuCl and the $Cp^*Ru(OCH_2CF_3)$ systems and show that enthalpies of reaction involving similar phosphine ligands are more exothermic for the Cp*RuCl moiety. This trend is understood to reflect the increased electron donation residing on the

metal when the ancillary ligand X is (OCH_2CF_3), leading to a tendency of the $Cp^*Ru(OCH_2CF_3)$ moiety to be able to accept less electron density from the incoming donor ligands, resulting in a lower exothermic value for the enthalpy of reaction.

2.2 Binding of Chelating Diphosphine Ligands to Cp-ruthenium Systems

Chelating diphosphine ligands (*see Chelating Ligands*) have been widely used in organometallic chemistry and are especially indispensable ligand systems in enantioselective catalytic transformations (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***).[28] With the complex Cp′Ru(COD)Cl (Cp′ = Cp and Cp*) at hand, solution thermochemical investigations of ligand substitution involving chelating diphosphines can be carried out, giving complexes of the type Cp′Ru(PP)Cl. It might be predicted that a major factor influencing the metal–diphosphine complex reactivity and stability must involve the metal–ligand enthalpy term. This bond disruption enthalpy (BDE) value can be viewed as a sum of the stabilizing metal–phosphorous interaction and the destabilizing strain energy caused by steric and torsional forces present in the metallacyclic fragment.

The enthalpies of ligand substitution for these chelating ligands are presented in Table 9.

Several trends are worth noting: (1) reactions of alkyl-substituted phosphines prove to be more exothermic; (2) ring strain is present in the four- and seven-membered ring systems. For this latter trend, a relative comparison of all the data of these chelating diphosphines with the corresponding monophosphines shows that the strain energy for the seven-membered metallacycle is smaller than for the four-membered analogue; (3) similar to the trend seen for monophosphines, the Cp ligand system shows an increased exothermicity in enthalpies of reaction.

Analogous to the studies with monodentate phosphorous ligands, a thermochemical study of ligand substitution involving diphosphine compounds with weak σ-donor and strong π-acceptor character involving the recently reported ligands $Ph_2PNMeNMePPh_2$, $(PhO)_2PNMeNMeP(OPh)_2$, $(C_4H_4N)_2PCH_2CH_2P(NC_4H_4)_2$, and $((EtO_2C)_2C_4H_2N)_2PCH_2CH_2P[NC_4H_2(CO_2Et)_2]_2$ was undertaken.[43] The results in Table 10 (for Cp and Cp*) clearly suggest that steric factors

predominate in all these cases, but at least some electronic effects must be present in minor extend, with reaction enthalpies markedly lower than for basic diphosphines.

2.3 Binding of Sterically Demanding Phosphine Ligands to Cp-ruthenium Systems

Sterically demanding phosphine ligands play an important role in organometallic chemistry in helping to stabilize very reactive species and play crucial roles in several catalytic systems such as the very successful ruthenium-alkylidene catalysts reported by Grubbs *et al.* (*see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***).[30,31] Direct solution calorimetric measurement of the relative donating properties of large cone-angle phosphines would therefore be highly desirable and have not been reported. The reaction of $(Cp^*RuCl)_4$ with sterically demanding monodentate tertiary phosphine ligands leads to rapid and clean formation of the unsaturated $Cp^*Ru(PR_3)Cl$ (where $PR_3 = P^iPr_3$ or PCy_3),[44] and is therefore amenable to such an investigation (equation 4). Furthermore, the very reactive nature of these unsaturated complexes can be exploited in order to thermodynamically link the $Cp^*Ru(PR_3)Cl$ to the $Cp^*Ru(PR_3)_2Cl$ systems discussed earlier according to equation (5). The results show that these two sterically demanding phosphines exhibit the weakest Ru–PR_3 bond yet investigated and relative bond disruption enthalpies were established and are shown in Table 11. As observed for smaller phosphines, the steric factors have a profound influence on the enthalpy of reaction and a direct relationship between the two can be established.

Table 11 Relative bond disruption enthalpies (kcal mol^{-1}) in the following reaction

$$(Cp^*RuCl)_{4(soln)} + nL_{(soln)} \xrightarrow[30\,°C]{THF} 4Cp^*Ru(L)_{n/4}Cl_{(soln)}$$

L	Complex	n	Relative BDE[a]

[a]Relative BDE values were derived by dividing the enthalpy value by the number of Ru–PR_3 formed during the reaction of interest.

$$(Cp^*RuCl)_{4(s)} + 4PR_{3(soln)} \xrightarrow[30\,°C]{THF} 4Cp^*Ru(PR_3)Cl_{(soln)} \quad (4)$$

$$PR_3 = PCy_3;\ \Delta H_{rxn} = -41.9 \pm 0.2\ kcal/mol$$

$$PR_3 = P^iPr_3;\ \Delta H_{rxn} = -37.4 \pm 0.3\ kcal/mol$$

$$Cp^*Ru(PR_3)Cl_{(soln)} + 2PR'_{3(soln)} \xrightarrow[30\,°C]{THF} 4Cp^*Ru(PR'_3)_2Cl_{(soln)} + PR_3$$

$$PR_3 = PCy_3, P^iPr_3;$$

$$PR'_3 = \text{phosphines with smaller } \theta \quad (5)$$

2.4 Phosphine Exchange in a Ruthenium-Alkylidene System

The utilization of neutral 16-electron ruthenium-alkylidene complexes as olefin metathesis catalysts (*see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***) has had a tremendous impact in both organic and polymer chemistry.[45,46] These complexes of type $(PR_3)_2Cl_2Ru{=}CR'_2$ (Where PR_3 = sterically demanding phosphine) have been thoroughly investigated, especially with regard to the role played by the phosphine ligands.[47] Yet, this understanding is based principally on kinetic studies and thermochemical investigations are highly desirable. In fact, complex $(PPh_3)_2Cl_2Ru({=}C{-}C{=}CPh_2)$[30] constitutes an ideal entryway into the thermochemistry of these ruthenium-carbene species insofar as PPh_3 replacement by a series of sterically demanding tertiary phosphine ligands can be investigated by batch calorimetry. This transformation and a list of all reaction enthalpies is provided in Table 12. With these data at hand, the interpretation of these enthalpies of ligand substitution in terms of phosphine steric and electronic parameters according to equation (3) (see above) shows that an excellent correlation

Table 12 Enthalpies of substitution (kcal mol^{-1}) for the reaction:

[a]Enthalpy values are reported with 95% confidence limits.

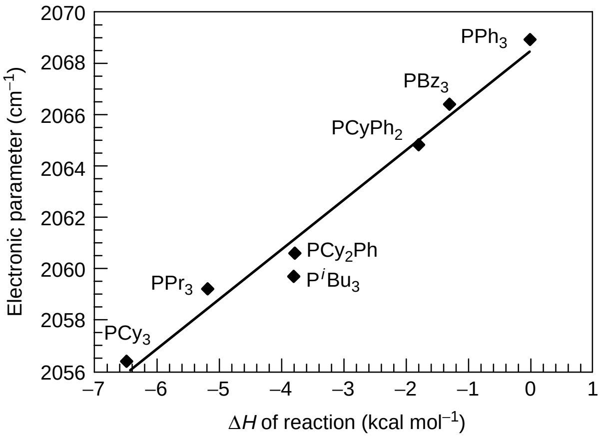

Figure 8 Enthalpy of phosphine exchange reaction (kcal mol^{-1}) vs Tolman electronic parameter (cm^{-1}) for *trans*-$(PR_3)_2Cl_2Ru{=}CH{-}CH{=}CPh_2$ complexes (*slope* $= 1.93$; $R = 0.98$)

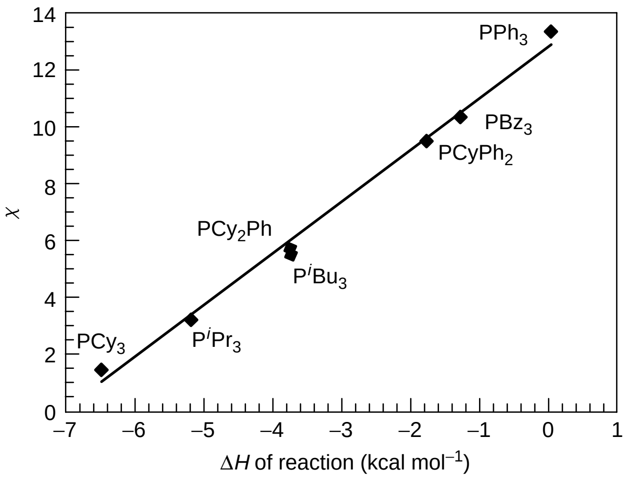

Figure 9 Enthalpy of phosphine exchange reaction (kcal mol^{-1}) vs χ for *trans*-$(PR_3)_2Cl_2Ru{=}CH{-}CH{=}CPh_2$ complexes (*slope* $= 1.813$; $R = 0.997$)

is found to exist between the enthalpies of phosphine exchange and the Tolman electronic parameter (Figure 8).

Another model from which to extract steric and electronic ligand characteristics is the quantitative analysis of ligand effects (QALE) developed by Giering and coworkers.[48,49] From the excellent correlation between χ and ΔH, the electronic parameter (χ) can be taken as the origin of any variations in measured enthalpies of reaction (Figure 9). In assessing the donor properties of the phosphine ligands, even a simple pK_a model can describe fairly well the overwhelming influence of phosphine electronics in the present system, as shown by the linear relationship found in Figure 10.

2.5 N-heterocyclic Carbene (NHC) Binding to Ruthenium Systems

The description of stereoelectronic factors characterizing tertiary phosphine ligands has greatly assisted synthetic and catalytic efforts. Nucleophilic N-heterocyclic carbenes (NHC) are increasingly attractive alternatives to phosphine ligands in organometallic catalytic systems.[50–52] Especially successful applications of this new ligand class include their use as ligands in ruthenium metathesis catalysts.[53,54] The subtle steric and electronic differences within the NHC class of ligands remain relatively unquantified. The tetrameric $[Cp^*RuCl]_4$ reacts with sterically demanding phosphines to afford coordinatively unsaturated complexes of the general formula $Cp^*Ru(PR_3)Cl$ and reacts rapidly with nucleophilic carbene ligands (L) to give the new NHC-complexes of general formula $Cp^*Ru(L)Cl$. Solution calorimetric investigations provide the enthalpies of ligand substitution shown in Table 13.

Several interesting trends are observed. First, comparing complexes bearing the isosteric (*see Isosteric Groups*) pair of IMes and IMes·Cl, it is clear from the enthalpy data that

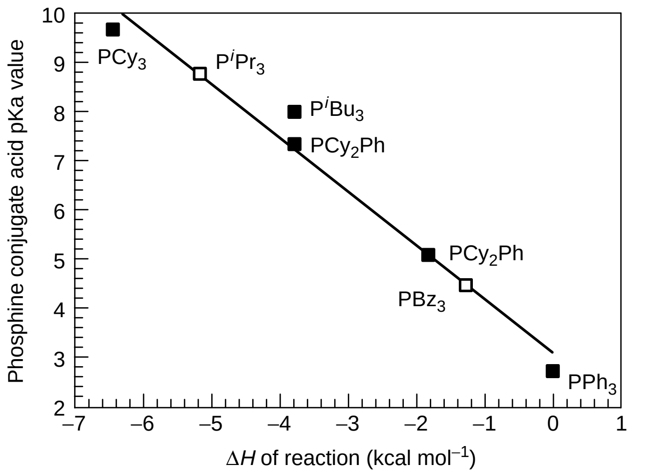

Figure 10 Enthalpy of phosphine exchange reaction (kcal mol^{-1}) vs pK_a of HPR_3^+ for *trans*-$(PR_3)_2Cl_2Ru{=}CH{-}CH{=}CPh_2$ complexes. (*slope* = −1.092; $R = 0.983$). Solid: literature value.[16] Hollow: predicted value

^{a}Enthalpy values are reported with 95% confidence limits. ^{b}Relative BDE values were derived by dividing the enthalpy value by the numb Ru–NHC formed during the reaction of interest.

the chlorides in the backbone act as electron-withdrawing groups when compared to H in IMes. ITol is a slightly better donor than IpCl, a trend that is again in line with electron-donating/withdrawing abilities of arene substituents.[55] Substituting an aryl group for an alkyl increases the donor ability of the carbene ligand. The case in point is the ICy, which is some 5.6 kcal mol^{-1} more exothermic than IMes. Finally, IAd is the least exothermic ligand examined and steric effects are at the origin of this low enthalpy of ligand substitution.

With the crystallographic data of complexes Cp*Ru(IMes)Cl, Cp*Ru(SIMes)Cl, Cp*Ru(IPr)Cl, Cp*Ru(SIPr)Cl, Cp*Ru(ITol)Cl, and Cp*Ru(IAd)Cl at hand, and knowing the importance of steric factors in the related phosphine systems, it would thus be of use to quantify the steric factors characterizing this class of ligands. They cannot be viewed in the same light as phosphine ligands since a cone angle (as defined by Tolman[37]) cannot be defined in the present system. As a first model to describe the steric parameters of NHCs and of phosphines, the amount of volume of a sphere centered on the metal, buried by overlap with atoms of various NHC ligands, $\%V_{Bur}$, was measured.[15] The volume of this sphere would represent the space around the metal atom that must be shared by the different ligands upon coordination. Of course, the bulkier the specific ligand, the larger the amount of that sphere will be occupied by the ligand, that is, greater $\%V_{Bur}$. A graphical representation of this geometrical analysis is reported in Figure 11 and a compilation of $\%V_{Bur}$ values is presented in Table 14. When the experimental BDEs are plotted versus $\%V_{Bur}$, a linear relationship is found to exist, not unlike the linear relationships found for BDEs versus phosphine cone angle in the corresponding $Cp^*Ru(PR_3)Cl$ and $Cp^*Ru(PR_3)_2Cl$ (Figure 12). This simple model is only a starting point to understand the steric requirements of ligand classes other than

phosphines, but might ultimately lead to a unified treatment of different ligand classes.

2.6 Binding of Phosphines to Rhodium Systems

The utilization of rhodium-phosphine complexes in homogeneous catalysis is widespread and encompasses industrially important processes, hydroformylation (*see Hydroformylation*) being one of the most widely known rhodium-mediated conversions (*see* ***Rhodium: Organometallic Chemistry*** and ***Carbonylation Processes by Homogeneous Catalysis***).[56,57] It was therefore of interest to perform thermochemical studies on a fundamentally important organorhodium–phosphine system, $RhCl(CO)(PR_3)_2$. Direct entry into the thermochemistry of $RhCl(CO)(PR_3)_2$ complexes is made possible by the rapid and quantitative reaction of $[Rh(CO)_2Cl]_2$ with stoechiometric amounts of phosphine ligands and a compilation of phosphine ligands with their respective enthalpies of reaction is presented in Table 15. In this rhodium system, a linear relationship is present between the enthalpy of reaction and corresponding Hammett σ_p parameters, a result that is indicative of the major role played by phosphine electronic effects.

Therefore, simple one-parameter relationships can be established with either the carbonyl stretching frequency (ν_{CO}, Figure 13) or Tolman's electronic parameter (χ, Figure 14),

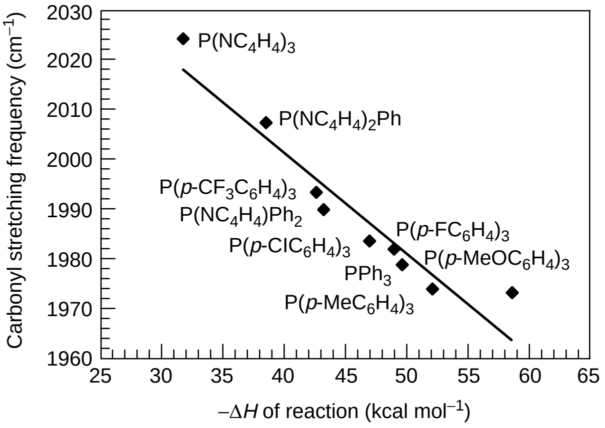

Figure 13 Carbonyl stretching frequency (cm^{-1}) vs enthalpies of reaction (kcal mol^{-1}) for the $RhCl(CO)(PR_3)_2$ system (*slope* $= -2.00$; $R = 0.96$)

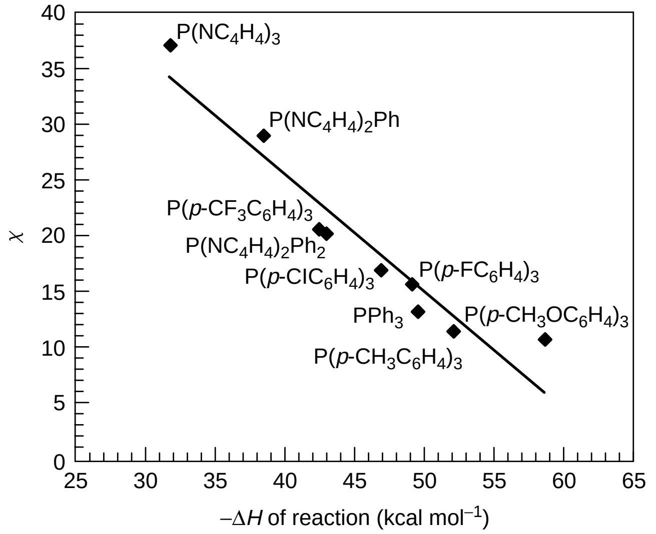

Figure 14 Electronic parameter (χ) vs enthalpies of reaction ($kcal\,mol^{-1}$) for the $RhCl(CO)(PR_3)_2$ system (*slope* $= -1.05$; $R = 0.96$)

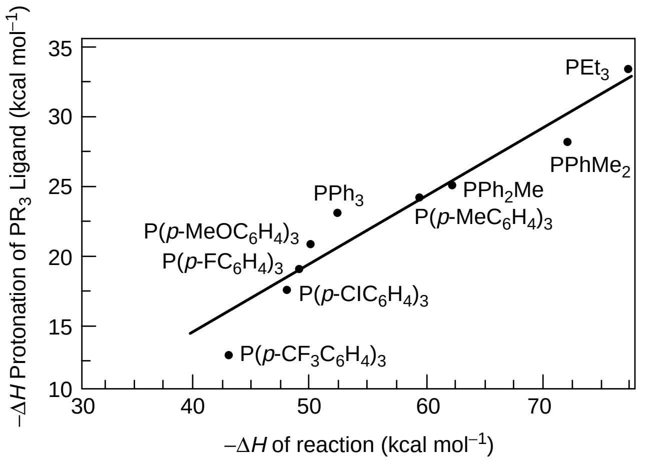

Figure 15 Enthalpies of protonation ($kcal\,mol^{-1}$) of phosphine ligands vs enthalpies of reaction ($kcal\,mol^{-1}$) for the $RhCl(CO)(PR_3)_2$ system (*slope* $= 0.49$; $R = 0.96$)

both exhibiting a very good correlation. The overwhelming influence of phosphine electronics that was found to exist in the ruthenium–carbene systems is also operating for the present rhodium system and a good correlation is provided with a simple relationship linking the measured enthalpies of reaction to the enthalpies of protonation of the free phosphine ligands as shown in Figure 15.

As shown above, the range in stabilities can be quite significant and the calorimetry data show that the enthalpy for the equilibrium shown in equation (6) favors products by $25.9\,kcal\,mol^{-1}$, when $PZ'_3 = P(p\text{-}CH_3OC_6H_4)_3$ and $PZ_3 = Ppyrl'_3$.

$$trans\text{-}RhCl(CO)(PZ_3)_2 + 2PZ'_3 \rightleftharpoons trans\text{-}RhCl(CO)(PZ'_3)_2 + 2PZ_3 \quad (6)$$

The data indicate that the exchange reaction is slowed down with phosphines that are good π-acceptors/weak σ-donors, which is the case in all the systems discussed so far. It would therefore be of interest to compare this system with a rhodium system where the observed trend is reversed, that is, where substitution is favored in the case of good π-acceptors/weak σ-donors. Such a system was found in the case of the chelating tridentate bis(phosphino)-amido ligands RPNP (Fryzuk's ligand).[58,59] Substitution of cyclooctene in [RPNP]Rh(COE) with phosphines (or CO) was investigated by solution calorimetry and shows conclusively and convincingly that better acceptor ligands give the more stable complexes in the [RPNP]RhL system (Table 16). An analysis for the reactions of both complexes supports the notion that the observed trends, although opposite, are electronic in nature (all the phosphine ligands being isosteric) and a good correlation was found for the reaction enthalpy versus Tolman's electronic parameter (χ) (Figure 16).

These results thus illustrate the importance of reorganization energies in thermodynamic analyses of metal–ligand bonding, especially in the presence of synergistic bonding involving σ-donor, π-donor, and π-acceptor ligands. The interactions of the whole ligand set of metal complexes through shared metal orbitals (electron push–pull) underscore the caution that must be employed when attempting to interpret experimental chemical results and bond dissociation enthalpies as intrinsic, transferable properties of individual bonds. In fact, even the concept of individual bond strength becomes somewhat ambiguous.

2.7 Addition Reactions to a Rhodium-phosphine System

Very few thermodynamic studies of addition reactions to metal fragments have been reported, and this situation stems in part from the fact that substitution reactions of such complexes generally proceed via facile associative mechanisms (*see Associative Substitution* and ***Mechanisms of Reaction of Organometallic Complexes***), precluding an estimation of BDEs based on rates of ligand dissociation. Goldman, Nolan *et al.* examined the thermodynamics of CO, H$_2$, Bu^{t}NC, aldehyde, and acyl chloride addition to the three-coordinate fragment Rh(PR$_3$)$_2$Cl, to give either square-planar (*see Square Planar*) complexes Rh(PR$_3$)$_2$Cl(CO) and Rh(PR$_3$)$_2$Cl(CNBu^t), or to give the corresponding d^6 five-coordinate adduct Rh(PR$_3$)$_2$Cl(X)(Y).[16–18] The three-coordinate fragment Rh(PR$_3$)$_2$Cl is generated from the dimer [Rh(PR$_3$)$_2$Cl]$_2$ by splitting of the chloride bridges, but is not isolable. This means that the calorimetric determinations of the enthalpies of reaction afford relative enthalpies of addition to the fragment Rh(P^{i}Pr$_3$)$_2$Cl, but not absolute values. On the basis of the observation that no measurable concentration of the monomer exists in solution, a lower limit for the bridge strength of the dimer [Rh(PR$_3$)$_2$Cl]$_2$ was calculated.

2.7.1 Thermodynamics of CO Addition

In order to avoid problems associated with calorimetric measurements with a gas-phase reactant, the following reactions (equation 7) were exploited to determine the enthalpy of equation (8). The enthalpy of equation (8) is subsequently determined using the available thermodynamic data for the components of equation (7).

$$\Delta H\,(\text{kcal mol}^{-1})$$

$$(\text{P}^i\text{Pr}_3)_2\text{RhCl}_{(\text{soln})} + \text{C}_8\text{H}_{16}\text{O}_{(\text{soln})} \longrightarrow (\text{P}^i\text{Pr}_3)_2\text{Rh(CO)(Cl)}_{(\text{soln})} + \text{C}_7\text{H}_{16(\text{soln})} \quad -36.0 \pm 0.5 \quad (7)$$

$$\text{C}_7\text{H}_{16(\text{g})} + \text{CO}_{(\text{g})} \longrightarrow \text{C}_8\text{H}_{16}\text{O}_{(\text{g})} \quad -3.3 \pm 0.5$$

$$(\text{P}^i\text{Pr}_3)_2\text{RhCl}_{(\text{soln})} + \text{CO}_{(\text{g})} \longrightarrow (\text{P}^i\text{Pr}_3)_2\text{Rh(CO)(Cl)}_{(\text{soln})} \quad -39.3 \pm 0.7 \quad (8)$$

2.7.2 Thermodynamics of H$_2$ and t-BuNC Addition

In this case, the gas-phase reactants were avoided by measuring two separate enthalpies of reaction (equations 9 and 10), and equation (11) is therefore calculated from equation (10) plus the reverse of equation (9).

$$(\text{P}^i\text{Pr}_3)_2\text{RhClH}_{2\,(\text{soln})} + \text{Bu}^t\text{NC}_{(\text{soln})} \longrightarrow (\text{P}^i\text{Pr}_3)_2\text{Rh(CNBu}^t\text{)(Cl)}_{(\text{soln})} + \text{H}_2 \quad \Delta H = -9.9 \pm 0.4\,\text{kcal mol}^{-1} \quad (9)$$

$$0.5[(\text{P}^i\text{Pr}_3)_2\text{RhCl}]_{2\,(\text{soln})} + \text{Bu}^t\text{NC}_{(\text{soln})} \longrightarrow (\text{P}^i\text{Pr}_3)_2\text{Rh(CNBu}^t\text{)(Cl)}_{(\text{soln})} \quad \Delta H = -33.5 \pm 0.5\,\text{kcal mol}^{-1} \quad (10)$$

$$0.5\,[(\text{P}^i\text{Pr}_3)_2\text{RhCl}]_{2\,(\text{soln})} + \text{H}_{2(\text{g})} \longrightarrow (\text{P}^i\text{Pr}_3)_2\text{RhClH}_{2(\text{soln})} \quad \Delta H = -23.6 \pm 0.6\,\text{kcal mol}^{-1} \quad (11)$$

2.7.3 Thermodynamic Studies of the Addition of N$_2$, C$_2$H$_4$, and Alkynes

[Rh(P^{i}Pr$_3$)$_2$Cl]$_2$ reacts in solution with N$_2$, C$_2$H$_4$ and diphenylacetylene, respectively, to give the corresponding adducts Rh(P^{i}Pr$_3$)$_2$ClL (L = N$_2$, C$_2$H$_4$, PhCCPh). The reactions of [Rh(P^{i}Pr$_3$)$_2$Cl]$_2$ with N$_2$ and C$_2$H$_4$ were measured calorimetrically, exploiting the method reported for the determination of the enthalpy of addition of H$_2$, according to equations (12) and (13). Equation (14) shows the enthalpies found for these addition reactions (ΔH_3). In the case of L = PhCCPh, the addendum is not volatile and the addition reaction was measured directly (equation 15).

$$(\text{P}^i\text{Pr}_3)_2\text{RhClL}_{(\text{soln})} + \text{Bu}^t\text{NC}_{(\text{soln})} \longrightarrow (\text{P}^i\text{Pr}_3)_2\text{RhCl(CNBu}^t\text{)}_{(\text{soln})} + \text{L} \quad (12)$$

$$0.5[(P^iPr_3)_2RhCl]_{2(soln)} + PhCCPh_{(soln)} \longrightarrow (P^iPr_3)_2RhCl(PhCCPh)_{(soln)}\ \Delta H = -14.2\ (0.4)\ \text{kcal mol}^{-1} \quad (15)$$

2.7.4 Thermodynamics of the Addition of Aldehydes and acyl Chlorides

Thermodynamic studies of the enthalpy of addition of aldehydes and acyl chlorides to $[Rh(P^iPr_3)_2Cl]_2$ and the hypothetical monomer $Rh(P^iPr_3)_2Cl$ gave unsaturated five-coordinate Rh(III) compounds according to equations (16) and (17) and afforded the values shown in Table 17.

$$0.5\ [(P^iPr_3)_2RhCl]_{2(soln)} + RCHO_{(soln)} \longrightarrow (P^iPr_3)_2RhClH[C(O)R]_{(soln)} \quad (16)$$

$$0.5\ [(P^iPr_3)_2RhCl]_{2(soln)} + RC(O)Cl_{(soln)} \longrightarrow (P^iPr_3)_2RhCl_2[C(O)R]_{(soln)} \quad (17)$$

Different interesting observations can be made when analyzing the enthalpy data for the addition of molecules to $[Rh(P^iPr_3)_2Cl]_2$. For the addition leading to square-planar rhodium(I) compounds, it can be seen that the better π-acceptors bind more strongly to the $Rh(P^iPr_3)_2Cl$ fragment with the minimum Rh–L BDE increasing from 16.5 kcal mol^{-1} (for N_2) to 48.2 kcal mol^{-1} (for CO). The enthalpies of the oxidative addition (*see Oxidative Addition*) reactions of aldehydes and H_2 are more exothermic than would be expected on the basis of thermodynamic data for related late–transition metal complexes and are more exothermic in comparison with the enthalpy of addition of acyl chlorides. All of the data, though, are quite high compared with previously reported values for second-row transition metals and are consistent with and help explain the remarkable catalytic activity of the $Rh(P^iPr_3)_2Cl$ fragment.

2.8 Binding of Fluorinated Phosphine Ligands

Recent developments in phosphine synthesis have allowed for catalysis to be carried out in nontraditional media, such as aqueous and fluorous solvents, as well as in supercritical carbon dioxide. Horváth and Gladysz have developed and utilized a fluorinated ligand that allows for biphasic segregation of a catalyst from the organic reactants and products.[60–62] The synthesis of this ponytail ligand, $P[CH_2CH_2(CF_3)_5CF_3]_3$, and the synthetic strategies employed for obtaining a series of fluorinated phosphine ligands with more tunable stereoelectronic properties are shown in equations (18–20).

Table 17 Enthalpy of addition of XY to $[(P^iPr_3)_2RhCl]_2$ ($-\Delta H_{rxn}$) and the hypothetical monomer $(P^iPr_3)_2RhCl$ ($-\Delta H_{min}$) in solution (kcal mol^{-1})

XY	$-\Delta H_{rxn}$	$-\Delta H_{min}$
H_2	23.6 (0.6)	32.5

PhC(O)Cl	21.7 (0.3)	30.6

$$PH_3 + 3CH_2CH(CF_2)_5CF_3 \xrightarrow{\text{AIBN}} P(CH_2CH_2(CF_2)_5CF_3)_3 \quad (18)$$

$$R_2PCl + R_fOH \xrightarrow[\text{NEt}_3]{\text{THF}} R_2POR_f + HNEt_3Cl \quad (19)$$

$$R = R_fO,\ {}^iPr,\ Ph,\ Cy;\ R_f = CH_2CH_2(CF_2)_5CF_3$$

$$R_2PCl + R_fMgI \xrightarrow{\text{Et}_2\text{O}} R_2PR_f + MgICl \quad (20)$$

$$R = Cy,\ {}^iPr;\ R_f = CH_2CH_2(CF_2)_5CF_3$$

The stereoelectronic properties of these new ligands were then investigated by solution calorimetry involving the rhodium complex $[Rh(CO)_2Cl]_2$ and infrared spectroscopy of the resulting complexes (ν_{CO} stretching) by using the ligand substitution reaction shown in equation (21). Table 18 gives an overview of the data obtained and compares them to previous studies involving nonfluorinated phosphorous ligands. In view of the mutually trans arrangement of the phosphine ligands in these complexes, of general formula $Rh(CO)Cl(PR_3)_2$, the predominant factor dictating the magnitude of the enthalpy of ligand substitution is associated with the electronic factor of the phosphine and a linear relationship exists between the enthalpy of reaction and the experimentally recorded carbonyl stretching frequency, as illustrated in Figure 17.

$$[Rh(CO)_2Cl]_{2(soln)} + 4PR_{3(soln)} \xrightarrow[30\,^\circ C]{CH_2Cl_2} 2Rh(CO)(Cl)(PR_3)_{2(soln)} + 2CO \quad (21)$$

[a]Enthalpy values are reported with 95% confidence limits. [b]Work performed in THF.

A measure of the steric parameter associated with the widely used fluorous tertiary phosphine ligand $P[CH_2CH_2(CF_2)_5CF_3]_3$ was obtained by measuring the reaction enthalpies for ligand substitution of this ligand and $Cp'Ru(COD)Cl$ ($Cp' = Cp^*$ and Cp). As discussed earlier, these two systems exhibit a marked dependence on steric parameters and by simple interpolation of the enthalpy reaction value of the phosphorous ligand (equation 22), they can be inserted into the linear relationship existing between the cone angle and the enthalpy of reaction. Respective values of 134° (from Cp^* data) and 127° (from Cp data) and an average value of $130 \pm 4°$ were obtained for the Tolman steric parameter θ of $P[CH_2CH_2(CF_2)_5CF_3]_3$.

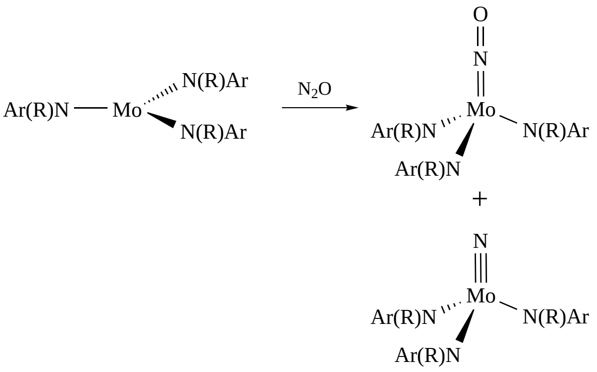
$$\underset{\text{soln}}{Cp'Ru(COD)Cl} + \underset{\text{soln}}{2PR_{f3}} \xrightarrow[30\,°C]{THF} \underset{\text{soln}}{Cp'Ru(PR_{f3})_2Cl} + \underset{\text{soln}}{COD} \quad (22)$$

$$\Delta H = -34.7\ (0.3)\text{kcal mol}^{-1},\ Cp' = Cp$$

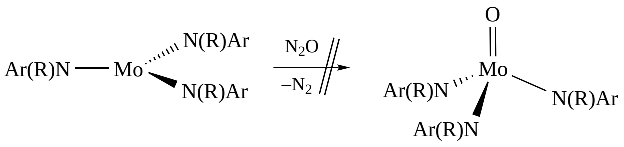
$$\Delta H = -26.1\ (0.3)\text{kcal mol}^{-1},\ Cp' = Cp^*$$

2.9 Reactivity of a Molybdenum System

The trigonal-planar molybdenum(III) compound (**1**) $Mo(N[R]Ar)_3$ (**[Mo]**, $R = C(CD_3)_2CH_3$, $Ar = 3,5\text{-}C_6H_3Me_2$), synthesized by Cummins *et al.*,[63,64] shows surprising reactivity toward dinitrogen and white phosphorous to give respectively $Mo(N)(N[R]Ar)_3$ and $Mo(P)(N[R]Ar)_3$ via reductive cleavage reactions. Furthermore, a dramatic selectivity for nitrogen over oxygen was observed in the reaction of $Mo(N[R]Ar)_3$ with nitrous oxide, a reaction found to proceed according to equation (23). Such selectivity is exceedingly unusual for reactions involving nitrous oxide, in that N_2O typically donates an oxygen atom to reducing agents, thereby liberating dinitrogen. One might therefore have predicted the reaction between $Mo(N[R]Ar)_3$ and nitrous oxide to occur according to equation (24).



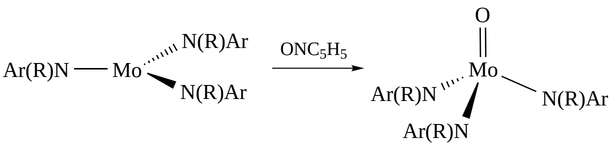
(23)



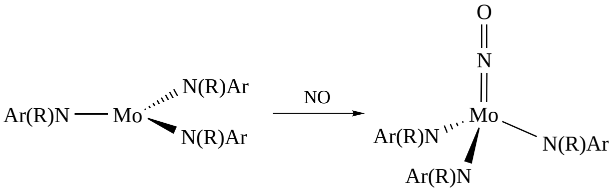
(24)

To explore the unusual display of reactivity of $Mo(N[R]Ar)_3$ (**[Mo]**), the oxo complex $Mo(O)(N[R]Ar)_3$ was synthesized by an independent route according to equation (25) and the nitrosyl compound $Mo(NO)(N[R]Ar)_3$ is obtained according to equation (26). The reaction chemistry of equations (23), (25), and (26) were studied in detail to get kinetic data for these transformations and solution calorimetry studies were carried out in order to assess enthalpic factors

relevant to the selective splitting of the nitrous oxide N–N bond by complex **[Mo]**. N_2O splitting reaction as well as the NO and O binding reactions were particularly amenable to analysis by solution calorimetry because of their rapid and essentially quantitative nature.



(25)



(26)

The enthalpies of these reactions were measured and the results are shown in Figure 18. NO binding to **[Mo]** gives C, the enthalpy of which is found to be $-82.5 \pm 2.5\,\text{kcal mol}^{-1}$, while the N_2O splitting reaction is indicated as D, the corresponding enthalpy change being $-123.8 \pm 0.8\,\text{kcal mol}^{-1}$. As an aside, the latter two values in combination with A, the $114\,\text{kcal mol}^{-1}$ literature value for the N–NO bond dissociation enthalpy,[65] yield the value B for the Mo≡N BDE of $155.3 \pm 3.3\,\text{kcal mol}^{-1}$. It appears

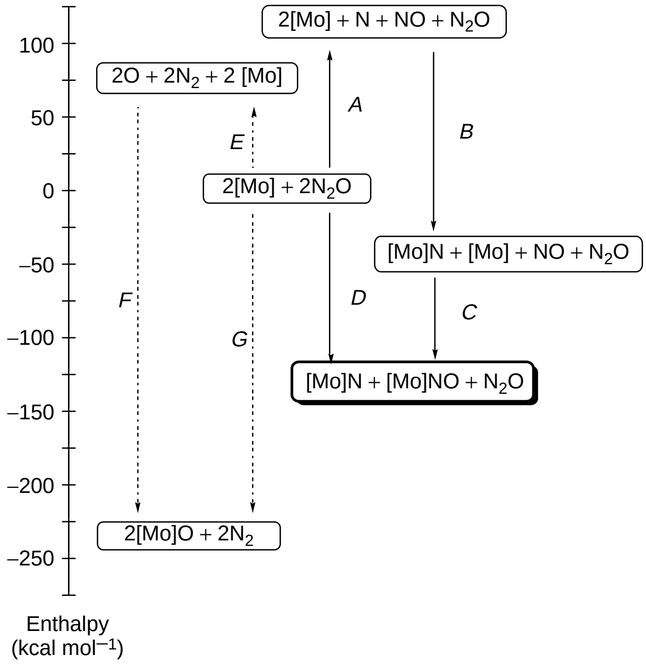


Figure 18 Thermodynamic parameters for the reaction between complex $Mo(N[^tBu]Ar)_3$, here represented as [Mo], and N_2O

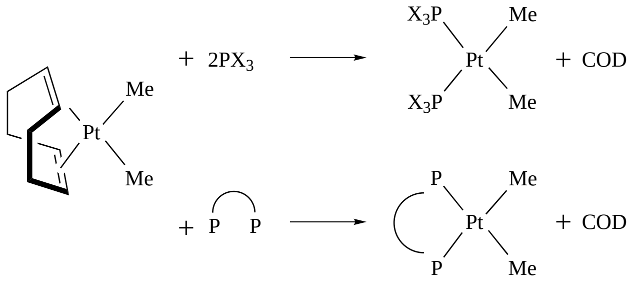
that the calorimetrically determined Mo≡N BDE for nitride **[Mo]-N** is the first such value to be so obtained, and it is of interest further in that it indicates that the splitting of N_2 by 2 equiv of complex (**1**), giving 2 equiv of **[Mo]-N**, is favored enthalpically by ca. $86\,\text{kcal mol}^{-1}$ and serves as a driving force for N_2 cleavage by complex (**1**). The **[Mo]-O** BDE was also determined and was found to be $155.6 \pm 1.6\,\text{kcal mol}^{-1}$, a value equal to $F/2$ in Figure 18. This fact, taken in conjunction with the knowledge that the NN-O BDE value is $40\,\text{kcal mol}^{-1}$, permits the conclusion that the conversion of 2 equiv of complex **[Mo]** to 2 equiv of **[Mo]-O** (if effected by 2 equiv of N_2O) would be downhill by a quantity equal to G, that is $231.2 \pm 3.2\,\text{kcal mol}^{-1}$. Since the latter value is in excess of the value of D by $107.4 \pm 4.0\,\text{kcal mol}^{-1}$, one sees that oxidation of complex **[Mo]** by nitrous oxide giving $Mo(O)(N[R]Ar)_3$ would have been vastly preferable to N–N bond splitting, the pathway that prevails evidently for reasons that are entirely kinetic in origin.

2.10 Binding of Phosphines to a Platinum System

Platinum(II) complexes of the type (COD)PtRX (COD = η^4-1,5-cyclooctadiene; R, X = alkyl, aryl, halide) are known for many combinations of R and X, and their reaction chemistry is well developed (*see* ***Platinum: Organometallic Chemistry***).[66] The lability of the COD–Pt interaction renders these compounds convenient sources of organoplatinum fragments for coordination to Lewis bases such as phosphines, according to equation (27). In an effort to better understand the factors that influence the stability of bis(phosphine)platinum(II) species, a thermodynamical study of the reaction in equation (27) was undertaken for a series of monodentate and bidentate phosphine ligands of varying steric and electronic character.



(27)

2.10.1 *Monodentate Phosphine Ligands*

Table 19 gives the measured enthalpies of reaction that span a range of $15\,\text{kcal mol}^{-1}$ and clearly establish that small-θ phosphines give the most stable complexes in the P_2PtMe_2 system, an observation intuitively satisfying, given that phosphine substitution occurs at mutually cis positions on platinum (see also results on $Cp'Ru(L)_2Cl$ systems).

Table 19 Enthalpies of substitution (kcal mol^{-1}) for the reaction:

$$Pt(Me)_2(COD) + 2PX_3 \longrightarrow PtMe_2(PX_3)_2 + COD$$

[a]Enthalpy values are provided with 95% confidence limit.

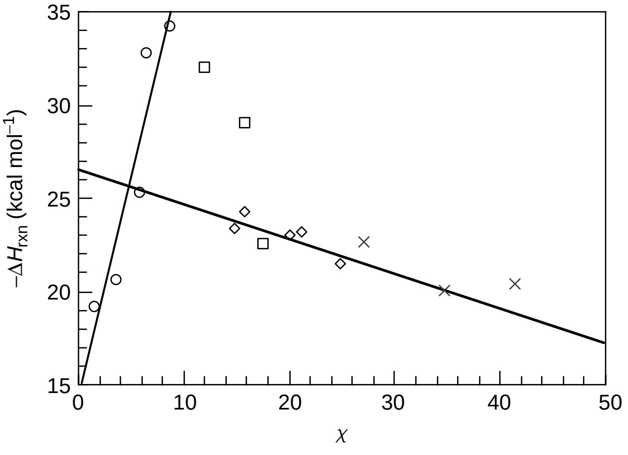

Figure 19 Enthalpy of reaction vs phosphine electronic parameter for $(COD)PtMe_2 + 2PX_3$: (circles) $P(alkyl)_3$ (*slope* = 2.34; $R = 0.932$); (squares) $PMe_{3-x}Ph_x$; (diamonds) $P(p\text{-}XC_6H_4)_3$ (*slope* = −0.189; $R = 0.769$); (crosses) $PPh_{3-x}(pyrl)_x$. Carbonyl stretching frequency (cm^{-1}) vs enthalpies of reaction (kcal mol^{-1}) for the $RhCl(CO)(PR_3)_2$ system (*slope* = 5.47; $R = 0.96$)

Less obvious is the fact that a small but significant χ effect is evidenced by the nonzero slope of the line for $P(p\text{-}XC_6H_4)_3$ and PPh_{3-x}-(pyrl)$_x$ in Figure 19. Without going into detail here, similar electronic effects can be seen when correlating ^{31}P NMR data (chemical shift and platinum–phosphorous coupling) to χ. In an effort to clarify the observed relationships, X-ray diffraction analysis of the complexes with $(PEt_3)_2PtMe_2$, $(PMe_2Ph)_2PtMe_2$, $(P(pyrl)_3)_2PtMe_2$, and $(PCy_3)_2PtMe_2$ were performed and analyzed. The most remarkable relationship between structural

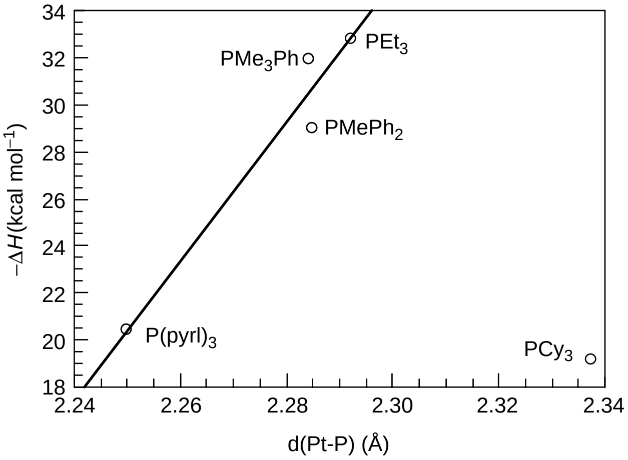

Figure 20 Enthalpy of reaction as a function of Pt–P bond length in $(PX_3)_2PtMe_2$ (*slope* = 2.95; $R = 0.975$)

and thermodynamic data is that reaction enthalpies are smallest in the complexes with the shortest Pt–P bond lengths, as apparent in Figure 20 (except for the sterically too demanding PCy_3 adduct). This counterintuitive result shows that thermochemical measurements such as described here can only determine the total energy difference between states. Energy terms due to distortions in the Pt coordination environment and internal ligand structure, that is reorganization energies (see discussion above), may induce a net destabilizing effect regardless of the intrinsic M–P bond strength.

2.10.2 Bidentate Phosphine Ligands

In light of the results obtained on monodentate ligands and the importance of chelating phosphorus ligands in coordination/organometallic chemistry and catalysis, a thermochemical study on the related bis(phosphine)$PtMe_2$ complexes was undertaken and 13 different chelating ligands were examined for the reaction in equation (27), forming the following complexes: $PtMe_2$(dpype), $PtMe_2$(dppf), $PtMe_2$((+)-diop), $PtMe_2$(dppb), $PtMe_2$(dppe), $PtMe_2$(dppp), $PtMe_2$(dppv), $PtMe_2$(dpmcb), $PtMe_2$(depe), $PtMe_2$(dmpe), $PtMe_2$(dcpe) (*see* ***Platinum: Organometallic Chemistry***).

As shown in Table 20, the overall order of stability is as follows: dpype < dppf < (+)-diop < dppb < dppe < dppp < dppv < dpmcb < depe < dmpe < dcpe. As the Tolman electronic scale predicts, the relative stability of the resulting complexes is strongly influenced by the electronic donor properties of the bidentate phosphine ligand if no larger steric factors are present. For example, better σ donors (*see σ-Donor*), such as, dmpe, depe, and dcpe, give more thermodynamically stable complexes while the isosteric (*see Isosteric Groups*) ligand dpype, which also

Table 20 Enthalpies of substitution in THF at 30 °C for:

[a]Enthalpy values are provided with 95% confidence limit.

possesses a five-membered ring, gives the lowest enthalpy of the series because of its weak donor properties. A similar enthalpic trend was observed for the related $PtMe_2(PR_3)_2$ complexes with monodentate phosphine ligands. The present enthalpy data allow for comparison to thermochemical studies for reactions of common chelating bis(phosphine) ligand in the Cp′Ru(PP)Cl (Cp′ = Cp* = η^5-C_5Me_5 or Cp = η^5-C_5H_5). The relative order of stability of the resulting complexes in the Cp*Ru(PP)Cl and CpRu(PP)Cl systems follow a similar trend as the $PtMe_2$(PP) system. A good correlation ($R = 0.96$) is found for the plot of ΔH_{rxn} versus ΔH_{rxn} for a series of common PP ligand substitution reactions in the CpRu(PP)Cl and $PtMe_2$(PP) systems (Figure 21) or the Cp*(PP)RuCl and $PtMe_2$(PP) systems (Figure 22). The thermochemical comparisons between these organoplatinum and organoruthenium systems thus illustrate that common electronic and steric factors of the bis(phosphine) ligands affect the thermodynamic stability of metallacyclic complexes (*see Metallacycle*).

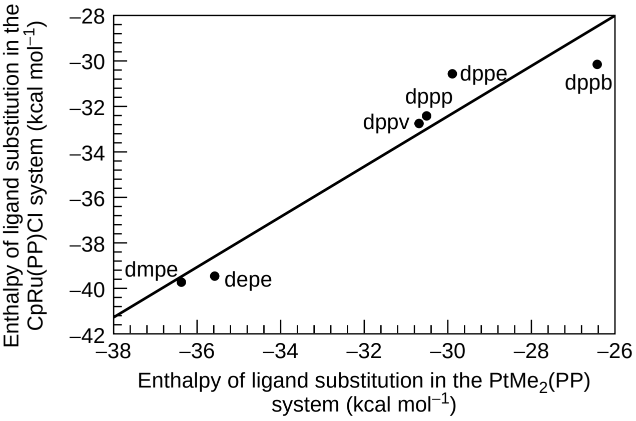

Figure 21 Enthalpy of ligand substitution in the CpRu(PP)Cl system and $PtMe_2$(PP) systems (*slope* = 1.1; $R = 0.96$)

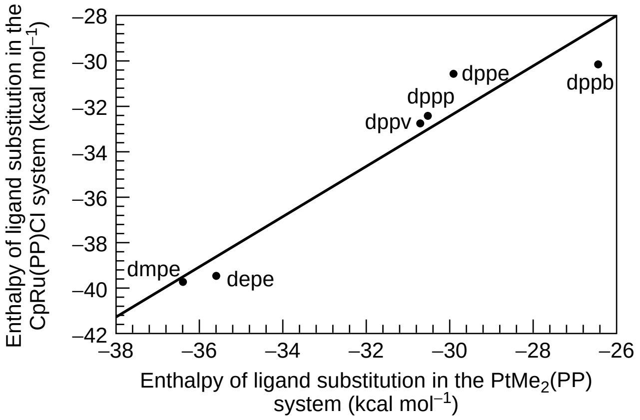

Figure 22 Enthalpy of ligand substitution in the Cp*Ru(PP)Cl system and $PtMe_2$(PP) systems. (*slope* = 1.0; $R = 0.97$)

2.11 Other Examples

Several other examples of calorimetric investigations have appeared in the last decade. For example, phosphine addition to the dimer $[(p\text{-cymene})RuCl_2]_2$ leads to rapid formation of compounds of the general formula (p-cymene)$RuCl_2(PR_3)$.[67] The enthalpies of reaction suggest a more even steric and electronic contributions in this system compared to the Cp′Ru-systems (Sections 3.1–3.3). Thermodynamic influences of ancillary ligand variations on the Ru–X BDE as well as calorimetric investigations on the oxidative additions (*see Oxidative Addition*) of substrates to a Ru(0) complex have also been reported.[68,69] A series of articles has appeared dealing with the thermochemistry of phosphine addition to the complex (BDA)$Fe(CO)_3$.[70–72] Finally, important new results have been obtained through calorimetry on the stability of amido and alkoxy ligands for late−transition metal systems.[73] The thermodynamics of addition of small molecules to iridium complexes of the type $Ir(PR_3)_2Cl$ have also appeared.[74]

3 CLOSING REMARKS

As can be seen above, a significant portion of the recent advances in the area of organometallic thermodynamics has been achieved using solution calorimetric methods. This is not to say that other techniques have not been successfully used to obtain data on such systems. Other methods include experimentally determined bond energy terms by mass spectrometry,[75,76] and a large number of DFT calculations[77–80] have been reported.

Ligand substitution, oxidative addition reaction, and absolute bond enthalpies afford insight into thermodynamic driving forces behind important processes. One of the most striking among the examples given above

is the markedly increased donor ability of NHC versus trialkylphosphines, experimentally determined by solution calorimetry and the stability/reactivity consequences that follow in ruthenium-based olefin metathesis (*see Alkene Metathesis*). There remains a great deal of work to be performed in the area of organometallic thermodynamics. The importance of metal–ligand bond energetics cannot be overstated, yet the physical organometallic chemist has so far played a catch-up role to rapidly moving areas of organometallic chemistry and catalysis. The predictive powers of such data are beginning to be realized, yet more data are needed in order to guide synthetic and catalytic chemistries.

1 INTRODUCTION

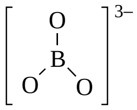
Borates are unique among the oxoanion compounds of the second-row elements in forming anhydrous substances that are both chemically and thermally stable. These characteristics provide a ready accessibility to a large number of synthetic examples that have widespread use. While the borate minerals, precursors to synthetic borates, comprise only a small percentage of the Earth's crust (*see* ***Boron: Inorganic Chemistry***), concentrated deposits in the United States, Turkey, Russia, Argentina, and China have provided an economical source of materials for exploitation. The overall demand for borates in the US for 1993, as measured by B_2O_3 content, is anticipated to be near 400 000 t.[1] More than 50% of this total is used for manufacturing glass, and approximately 25% is used for fiber glass insulation. In other applications, alkali metal borates are active as herbicides, insecticides, fertilizers, and detergents, and high quality borax ($Na_2B_4O_7{\cdot}10H_2O$) is employed in electrolytic capacitors and by the nuclear industry. Selected materials find use in powder and single-crystal form as high-end optical components.

Crystalline metal borates, like silicates, have a rich structural chemistry that extends from the simple orthoanions to their condensation into complex rings, chains, networks, and frameworks. Unlike the fixed coordination number of four for the Si atom in silicates, however, the coordination number of the B atom in borates can be either three or four. This unique feature leads to a variety of unusual structural arrangements that are not found with any other homonuclear polyoxoanion. These arrangements appear extensively, both in anhydrous and hydrated crystals. In fact, many of the large-scale applications of metal borates involve use of hydrated forms. Because the chemistry and technology of these materials have recently been reviewed,[2,3] they will not be considered here. Instead, only those characteristics that are unique to anhydrous borates will be discussed.

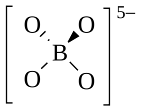
2 ELECTRONIC STRUCTURE

2.1 Triangular and Tetrahedral Units

A wide range of borate structures contain the isolated triangular $BO_3{}^{3-}$ group (**1**), while a fewer number contain the isolated tetrahedral $BO_4{}^{5-}$ group (**2**). The triangular group tends to be quite symmetrical with O–B–O angles near 120° and a B–O distance near 1.375 Å[4] that varies as the sum of the B and appropriate O crystal radii. The tetrahedral group exhibits individual O–B–O angles in the range 95.7–119.4° (mean value = 109.4°) and individual B–O distances from 1.373 to 1.699 Å (mean value = 1.47 Å); exaggerated distortions from the triangular and tetrahedral geometries have been compiled.[5]



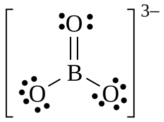
(**1**)



(**2**)

The occurrence of triangular versus tetrahedral coordination in a particular compound may be addressed by considering the information available on the electronic structures of each group. The atomic charge distributions in these groups have commonly been approximated with one of two extreme formalisms: the purely covalent *Formal Charge* model or the purely ionic *Oxidation Number* model. In the triangular unit the formal charge of each O atom is -1 and that of the B atom is 0; these values sum to the overall oxoanionic charge of -3. In the tetrahedral unit the formal charge of each O atom remains -1, but that of the B atom is reduced to -1; again these values sum to the overall charge, now -5. The oxidation numbers in both borate groups are -2 for the O atoms and $+3$ for the B atom, and appropriate overall charges for each group are produced. The charges assigned with the formal-charge model emphasize the strong polarizing power of the B^{3+} ion and the covalent interactions that result from overlap of B and O orbitals having the same principal quantum number ($n = 2$). This model, however, fails to portray the considerable polarity of the B–O bond that results from the

significant *Electronegativity* difference ($\Delta\chi = 1.5$) between the B and O atoms. This particular aspect is emphasized in the oxidation-number model. Considering the B–O interaction in the context of a composite model, a small positive charge should be associated with the B atoms in both the triangular and tetrahedral units and a small negative charge with the O atoms; orbital overlap then produces a polar covalent bond. Such a description is consistent with the electron population analysis of the X-ray diffraction data from the mineral Kernite[6] ($Na_2B_4O_6(OH)_2{\cdot}3H_2O$) and the results of molecular orbital calculations (*see* ***Molecular Orbital Theory***).[7]



(**3**)

Lewis diagram (**3**) presents an alternative electron structure where the octet rule is satisfied for the B atom. This diagram represents one form of the resonance hybrid associated with delocalization of electron density through the π system of the unit. The relatively short B–O distances of the triangle in comparison to the longer distances of the tetrahedron have been attributed to these $p_\pi - p_\pi$ interactions. The significance of these interactions to the stability of the triangular group, however, remains unclear. The percentage difference between the average B–O distances of the triangle and tetrahedron are smaller than those observed for N- and C-centered oxoanions.[8] The out-of-plane bending force constant for the $BO_3{}^{3-}$ group has been reported to be approximately 65% of the equivalent values found for $CO_3{}^{2-}$ and $NO_3{}^{-}$.[9] These results indicate that π bonding is less significant in borates in comparison with similar interactions in carbonates and nitrates. This is to be anticipated from the large electronegativity difference between the B and O atoms which limits orbital mixing. Additional information on the distribution of charge in B–O interactions may be obtained from NQR data.[10]

The extensive base of structural data on borates also lends little support to the view that the π interaction produces a significant stabilizing energy for the triangle in a particular crystal structure. The adoption of a triangular or tetrahedral coordination by a B atom is largely dictated by the electronic characteristics of the other metal atoms in the matrix. It is well known from studies of aqueous solutions that the central atom of an oxoanion can satisfy its requirements for bonding electron density by adopting a smaller coordination number in a basic solution where the available charge density on the O atoms is greater. Higher coordination numbers are observed in acidic solutions where the central metal atoms must compete with H^+ for the available O electron density. A similar trend is observed for the structures of solid metal borates. Borates rich in metal atoms that form binary basic oxides contain a high or exclusive proportion of BO_3 groups, while those rich in metal atoms that form binary acidic oxides contain a higher concentration of BO_4 groups. These trends are demonstrated with examples in Section 3. In terms of *Crystal Field Theory*, the higher charge of the BO_3 groups also generates stronger crystal fields at the associated metal sites; examples of this effect are given in Section 5.

3 CRYSTAL STRUCTURE

The known structural chemistry of anhydrous borates through 1985 has been summarized,[11] and those borate minerals containing fused octahedra and triangles have been classified according to selected fundamental building blocks.[12]

3.1 Structures with Isolated Triangular Groups

A common packing of planar triangular groups results in the formation of layers, as illustrated by the calcite-type structures of $AlBO_3$, $GaBO_3$, $FeBO_3$, $RhBO_3$, and $ScBO_3$ (Figure 1). In this structure, the BO_3 layers are interleaved by metal atoms occupying distorted octahedral environments. The octahedra are linked by sharing vertices, and each O atom binds one B and two metal atoms. A closely related structure is adopted by the large family of materials having the formula $LnM_3(BO_3)_4$ (Ln = lanthanide; M = Al, Ga, Fe, or Sc). These compounds form in a similar layered structure (Figure 2), except the orientations of the BO_3 groups within the layers are altered to produce a trigonal prismatic O environment about the Ln atom. These materials commonly crystallize in

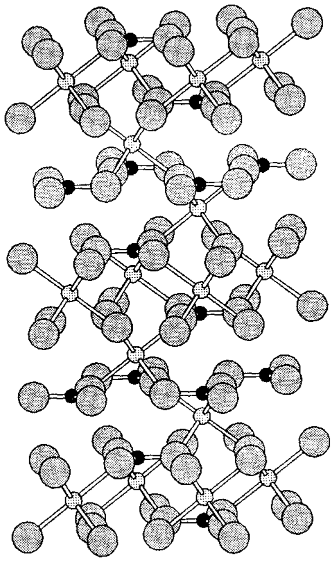


Figure 1 Calcite structure of MBO_3. Small filled circles represent B atoms, large shaded circles represent O atoms, and stippled circles represent M atoms, here, and in Figures 2, 3, and 8

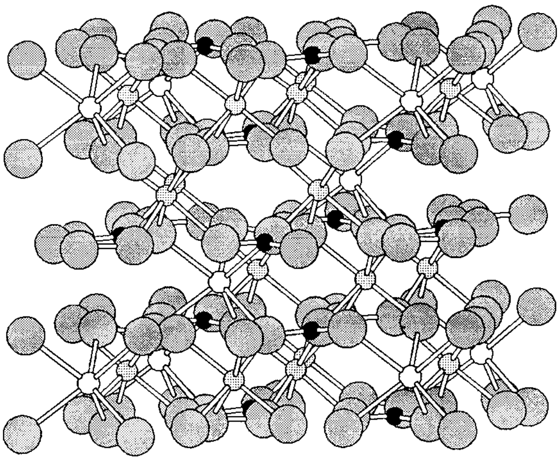

Figure 2 Huntite structure of $LnM_3(BO_3)_4$. Open circles represent Ln atoms

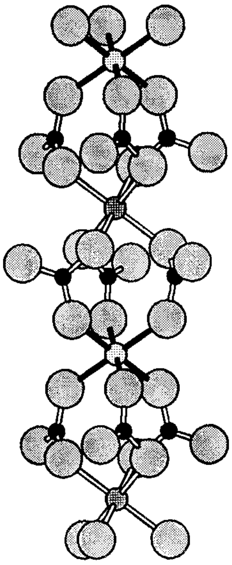

Figure 3 Chain structure of STACK compounds $A_6\,MM'(BO_3)_6$. M atoms are indicated with open bonds and M′ atoms with filled bonds

the noncentrosymmetric trigonal form of the mineral Huntite, $CaMg_3(CO_3)_4$, but other forms are known where the packing of the BO_3 groups within the planes is again modified to afford centrosymmetric structures having lower symmetry. Derivatives containing each of the lanthanides have been reported for the Al and Ga compounds, but only those Sc compounds containing the lanthanides La, Ce, Pr, Nd, Sm, Eu, and Gd exist. Apparently, the large size of the Sc atom produces a Sc–borate matrix with a trigonal prismatic site that is too large to be stabilized by the smaller lanthanides.

On the basis of the coordination environments of the metal atoms in this structure type, it is difficult to rationalize the existence of the family. The six-fold coordination at the Ln site is small for a lanthanide atom (*see* ***Coordination Numbers & Geometries*** and ***Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry***). It might be anticipated that the stoichiometric combination $LaSc_3(BO_3)_4$ would be more thermodynamically stable as a mixture of the separate phases $3ScBO_3 + LaBO_3$ where the coordination number of the La atom in $LaBO_3$ is nine. The stability of the Huntites must then be associated with a higher coordination number for the O atoms. As noted above, the coordination number of the O atoms in the calcite structure of $ScBO_3$ is three, but in the Huntite structure this number is four. The higher number and the attendant increased metal–O interactions provide the stability for the existence of the family. The compound $LaSc_3(BO_3)_4$ does undergo the peritectic reaction $LaSc_3(BO_3)_4 \rightarrow LaBO_3 + 3ScBO_3$ above 1550 °C.

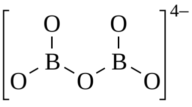
The STACK family[13] of compounds provides an example of a simple orthoborate structure type where the BO_3 groups do not pack in such readily perceived planes. These compounds are characterized by the formula $A_6MM'(BO_3)_6$ where A = Sr or Ba, and M and M′ = any cation of formal charge +2, +3, or +4 that occupies an octahedral site. With more than 125 known derivatives, these compounds form one of the larger structural families of solid-state oxides. Example formulations are $Sr_6HoFe(BO_3)_6$ (A = Sr, M = Ho, M′ = Fe), $Ba_6GdSc(BO_3)_6$ (A = Ba, M = Gd, M′ = Sc), and $Sr_3Sc(BO_3)_3$ (A = Sr, M = Sc, M′ = Sc).

The structure is characterized by chains formed from a series of M- and M′-centered distorted octahedra that are stacked one atop the other and separated by BO_3 groups (Figure 3). By virtue of their connectivity to the A atoms, the octahedra are crystallographically and chemically dissimilar; the M-centered octahedron is larger than the M′-centered site. As a result, larger cations preferentially occupy the M site and smaller cations the M′ site. These octahedra are bridged by intervening A atoms in nine-coordinate AO_9 sites. Although the structure may be portrayed with this chain description, the rich A concentration and high density of AO_9 interconnections actually produce a fully three-dimensional arrangement of the atoms.

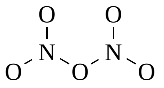
3.2 Oligomeric and Polymeric Condensation of Triangular Groups

Like M–O–M linkages in complex oxoanions of the heavier congeners of Groups 14 and 15 (*see* ***Phosphates: Solid-state Chemistry***), B–O–B couplings result in the formation of higher order polyanions. The simplest condensation of BO_3 units affords the pyroborate group (**4**). In this group the terminal B–O distances tend to be somewhat longer than the bridging B–O distances, and a wide variation (111.8–180°) in the bridging B–O–B angle is observed. Although illustrated here as a planar group, a considerable range of interplanar angles between the terminal BO_2 groups has been reported; the angle varies from 0° in the compound $Sr_2Sc_2B_4O_{11}$[14] to the nearly orthogonal angle of 84° in the compound $Ba_5(B_2O_5)_2F_2$.[15]

This angular variation is not unexpected in view of the isoelectronic relationship between the pyroborate group, the molecule N_2O_5 (**5**), and the malonate anion, where considerable rotations about the N–O and C–O bonds are also observed.

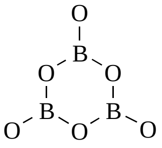


(**4**)

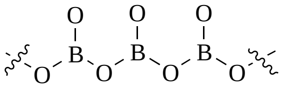


(**5**)

Condensation of three BO_3 groups is known to yield the cyclic metaborate ring B_3O_6 (**6**), but not a linear trimer. Examples of anhydrous materials containing this ring are ABO_2 (A = Na, K, Rb, Cs) and BaB_2O_4 ($\equiv Ba_3(B_3O_6)_2$). Condensation to other oligomeric species of higher order is unknown, except for full condensation to the linear metaborate chain $(BO_2)_n{}^{n-}$ (**7**) in the compounds $LiBO_2$-Type I, CaB_2O_4-Type I, and $La(MoO_4)BO_2$.



(**6**)



(**7**)

3.3 Structures with Tetrahedral Groups

Compounds containing isolated BO_4 groups are uncommon; examples include $MgAlBO_4$, $MgGaBO_4$, $SrAlBO_4$, $LiGeBO_4$, $NbBO_4$, and $Lu_3O_2BO_4$. Fusion of two or three BO_4 tetrahedra (in the absence of connectivity to BO_3 triangles) to form low-order oligomers is currently unknown in anhydrous systems. Full condensation to form three-dimensional frameworks through vertex-shared BO_4 units occurs in the mineral Johachidolite, $CaAlB_3O_7$, the sodalite analogs typified by $Zn_4O(BO_2)_3$, and the compound SrB_4O_7.

3.4 Structures with Admixture of Triangular and Tetrahedral Groups

Borates containing both BO_3 and BO_4 groups exist as polyborates where the two types of groups fuse by sharing O vertices. A description of these complex anions as the condensation of smaller B–O cyclic systems has been given.[4] For example, the polyborate structure of LiB_3O_5 (Figure 4) is characterized as the condensation of B_3O_7 rings where each ring (**8**) contains two BO_3 units (a pyroborate group) fused to a BO_4 unit. The rings fuse by sharing each terminal O atom to give the polyborate formula $(B_3O_3O_{4/2})^- \equiv (B_3O_5)^-$.

Because several types of small rings exist and their modes of condensation vary depending on the nature of the associated metal atoms, a large number of polyborate structures exist. The compounds LiB_3O_5, CsB_3O_5, and $SrLi(B_3O_5)_3$[16] (Figure 5) all contain a B_3O_5 polyborate framework resulting from the condensation of B_3O_7 rings (**8**), but the details of joining

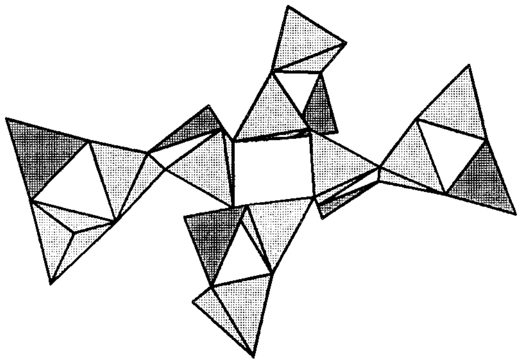

Figure 6 Polyhedral representation of the polyborate anion in the compound $LaMgB_5O_{10}$

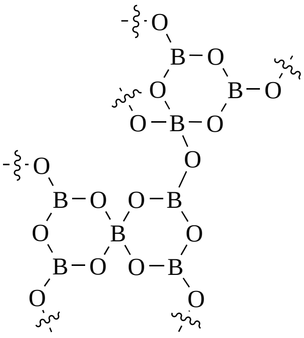
the rings differ for each material. To satisfy the bonding requirements of the associated metal atoms (Li, Cs, Sr) the condensed B_3O_7 groups must be rotated, one relative to the other, about selected B–O bonds.

Two additional examples of polyborate anions are illustrated by the arrangements in the compounds $LaMgB_5O_{10}$ and $SrNaB_5O_9$.[17] The La compound contains B_3O_8 rings (**9**) that fuse by sharing a common BO_4 group (Figure 6). The structure of the polyanion in the compound $SrNaB_5O_9$ contains an admixture of this ring and the B_3O_7 ring (Figure 7).

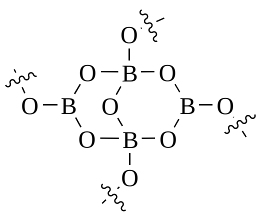
3.5 Glass Structure

Because of the importance of borates in the production of specialty glasses such as Pyrex and Vycor, among others, the structures of vitreous alkali-metal borates have been of considerable interest. Like SiO_2, boron oxide, B_2O_3, is a natural glass-forming substance; alkali metal oxides fuse with H_3BO_3 or B_2O_3 to form clear melts. If these liquids have a significant boron oxide content they become viscous on cooling and form glasses[18] (*see* ***Noncrystalline Solids***).

Much of the interest in alkali-metal borate glasses has centered on reports indicating anomalous behavior in physical properties such as viscosity and thermal expansion coefficient as a function of metal oxide content.[19] Each of these properties has been correlated to changes in the molecular structure of the glass. X-Ray[20] and neutron[21] diffraction, NMR[22], Raman,[23] and NQR[10] studies indicate that 75–85% of the B atoms in vitreous B_2O_3 are contained in condensed B_3O_6 boroxin rings; these rings are spatially identical to those of the cyclic metaborate unit (**6**). On addition of A_2O (A = alkali metal) to B_2O_3, the fraction of boroxin groups decreases and the fraction of four-coordinate B atoms increases. Near a mole fraction of 0.20 A_2O, Krogh–Moe complex[24] (**10**) exhibits its maximum concentration, and near a mole fraction of 0.35 A_2O, complex (**11**) appears at its maximum concentration. Beyond a mole fraction of 0.40 the concentration of BO_4 groups diminishes, and the proportion of O atoms that do not bridge B atoms increases. These nonbridging O atoms are associated with orthoborate, pyroborate, and cyclic metaborate groups.



(**10**)



(**11**)

The system $Na_2O–B_2O_3–SiO_2$ contains many technologically important glass compositions. At low Na concentrations ($Na/B < 0.5$), structures are dominated by fused six-membered rings containing one or two BO_4 groups.[25] This B–O framework is separated from a matrix of condensed SiO_4 tetrahedra similar to that found in SiO_2. At intermediate concentrations of Na ($Na/B > 0.5$), ring metaborate, pyroborate, and orthoborate units form in conjunction with isolated SiO_4 units. At higher concentrations ($Na/B = 1$), metaborate ring numbers are observed to increase with SiO_2 content. Again, BO_4 groups are not incorporated into the framework of condensed SiO_4 units, unlike the mixed frameworks of aluminum silicates (*see* ***Zeolites***). Like the binary alkali-metal borate glasses, some loose BO_3 and BO_4 groupings persist in these structures.

4 SYNTHESIS

4.1 Crystalline Solids

Anhydrous metal borates are conveniently prepared by heating hydrated salts or by direct fusion or firing of one or more metal oxides with H_3BO_3 or B_2O_3. Because the melting points of most borates fall well below 1500 °C, heating suitable reagents for only a few hours near 1000 °C generally produces homogeneous microcrystalline powders. Careful consideration should be given to the selection of a crucible when fusing a borate as the melts wet most metals and react with most oxide ceramics.

Crystalline anhydrous metal borates have also been synthesized by hydrothermal methods.[26] To limit the formation of hydrates, many materials have been prepared from highly concentrated aqueous solutions of H_3BO_3. The high B_2O_3 content of these fluids favors the formation of polyborates, e.g. $Ca_2B_6O_{11}$, in many phase systems.

4.2 Crystal Growth

Because of the technological importance of the compounds β-BaB_2O_4 (BBO) and LiB_3O_5 (LBO) as optical frequency converters, considerable effort has been expended on their crystal growth. BBO exists in two modifications, a low-temperature β phase and a high temperature α phase. The phase transition occurs near 925 °C, and the α phase melts at 1095 °C. The low-temperature β phase is noncentrosymmetric and exhibits the desired optical properties. As a result, much of the work on BBO has centered on the development of an efficient top-seeded flux method. From studies on a variety of melt additives, pure Na_2O has emerged as the solvent of choice,[27] although high growth rates have been reported with NaCl.[28] The viscosity of the melt is minimized by achieving saturation as close as possible to the phase transition temperature through incorporation of 20–22 mol% Na_2O. The melt is then generally cooled at 0.5–2 °C day^{-1} to yield a growth rate of 1.5–2.0 g °C^{-1} from a 1 kg melt. This growth method, however, still suffers from a high melt viscosity that contributes to inclusion of solvent in the crystal. With appropriate temperature gradients at the melt–growth interface, it has been found that the low-temperature β phase can be crystallized directly from the stoichiometric melt near 1100 °C.[29] In this way, Czochralski and Bridgman methods may be used to grow the crystals; incorporation of solvent is eliminated and the higher growth temperature reduces the viscosity and contributes to a faster growth rate (4 mm h^{-1}).

LBO also undergoes a peritectic decomposition (834 °C) and must be grown by a flux method. The original phase diagram for the system Li_2O–B_2O_3 indicated that LBO decomposed into $Li_2B_4O_7$ and $Li_2B_8O_{13}$ below 595 °C, but this was subsequently disproved. A stable melt can be produced below 834 °C by adding excess B_2O_3.[30] While pulling crystals from this melt limits the incorporation of impurities, the high viscosity hinders mass transfer and results in the formation of inclusive crystal defects. Addition of LiF to the melt has been found to decrease the viscosity and improve the growth characteristics. Under suitable conditions, crystals of high optical quality can be grown, but at the very slow rate of 1 mm day^{-1}.

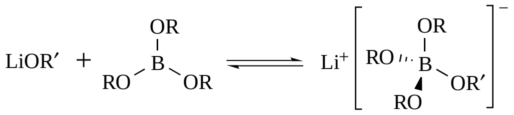
The defect chemistry of BBO and LBO crystals appears to be extrinsically controlled by the incorporation of impurities.[31] The total impurity content of selected BBO crystals has been estimated from spark source mass spectrography to be 150 ppm by mass. Carrier concentrations of 0.1–10 ppm (atomic) from conductivity data are consistent with this impurity level. Considering the presence of strong polar covalent interactions in the metaborate rings, it is likely that a greater proportion of the defects are to be found in the Ba sublattice. The intrinsic UV absorption edge for BBO is 190 nm at room temperature. To use the material with high efficiency for frequency doubling near 200 nm the transmittance should be as high as possible. At lower temperatures, additional absorption features at wavelengths longer than that associated with the absorption edge have been observed; the transmittance of a 1-cm thick crystal at 222 nm can fall to 22% at 0 °C. These absorption features have been attributed to unspecified impurities, indicating that the foreign atoms contribute to both the defect structure and the optical transparency.

Impurity concentrations for LBO have been determined to be 500 ppm by mass. Carrier concentrations of several hundred ppm (atomic) from conductivity measurements are consistent with the lithium vacancy concentration determined from the type and amount of impurity atoms. This result again indicates that the defect structure of a borate is dominated by impurities. The extrinsic control and limited defect chemistry in these materials is not surprising, because the small size of the B atom and its strong interaction with the O atoms should limit substitution of other atoms on the B sites.

4.3 Sol–Gel Synthesis

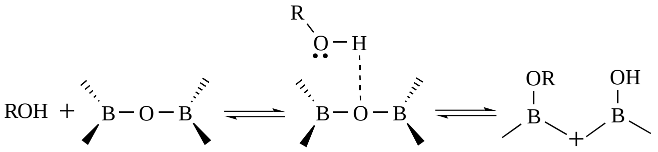
Most of the work on the synthesis of borates by sol–gel processes has centered on the preparation of glasses and glass fibers.[32–34] Precursors to these glasses have included alkoxides and basic aluminum oxides, e.g. $Al(OH)_2(OOCCH_3)\cdot 1/3H_3BO_3$. Detailed studies on the successive hydrolysis and condensation reactions of B alkoxide compounds have been reported. ^{11}B NMR studies of borate gels prepared from $LiOCH_3$ and tri-n-butylborate in the system $x\mathrm{Li_2O}\cdot 1 - x\mathrm{B_2O_3}$ have revealed that the fraction of tetrahedrally coordinated boron atoms $\langle N_4 \rangle$ increases linearly with x according to the equation $\langle N_4 \rangle = 0.43x + 0.104$. The reaction between lithium methoxide and the boron alkoxide is

believed to produce the four-coordinate B atom (equation 1).



(1)

To form gels in this mixed alcohol solvent system, a critical value of $\langle N_4 \rangle$ must be exceeded. This observation has been rationalized on the basis of the kinetic stability of B–O–B bonds toward hydrolysis or alcoholysis. Because tetrahedrally coordinated borate groups are coordinatively saturated (*see Coordinative Saturation & Unsaturation*), this group is unable to participate in dissociative reactions of the triangular group that hinder polymerization and the formation of gels (equation 2).



(2)

A sufficient $\langle N_4 \rangle$ is required to give at least one tetrahedrally coordinated B atom as a connection between the oligomeric structural units. Comparison of FTIR spectra of gels with those of molecular and crystalline alkali-metal borates indicates that the initial polyborate species to emerge during hydrolysis are units composed of six-membered rings. Additional hydrolysis is associated with condensation reactions between these rings. Since $\langle N_4 \rangle$ must be >0.23 for formation of stable gels, a network of BO_3 and BO_4 groups has been proposed for the lithium borate polymers near the gel point.

5 OPTICAL PROPERTIES

5.1 Laser Materials

Broad-band laser emission has been observed from Cr^{3+}-doped $ScBO_3$.[35] The luminescence band extends from 700 to 1000 nm, with a peak at 810 nm. This emission is a vibrationally assisted transition from the excited $^4T_2$ level to the ground ^4A level of the Cr^{3+} ion (*see* ***Ligand Field Theory & Spectra***). The centrosymmetric symmetry of the dopant site affords a relatively long fluorescence lifetime of 115 µs. The laser tuning range is 787–892 nm, and the laser pumped output efficiency is near 29%. This value may be compared to the high efficiencies of 51% for Cr^{3+}:$BeAl_2O_3$ and 52% for Cr^{3+}:$LiCaAlF_6$.

Cr^{3+} laser emission has been obtained from a variety of crystals in two very different ways, depending on the strength of the crystal field at the dopant site and whether the emission arises from the excited ^2E or $^4T_2$ state. With its sharp line emission, ruby (Cr^{3+}:Al_2O_3) is an example of a Cr^{3+} laser operating on the basis of ^2E emission. Because this emission occurs primarily in the zero-phonon lines, the ruby laser operates as a three-level system with a rather high threshold for oscillation.

In the late 1970s, Cr^{3+}-doped alexandrite ($BeAl_2O_4$) was found to lase on the vibrational sideband of the $^4T_2 \rightarrow {}^4A$ transition. Because this transition terminates on vibrationally excited states of the ground level, the laser operates as a four-level system with a much lower threshold. Several similar Cr^{3+} lasers were subsequently developed.[36] A limitation in all these systems, however, arises from the $^4T_2 \rightarrow {}^4T_1$ a excited state absorption which overlaps to some extent the $^4T_2 \rightarrow {}^4A_2$ emission. Materials exhibiting higher excited state absorption cross sections and greater overlap with the emission band are found to be less efficient lasers. Examples of Cr^{3+} laser crystal systems with low excited state absorption losses (and therefore high laser efficiency) are emerald, and the aforementioned hosts $BeAl_2O_4$ and $LiCaAlF_6$.

Because excited state absorption losses are generally higher for those materials that emit at longer wavelengths, the compound $Sr_3Sc(BO_3)_3$ was synthesized as a host for shorter wavelength emission.[37] This compound contains BO_3 triangles and a high concentration of the basic oxide SrO that in combination produce a relatively strong crystal field at the Cr^{3+} dopant site. Luminescence from the doped host at room temperature is centered in a broad band at 750 nm (cf. 810 nm in Cr^{3+}:$ScBO_3$), representing a considerable blue shift that could lead to an increased lasing efficiency. As a host, the material is similar to alexandrite in that transitions from both ^2E and $^4T_2$ levels are observed at room temperature.

The huntite Nd:$YAl_3(BO_3)_4$ has also been lased.[38] This crystal has generated interest because, as noted in Section 3, it is noncentrosymmetric and can also function as an optical frequency converter. This host can then self-double the 1064-nm emission line of the Nd^{3+} ion directly to 532 nm, eliminating the need for separate laser and frequency conversion crystals. With diode pumping, the crystal provides a compact source of green light. Because the Nd^{3+} ion absorbs near the doubled frequency, the dopant concentration must be near 4% to achieve an efficient production of green light.

5.2 Nonlinear Optical Materials

Crystals of BBO[39] and LBO[40] are extensively used for generating visible and UV light from high-power pulsed lasers. The general utility of the materials derives from their high optical damage thresholds and transparency ranges that extend to 190 nm for BBO and 170 nm for LBO.

The second-order susceptibility of LBO ($d_{\text{eff}} = 0.7$ pm V^{-1}) for doubling 1064-nm light from a Nd:YAG laser is approximately 40% of that of BBO ($d_{\text{eff}} = 2.0$ pm V^{-1}). These susceptibilities have been modeled by summing the

second-order polarizabilities of the individual borate rings according to their orientations in the crystals.[39] Although the susceptibility for BBO is larger, LBO generally exhibits the greater efficiency for doubling 1064-nm light because of its favorable linear optical properties. As light travels through a crystal, energy will be efficiently transferred from the fundamental to the second harmonic only if the fundamental and second harmonic have the same phase velocity. This velocity (v) is inversely proportional to the refractive index ($v = c/n$), so efficient second-harmonic generation will occur if $n(\omega) = n(2\omega)$. This condition can be satisfied though the process of angular phase matching with a birefringent crystal.

BBO is an example of a material having a high birefringence. The birefringence is a direct result of the packing of the cyclic metaborate rings into discrete layers (Figure 8). Light polarized parallel to the layers will interact strongly with the rings by moving electron density through the B–O bonds. This interaction will retard the phase velocity of light as indicated by the value of $n_o = 1.6551$ at $\lambda = 1064$ nm. Light polarized orthogonal to the layers will induce less polarization as electron density can not be redistributed through B–O bonds. As a result the phase velocity will be faster and the refractive index smaller, $n_e = 1.5425$ at $\lambda = 1064$ nm. The difference between n_o and n_e ($\Delta n = 0.11$) represents the magnitude of the birefringence. The phase velocity of light having a polarization direction intermediate to these two extremes will be dictated by a value of n between n_o and n_e.

By combining birefringence and the dispersion of the refractive indices with wavelength, the phasematching condition $n(\omega) = n(2\omega)$ can be satisfied. The dispersion curves for BBO are given in Figure 9. Points are indicated where the refractive indices are equivalent for a fundamental wavelength at 1064 nm and its second harmonic at 532 nm. From the diagram, it is seen that the index $n(2\omega)$ occurs at an angle of 22.7° with respect to the n_o (optic) axis. For light traveling at this angle, energy can be efficiently transferred from the fundamental to the second harmonic.

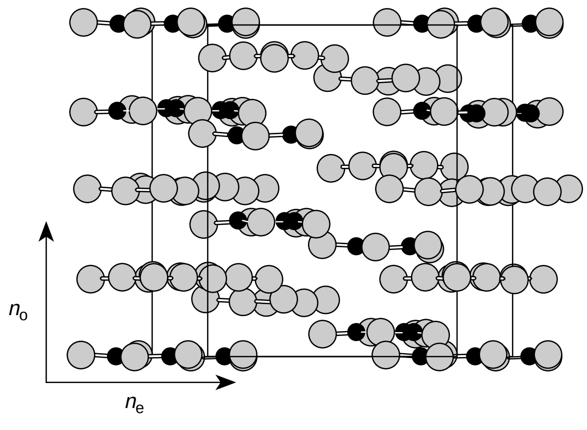


Figure 8 Packing of the cyclic metaborate rings in the structure of β-BaB_2O_4

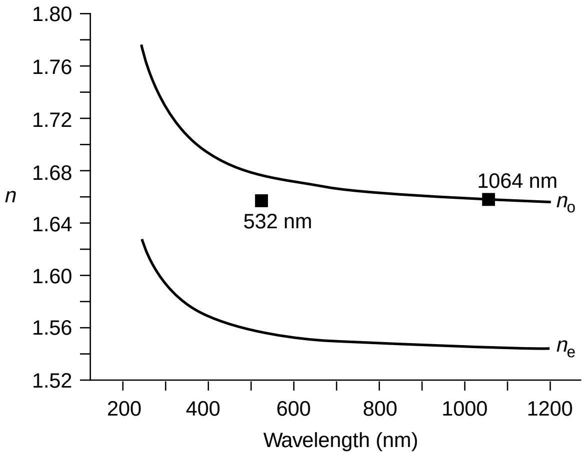

Figure 9 Refractive index dispersion curves for β-BaB_2O_4

The birefringence of BBO is much greater than that of LBO ($\Delta n = 0.025$). Because the flat portions of the B_3O_7 rings are skewed from coplanarity in the condensed framework (Figure 4) of LBO, a smaller Δn is produced. Two important features arise from these differing values. Since Δn is large in BBO, a higher angular sensitivity to phase matching is observed. This sensitivity arises from the variation of n with changes in polarization angle. For intermediate angles between the axes n_o and n_e, n varies rapidly with angle changes, and this variation is amplified by the large Δn of BBO. If a slightly divergent laser beam is directed into a BBO crystal at the phase matching angle, it will sample a range of refractive indices and the condition $n(\omega) = n(2\omega)$ will not be strictly satisfied for the entire beam. The net result is a reduction in conversion efficiency. For LBO, Δn and the variation in n with angle are smaller. The phase matching condition is much less sensitive to angular variations and higher conversion efficiencies obtain.

The magnitudes of the birefringence in each of these materials also governs the method for obtaining UV light. For example, in BBO the birefringence is sufficiently large to allow generation of 266-nm radiation directly from a 532-nm fundamental beam. This is not the case for LBO, where the birefringence is not large enough to provide a value of $n(2\omega)$ that is sufficiently small to achieve phase matching. As a result, LBO is not useful for direct conversion to short wavelengths. Generation of UV light with LBO must be accomplished through other sum frequency-mixing techniques.

5.3 Phosphors

The doped compounds Ce^{3+},Tb^{3+}:$GdMgB_5O_{10}$, and Ce^{3+},Mn^{2+}:$GdMgB_5O_{10}$ are used as phosphors[41] in efficient fluorescent lamps having a high color rendition index (*see* ***Luminescence***). The host is isostructural to the compound

$LaMgB_5O_{10}$ which was described in Section 3. In this structure the Mg-centered distorted octahedra share vertices with the Gd-centered sites, and the Gd-centered environments fuse by sharing edges. The high efficiencies of these materials derive from the efficient transfer of energy from one ion to the next.[42] The Ce^{3+} dopant effectively absorbs the 254-nm light of the Hg emission in the fluorescent lamp. The emission band of this ion is at a sufficiently high energy to provide for the complete transfer of excitation energy to the Gd^{3+} ions. In the Tb^{3+}-doped material the energy migrates through the Gd^{3+} sublattice until it encounters a Tb^{3+} center, where energy transfer ($Gd^{3+} \rightarrow Tb^{3+}$) results in the production of green light at 545 nm. In the Mn^{2+} compound the ion substitutes on the Mg^{2+} site. Similar energy-transfer steps lead to the production of red light characterized by a broad-band emission centered at 620 nm.

Two important characteristics, one electronic and one structural, contribute to the success of these materials. The weak crystal field produced by the polyborate at the Ce^{3+} ion leads to a high-energy emission and a significant overlap between the Ce^{3+} relaxed excited state and Gd^{3+} absorption bands, allowing efficient energy transfer from Ce^{3+} to Gd^{3+}. Also, the linkage of the metal–atom coordination environments provides a pathway for energy migration through the Gd sublattice to the luminescent ions.

The phosphor Tb^{3+}:$InBO_3$ has been promoted as a green phosphor in cathode-ray tubes and as a possible scintillator.[43] It exhibits a quantum efficiency under cathode-ray excitation of 8%, and it is stable to intense electron beams. The emission lifetime of 7.5 ms, however, is likely to be too long for some applications.

6 INDIVIDUAL BORATES

6.1 Borate halides

Although several borate halides exist in Nature, few synthetic examples have been described. Because their stoichiometries mimic that of the fluoride apatite, $Ca_5(PO_4)_3F$, the borates $AE_5(BO_3)_3X$ (A = Ca, Sr; X = F, Cl, Br)[44,45] have generated some interest. The structures of these materials are substantially different from that of apatite, and they vary depending on the identity of the A and X atoms. Interestingly, in the compound $Ca_5(BO_3)_3F$, one of the Ca atoms and the F atom may be replaced by a Ln = lanthanide atom and an O atom, respectively, to give materials of the type $Ca_4Ln(BO_3)O$.[46]

The compound $Ba_5(B_2O_5)_2F_2$ represents the first established example of a pyroborate halide. The pyroborate group in this compound exhibits the largest deviation from planarity of any such unit.[15]

6.2 $BaLnB_9O_{16}$ (Ln = lanthanide)[47]

The host $BaGdB_9O_{16}$ exhibits a quantum efficiency = 0.65 when doped with the ion Eu^{3+}. Eu^{2+} emission from the same host is characterized by a broad band peaking in the blue at 460 nm. Structural data for these compounds have not been reported.

6.3 $LiBGeO_4$ and $LiSiGeO_4$[48]

These mixed oxides have been considered as nonlinear optical materials (*see Nonlinear Optical Materials*).[49] They crystallize as ordered derivatives of the cristobalite structure. As early X-ray structural studies were performed on twinned crystals grown from congruent melts, their true symmetry was not firmly established. Untwinned single crystals have been produced by hydrothermal methods, and the space group has been convincingly established as $I\bar{4}$.

1 INTRODUCTION

The borides are characterized by a great number of unique properties. Most of them are refractory with melting points well above 2000 K and have a high hardness, excellent wear resistance, and very good chemical inertness, for example, toward reactive liquid metals, and a relatively good oxidation resistance. Many properties vary with the nature of the metal component and with composition. As an example, some of the borides display Pauli paramagnetism, some are strong ferromagnets, but some of them are also diamagnets. The electrical properties of the borides include metallic conductivity (five times larger than that of the component metal in TiB_2), high-temperature semiconductivity, which occurs, in particular, in boron-rich borides, and superconductivity. Among the borides several heavy Fermion systems have been discovered and studied in detail. In particular the boron-rich borides display a high stability toward neutron and other types of radiation. Some boride phases have attracted interest for their use as thermionic emitters and as high-temperature thermoelectrics.

In comparison with the related carbides and nitrides, borides are characterized by a great structural complexity, a statement that is valid for both metal-rich and, in particular, for boron-rich compositions. Presently, a total of more than 950 binary and ternary borides have been prepared and characterized. They crystallize in well above 130 different structure types. Some of these have large unit cell volumes in the range 2000–3000 Å^3. The range of composition is extremely large, the metal/boron ratio varies with more than three orders of magnitude in binary and ternary borides. In a systematic approach to the crystal chemistry of borides, it is convenient to consider packing and relative size of the atoms, space filling, the electron deficiency of boron, and the strong tendency toward the formation of boron–boron bonds as the boron/metal ratio increases. The electron deficiency of boron is also of major importance in the theories of bonding and band structure of the borides.

Binary borides are formed with transition and inner transition elements, with alkali and alkaline-earth elements, and with the *p* elements, aluminum, and silicon. In addition, a group of more electronegative elements (C, O, P, S, As, Se) form compounds with boron, which display properties and structures closely related to those of some borides. This group of compounds is also briefly described in the present article as well as the polymorphs of elemental boron.

2 OCCURRENCE AND CRYSTAL CHEMISTRY OF BORIDES

2.1 Occurrence of Borides

Preparation and phase characterization of a great number of binary borides were carried out in the period 1950 to 1980,[1–4] while interest was focused on ternary borides in the time that followed.[5–10] Recently published reviews on phase diagrams RE–T–B[6,8] and surveys on the formation of borides[7–10] contain more details on borides than what is available in general phase diagram compilations.[11] Of particular interest in this connection are the proceedings from a series of 13 international symposia on boron, borides, and related compounds, held after the first symposium on boron in Asbury Park, N.J., USA, 1959. The topics covered in these symposia are synthesis, phase diagrams, chemical bonding, physical properties, and applications. Most of the proceedings from symposia held later than 1972 are available as special issues of international journals. The most recent ones of these are included in the list of references.[12–16]

Improved phase diagrams can be obtained by computer coupling of phase diagrams and thermochemical data. Such modeling has been performed for several boride systems, for instance, V–B, Cr–B, Mn–B, Co–B, Ni–B, Fe–B, and Cu–B.[17]

The occurrence of the binary borides of the alkaline, alkaline earth, aluminum, and transition elements has been collected in Table 1, together with boron compounds of the right main group elements (carbides, etc.). Only relatively well-established phases have been included. Noncorroborated and/or badly characterized borides lacking precise composition and structure data are not included. The reader is referred to other sources for references.[8–11] There are no binary borides among the Cu, Zn, Ga, and Ge group elements with the exception of a noncorroborated early report on diborides in the Ag–B and Au–B systems. Two silicon borides have been established, namely, SiB_{3-4} and SiB_6.

[a]Notations: o = orthorhombic, t = tetragonal, h,l = high, low temperature, meta = metastable, hp = high pressure. [b]and higher boranes.

In addition to the phases of Table 1, there are a large number of lanthanide and actinide borides crystallizing in the structure types of AlB_2, Sm_2B_5, ThB_4, CaB_6, ScB_{19}, UB_{12}, YB_{25}, YB_{50}, and YB_{66}. A total of more than 200 binary borides have been reported until now. More or less complete binary phase diagrams of most of the systems of Table 1 are available[11] with the exception of those of the alkali metals.

A total of more than 700 ternary borides have been prepared and characterized.[3,5,6,8] Most of these phases occur in the RE–T–B systems. A maximum of 12 ternary phases has, for instance, been found in each of the Sm–Co–B and Ce–Co–B systems[6] (see Figure 1). There are also ternary systems without any ternary phase at all, for instance, the system La–Cu–B.

It is very often difficult to establish the existence and composition of borides owing to one or more of the following reasons. The great reactivity of boron toward, for instance, the crucible material leads to the occurrence of impurities in the products. The impurities are often said to ‘stabilize’ a structure type, while in reality a ternary compound has been formed although unintentionally. It is also difficult to analyze chemically or by microprobe the boron content owing to low accuracy of the methods. Indeed, in many cases a single–crystal-structure determination is, together with complementary structural information obtained by other

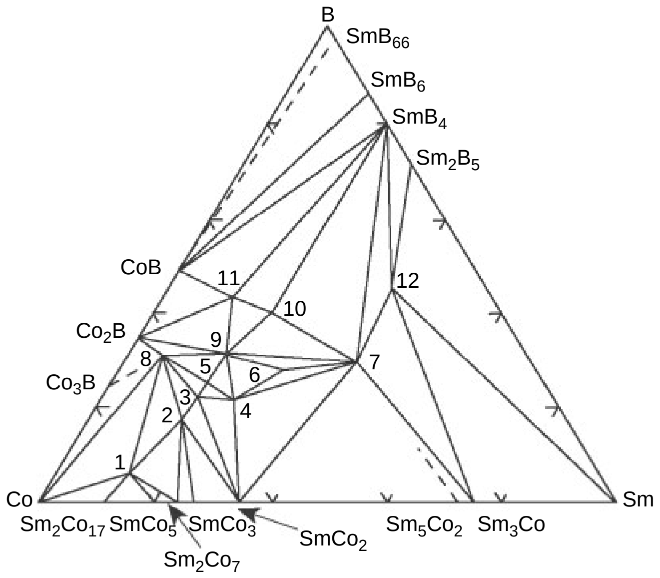

Figure 1 The ternary section Co–Sm–B. 0–33 atom% Sm at 900 K and 33–100 atom% Sm at 700 K. methods, the most profitable procedure to determine the composition of a boride. Such studies are, however, often hampered by the nonavailability of single crystals, which means that only powder diffraction methods can be used (*see* ***Solids: Characterization by Powder Diffraction***). This fact may not, however, involve too many restrictions presently, since high-intensity X-ray sources and improved computer capacity and programs are available. Problems are also connected with neutron diffraction studies (*see* ***Diffraction Methods in Inorganic Chemistry***), since B-11 enriched boron is required in the borides owing to the high neutron absorption of the B-10 isotope.

Sluggish reactions are often met with in boride systems even at high temperatures, especially at boron-rich compositions. This often hinders phase equilibria to be established and phase transformations under equilibrium conditions to be investigated.

2.2 Crystal Chemistry

Owing to the great number of structure types represented among the binary and ternary borides, it is not possible to present in this article even a simple description of all known structure types. The following presentation deals mainly with binary boride structures. Ternary boride structures show many similarities with those of binary boride phases but cannot be treated in any detail in the present paper because of space limitations. Binary and ternary boride structures are treated in more detail elsewhere.[3,6,8] It is convenient to describe here some structural principles using coordination polyhedra and cluster formation and to supplement this by selected examples.

The boron atoms of metal-rich borides are usually surrounded by metal atoms, situated at the corners of trigonal prisms (Figure 2a). Outside the rectangular faces of the prism there are three further metal atoms, of which one, two, or all three can be replaced by boron atoms (a tricapped trigonal prism or a tetrakaidecahedron). The coordination polyhedron of a boron atom occasionally consists of an octahedron or an Archimedian antiprism (Figure 2b), consisting of six and eight metal atoms, respectively. The packing of these atomic units in the structure is such that a good space filling is obtained. Furthermore, the linking of the polyhedra is such that with increasing boron content the number of boron–boron contacts increases. In this manner, boron–boron pairs, fragments of boron chains, single chains, double chains, triple chains, branched chains, and hexagonal networks are formed, as illustrated in Figure 3. This tendency toward forming B–B bonds is in contrast to the situation in carbides and nitrides, where contacts between the nonmetal atoms are formed at much higher nonmetal contents than in borides. It is natural that compounds with higher boron–metal ratios display more boron–boron contacts, for instance, monoborides (CrB, MoB, FeB) are characterized by zig–zag boron chains, while V_2B_3-type structures contain triple chains of boron atoms (see Figure 3).

There are no sharp metal–boron ratios for which the transition from isolated boron atoms to boron pairs to boron chains and so on occurs. For example, isolated boron atoms solely occur in borides, crystallizing in the relatively metal-poor $REFe_2B_2$ ($ThCr_2Si_2$)-type structure ($M/B = 1.5$), while

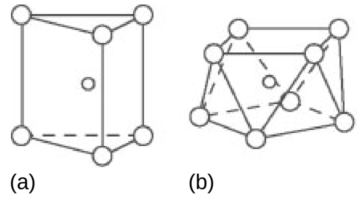

Figure 2 Trigonal prismatic and Archimedian prismatic coordination of boron (small circles)

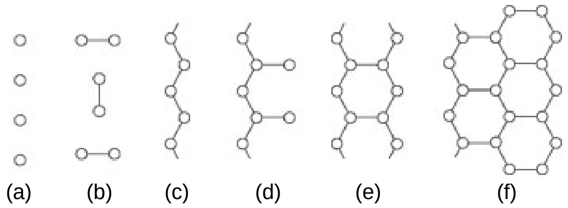

Figure 3 Boron–boron contacts in some metal-rich borides: (a) isolated boron atom ($Nb_2Fe_{14}B$); (b) boron pair (Cr_5B_3); (c) zig–zag chain (FeB); (d) branched chain ($Ru_{11}B_8$); (e) double chain (Ta_3B_4); (f) triple chain (V_2B_3)

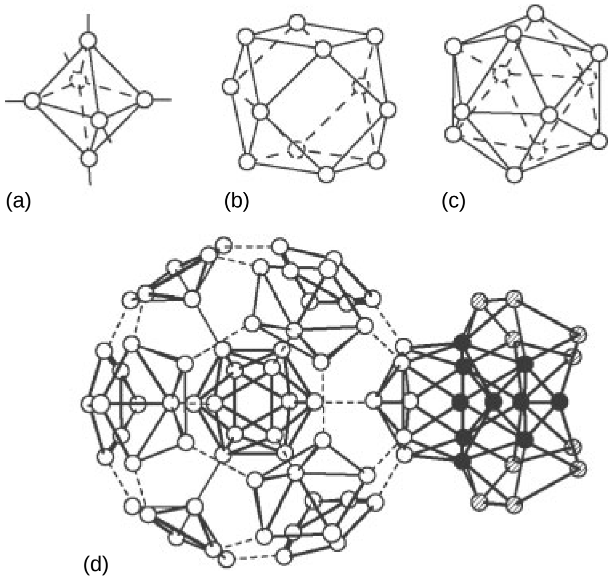

Figure 4 Boron clusters occurring in boron-rich borides and elementary boron; (a) octahedron; (b) cubooctahedron; (c) icosahedron; (d) the main part of a B_{84} unit (β-rh. boron) and an attached B_{10} unit (black circles) with two half-icosahedra (hatched circles)

boron pairs along with isolated boron atoms are found in the relatively metal-rich $Sc_4Ni_{29}B_{10}$-type structure (M/B = 3.3).

In boron-rich compounds the structure can often be described as being built up of a three-dimensional network of boron clusters, for instance, octahedra, icosahedra, and cubo-octahedra (see Figure 4), which are linked to each other directly or via noncluster atoms. The metal atoms are accommodated in cages between the octahedra or icosahedra, thereby providing external bonding electrons to the electron deficient boron network. The structures of the boron modifications are also built up of icosahedral boron units.

2.2.1 Modifications of Elementary Boron

The existence of three crystalline and one amorphous modification of boron has been established (Table 2). Reports on further modifications are unreliable and refer to uncharacterized and/or impurity stabilized material. α-tetr. boron, also denoted tetr. I boron (a = 8.75 Å, c = 5.06 Å), was earlier believed to be a boron modification, but has been shown to be a phase of composition $B_{50}(C_{1-x}N_x)_2$[3].

Table 2 Crystallographic data for the boron modifications

		Unit cell dimensions	
Modification	Space Group	a(Å)	c(Å)
α-rh. boron[21]	$R\overline{3}m$	4.927(3)	12.564(7)
β-rh. boron[22]	$R\overline{3}m$	10.930(1)	23.815(3)
β-tetr. boron[18]	$P4_1$ or $P4_3$	10.14(1)	14.17(1)

Owing to sluggish phase transformations, the temperature regions of stability for the different modifications are not known with certainty. The β-rh. modification is, however, stable from the melting point of boron, 2573 K, down to 1473 to 1673 K. The β-tetr. modification (also denoted tetr. II boron) is stable in the intermediate range down to approximately 1300 K. α-rh. boron is a low-temperature modification, stable up to approximately 1300 K.

The structures of the boron modifications all display boron icosahedra as structural subunits. In α-rh. boron, which has the simplest structure, the icosahedra form a rigid three-dimensional boron network by direct covalent boron–boron contacts and, in addition, by three-center bonds between boron atoms situated in three different icosahedra.[21] The crystal structure of β-rh. boron can be described as containing B_{84} units (Figure 4d), which consist of a central icosahedron and 12 half-icosahedra. The B_{84} units are linked together via B_{10} units (black atoms in Figure 4d) and via the formation of new icosahedra from two half-icosahedra from different B_{84} units.[22] In addition there are also nonicosahedral boron atoms in the structure. The crystal structure of β-rh boron is highly defective. Of the 20 different symmetry equivalent atomic positions required to describe the structure as many as six positions are only partially occupied. The occupancies of these positions range from 3.7(4)% to 75.5(6)%. Elementary β-rh. boron is a highly defective solid (*see* ***Defects in Solids***), containing numerous twin boundaries in addition to the vacancies mentioned. The structure of tetr. II boron is closely related to that of α-AlB_{12}.[18] It is basically a three-dimensional network structure built up of B_{12} icosahedra and B_{21} units, consisting of completely twinned icosahedra with a common triangular face. In this boron skeleton, some interstitial positions are partially or completely filled with boron atoms.

2.2.2 Solid Solutions of Transition Elements in β-rh. Boron

The boron modifications are semiconductors. β-rh. boron is a high-temperature semiconductor with a band gap of ~1.5 eV. The transition elements and some p elements (C, Si) form solid solutions in β-rh. boron.[10] In this manner, the electrical characteristics are changed (doping). The maximum solid solubility varies with solute and can be as high as 4 to 5 atomic percent. The well-known difficulties to prepare ultra-pure β-rh. boron is partially due to the solid solutions that most of the elements form with boron.

The structure of the solid solutions is very complex. Investigations have shown that partial (and only partial) occupancies of up to five interstitial atomic positions occur. These atomic positions are situated between the icosahedra of the structure. In a few cases a substitutional mechanism for the solid solubility has been demonstrated, similar to the silicon

substitution for boron in the structure of $B_{2.89}Si$, which has the ideal composition B_6Si.[23]

2.2.3 Borides with Isolated Boron Atoms

Following Rogl,[8] we distinguish three subgroups among the borides with isolated boron atoms, namely, metal framework structures, substitutional metal borides, and proper metal boride structures. The metal framework structures include elemental or binary compound types, which are stabilized by boron atoms filling the voids of the metal host lattice. Examples of such structures are the κ-borides (Hf_9Mo_4B), the τ-borides (mostly ternary $M_{21}M'_2B_6$ phases), and the Cu_3Au-type phases ($Ni_3InB_{0.15}$), with prismatic, antiprismatic, and octahedral coordination of the metal atoms around the boron atoms, respectively.

In substituted metal borides, the boron atoms replace partially or completely, in an ordered or disordered manner, metal atoms in the structure. Structure types belonging to this subgroup are, for instance, two structural series based on the substitution of boron for small metal atoms in the intermetallic structure types $CaCu_5$ and $MgZn_2$, respectively. The structural relationship is nicely demonstrated in the series $CaCu_5 \rightarrow CeCo_3B_2 \rightarrow ErIr_3B_2 \rightarrow ErRh_3B_2$. Another very important structure type belonging to this subgroup is that of $Nd_2Fe_{14}B$, a compound which displays excellent permanent magnetic properties. In the structure of the $Nd_2Fe_{14}B$, the boron atom has a trigonal prismatic environment of metal atoms. In addition, there is a close correspondence between the metal arrangement of $Nd_2Fe_{14}B$ and the intermetallic σ-phase. Thus this structure is also closely related to the metal framework structures already discussed. The substitutional metal borides include approximately 30 structure types.

The proper metal boride structures with isolated boron atoms include approximately 20 structure types with many ternary representatives. The boron coordination is trigonal prismatic (in the Fe_3C, Ti_3P, Re_3B Th_7Fe_3 structure types), octahedral (in Rh_5B_4), or Archimedian prismatic (in the $CuAl_2$-type structure with many M_2B representatives).

2.2.4 Borides with Chains and Fragments of Chains

In o-Mn_2B (earlier denoted Mn_4B) and t-Mn_2B ($CuAl_2$ type), a tendency toward chain formation is observed, although the B–B distance in the structures is relatively large, namely, 2.1 Å, as compared 1.8 Å (±0.1 Å) in normal chains. In these structures, the metal surrounding of the boron atom consists of an Archimedian or a distorted Archimedian antiprism. A closer contact between the boron atoms of about 1.8 Å is, however, brought about when trigonal prismatic coordination polyhedra of the boron atoms share rectangular faces. Chain fragments consisting of boron pairs occur in Cr_5B_3 and in V_3B_2 (U_3Si_2-type structure). Chain fragments consisting of three or four boron atoms occur in the structure types of W_3CoB_2 and Mo_2IrB_2, respectively. Distorted prisms are common among ternary compounds containing large and small metal atoms. Chain fragments can also occur as a consequence of boron defects.

Infinite boron zig–zag chains with B–B distances 1.65 to 1.90 Å and bond angles of ~115° are found in the structure types of FeB, CrB, and MoB. The boron coordination is trigonally prismatic with two boron atoms and one metal atom situated outside the rectangular faces. There are a large number of binary and ternary representatives of these and other related structure types. Double and triple chains characterize the structure types Ta_3B_4 and V_2B_3, respectively. Single and double chains occur in the structure type of V_5B_6. In the ternary structures of Cr_2AlB_2 and Cr_3AlB_4, single and double boron chains, respectively, occur together with CsCl-type units. Branched boron chains are found in the $Ru_{11}B_8$ structure and also in the UBC structure with carbon atoms branching off the zig–zag boron chain. Chains or fragments of chains also occur in borocarbides of many structure types, for instance, Sc_2BC_2.[19]

Studies of borides with the composition RT_4B_4 are very rewarding to clarify the interplay between superconductivity and magnetism. A large number of RT_4B_4 compounds have been reported with T = Fe, Co, Ru, Rh, Os, and Ir and with RE comprising nearly all rare-earth metals. The compounds crystallize in at least six structure types, namely, $CeCo_4B_4$, $LuRh_4B_4$, $LuRu_4B_4$, $NdCo_4B_4$, YOs_4B_4, and $Ce_{1+x}Fe_4O_4$ of tetragonal or orthorhombic symmetry. Another group of boron-containing materials of interest for superconductivity and magnetic studies are quaternary borocarbides of composition RE–T–B–C, for instance, $LuNi_2B_2C$, LuNiBC, and Lu_2NiBC_2. A review was published in 2000.[20]

2.2.5 Borides with Two-dimensional Boron Networks

Many borides in the composition range B/Me 1.5 to 2.5 crystallize with various stacking sequences of metal layers and boron layers.[8] Ordered or disordered defects often occur in the layers. Most of the structures belonging to the AlB_2 structure family[24] can be described by the stacking sequence of planar or puckered boron and metal layers as shown in Figure 5. The common, simple hexagonal AlB_2 structure is, for instance, described by the sequence AHAH... and the structure of W_2B_{5-x} by AHAK'BHBH'..., where the K′ boron layers are slightly puckered. Orthorhombic stacking variants, for instance, RuB_2 and $IrB_{1.35}$, also belong to this structure family. $Mo_{1-x}B_3$ (x small) is a relatively boron-rich compound built up of defective metal layers (every third atom is lacking) and H type layers occurring in AlB_2. It is noticeable that MgB_2, belonging to the simple AlB_2-type structure, is a superconductor with T_c as high as 39 K.[25] The superconducting properties of MgB_2 were not discovered until 2001 although the compound was synthesized already in the 1950s.

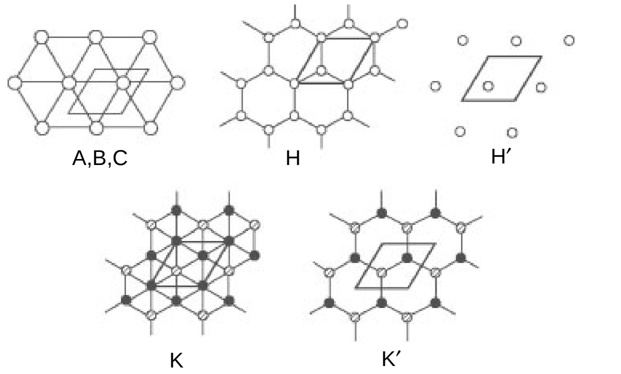

Figure 5 Layers of metal atoms (A, B, C), planar boron layers (H, H′), and puckered boron layers (K, K′), occurring in the AlB_2 and related type structures

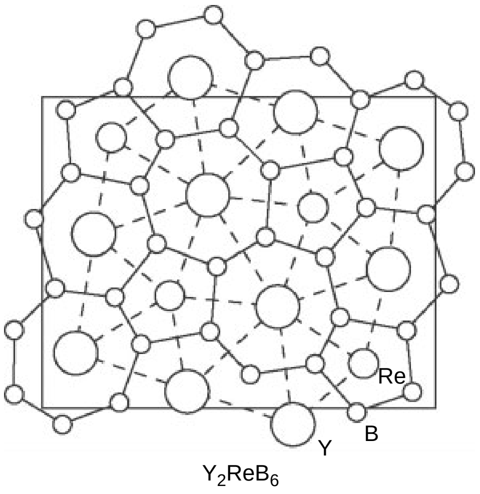

Figure 6 Projection of Y_2ReB_6 along the short axis. The metal atoms are connected with fully drawn lines while the boron atoms are connected with dashed lines within their planes, respectively

There are a large number of ternary compounds crystallizing in $YCrB_4$ and Y_2ReB_6 type structures. These structures are also described as a simple stacking of metal layers and boron layers. The axis perpendicular to the layers is short (3.2–3.6 Å) and comparable to the c axis of the AlB_2-type structure. The boron layers, however, contain 5-atom and 7-atom rings and no 6-atom rings as in the AlB_2-type structure, see Figure 6. In borocarbides of the ScB_2C_2-type, there is boron carbon ordering within the layers. Also planar nets of 8-atom rings linked by a boron pair exist in $ErNiB_4$. Puckered nonmetal layers in ternary structures were reported, for instance, in Er_4NiB_{13} (7- and 4-atom rings).

2.2.6 Borides with Three-dimensional Boron Networks

A presentation of binary and ternary boride structure types, which are built up of a rigid three-dimensional boron network, is given in Table 3. Many ternary boride phases also crystallize in the structure types collected in Table 3. It is noticeable that the B/M ratio ranges as much as from 2.5 to 66.

The structures of Sm_2B_5, Pr_2B_5, and ThB_4 are built up of boron octahedra. In ThB_4, the octahedra are interconnected

Table 3 Structure types of some binary boron-rich compounds

Phase	Symmetry	a(Å)	b(Å)	c(Å)	β(°)	Structural characteristics
Sm_2B_5	Monoclinic	7.183	7.191	7.216	102.03	Octahedra, B pairs[9]
BeB_3	hexagonal	9.800		9.532		Icosahedra, B_{15}[26]
MgB_4	Orthorhombic	5.464	7.472	4.428		Half-icosahedra, chains[9]
CrB_4	Orthorhombic	4.744	5.477	2.866		B-squares in three dimensions[9]
MnB_4	Monoclinic	5.503	5.367	2.949	122.71	B-squares in three dimensions[9]
ThB_4	Tetragonal	7.526		4.113		Octahedra, B pairs[9]

α-AlB_{12}	Tetragonal	10.158		14.270		Icosahedra, B_{19} units[29]
γ-AlB_{12}	Orthorhombic	16.573	17.510	10.144		Icosahedra, B_{19} units[29]
UB_{12}	Cubic	7.473				Cubo-octahedra[9]
Na_2B_{29}[b]	Monoclinic	5.874	10.403	8.359	90.17	Icosahedra, interstitial B[30]
ScB_{19}	Tetragonal	10.292	14.2463			Icosahedra, related to α-AlB_{12}[31]
YB_{25}	Monoclinic	8.2842	10.3203	5.8570	90.402	Icosahedra, related to $YAlB_{12}$[32]
YB_{50}	Orthorhombic	16.625	17.620	9.4797		Closely related[33] to $YB_{41}Si_{1.2}$[34]
YB_{66}	Cubic	23.446				Icosahedra, Y tunnels[9]

[a]Isostructural to $MgAlB_{14}$. [b]Earlier denoted NaB_{15}.

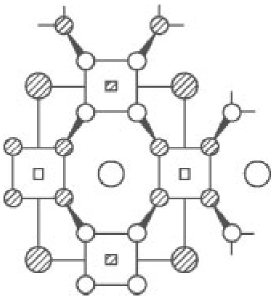

Figure 7 The crystal structure of CrB_4 as seen along the short c axis. Boron atoms (small circles), chromium atoms (large circles) are at $z = 0$ (hatched) or at $z = 1/2$ (open). Squares denote cages

by direct bonds in the c direction and via boron pairs in the ab plane. In Sm_2B_5, the octahedra are interconnected via boron pairs in the c direction as well. In the unique structure of CrB_4 (Figure 7), squares of B_4 units are linked to other squares in the third direction so that all boron atoms are four-coordinated by other boron atoms. MnB_4 is a monoclinic distortion of CrB_4.

The structures of B_4C, B_6P, and B_6O are closely related to that of α-rh. boron. The structure of boron carbide is shown in Figure 8, projected in the c direction. In the Figure are seen icosahedra centered at (0,0,0). In the three-dimensional structure, icosahedra are also centered at (1/3, 2/3, 1/3) and (2/3, 1/3, 2/3). An elongated cage, denoted x in Figure 8, is formed in this manner. In α-rh. boron, the atoms B(1), B(2), and B(3) are linked by a three-center bond. In the carbide, phosphide, and oxide, the end atoms of a three- or two-atom chain are linked to these three boron atoms. In the carbide, the chain can consist of a C–B–C or C–B–B sequence depending on composition, while in the phosphide a phosphorus pair (the P atoms are at bonding distance) bonds to two different B(1)-B(2)-B(3) triangles. A study of boron-carbide-like structures has shown that B_6As, $B_{12}S$, and the new $B_{12}Se$ phase display chains of two atoms as B_6P.[23] In the oxide, however, two isolated oxygen atoms are situated more than 3 Å from each other. Each oxygen atom bonds to a triangle of boron atoms, of which each boron belongs to three different boron icosahedra.

Borides, crystallizing in the CaB_6-type structure, are formed by potassium, alkaline earths, and the larger rare-earth elements. The octahedra form a rigid boron network by direct B–B bonds and the metal atoms are accommodated in cages, surrounded by 24 boron atoms (Figure 9). The UB_{12}-type borides can be described on the basis of B_{12}-cubooctahedra, which form a three-dimensional boron skeleton containing B_{24}-cubooctahedral cages. These cages accommodate metal atoms, including Zr, Hf, most of the rare earths, and some actinides.

The remaining icosahedral structures are very complex and contain, in addition to icosahedra, icosihexaedral B_{15} units (SiB_6 and BeB_3) and condensed icosahedra as B_{19} units (α-AlB_{12}), sharing one trigonal face. In SiB_6, some boron atoms in the B_{15} unit are replaced by silicon,[27] while in BeB_3 there are three beryllium atoms and 12 boron atoms in the B_{15} unit.[26] Several new boron-rich phases of the rare-earth elements have been reported recently, of which the binary phases ScB_{19},[31] YB_{25},[32] and YB_{50}[33] are included in Table 3. These structure types also occur as ternary compounds with C, N, or Si as the third component. A total of more than 60 binary or ternary representatives, crystallizing in the structure types mentioned, are known to exist presently. The structure of ScB_{19} is closely related to that of α-AlB_{12}.[31] Furthermore, the structure of $YB_{41}Si_{1.2}$[34] is closely related to that of YB_{50} as apparent from the similarity of the unit cell dimensions.

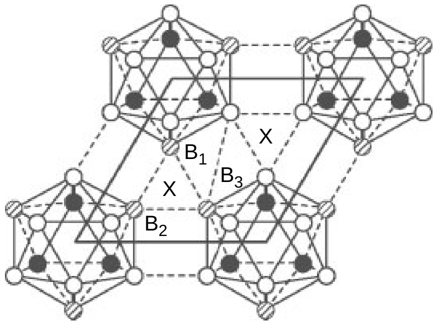

Figure 8 Projection of the B_4C-type structure along the trigonal axis. The end-on view of the three-atom chain (C–B–C or C–B–B) is denoted X. For α-rh. boron, X denotes the three-center bond

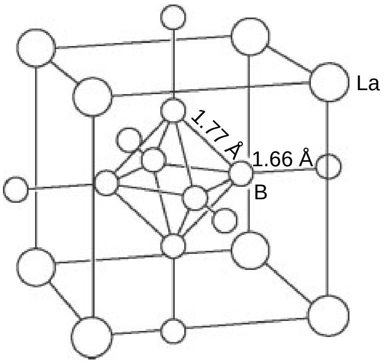

Figure 9 The crystal structure of LaB_6. The boron atoms (small circles) form a three-dimensional rigid network with ≈0.1 Å shorter bonds between the octahedra than within the octahedra

3 SYNTHESIS

The synthesis of borides often requires high temperatures, involving difficulties in obtaining pure products while simultaneously using simple methods. Direct synthesis from the elements is of particular interest in fundamental research since high-purity products can be obtained. Other processes are

suitable for industrial production. The methods for preparation of borides may be classified as follows.

3.1 Direct Combination of the Elements

Direct reaction of the elements is carried out under vacuum or inert gas by melting or by reaction sintering at a temperature below the melting point. The melting procedure is often associated with the crucible problem, which is pronounced at high temperature.[24] The metal–boron melt invariably attacks oxide ceramics, in particular, boron-rich compositions, and to avoid impurities or stabilization effects from such attacks, levitation melting or cold crucible techniques (for instance, arc melting) are preferable, in particular for the highest temperatures. Boron nitride is an excellent crucible material for boron-rich compositions at not too high temperatures. Synthesis can be difficult owing to high volatility of the metals and/or their reactivity toward oxygen (alkali, alkali-earth, and rare-earth metals), which requires a sealed crucible technique and high vacuum or inert gas atmosphere.

3.2 Reduction of a Metal Oxide and Boron Halide with Hydrogen

A mixture of, for instance, metal and boron halides is reduced at temperatures of 1300 to 1600 K. Borides of Ti, Zr, and Hf have been prepared according to:

$$MCl_4(g) + 2BCl_3(g) + 5H_2(g) \longrightarrow MB_2(s) + 10HCl(g) \quad (1)$$

Adherent coatings of diborides can also be obtained by thermal decomposition of boron halides.

3.3 Reduction of a Metal Oxide or Other Metal Compound Using B, C or Boron Carbide

The borothermic process for diborides proceeds in vacuo at high temperature (>1300 K) according to the equation:

$$M_nO_m(s) + (2n + m) \cdot B(s) \longrightarrow n \cdot MB_2(s) + 1/2m \cdot B_2O_2(g) \quad (2)$$

It can be used for hexaborides as well. Reduction with boron carbide can also be used for diborides as well as hexaborides, although in that case alkaline-earth and rare-earth hexaborides will dissolve some carbon forming $RB_{6-x}C_x$ borocarbides.

3.4 Reduction of Boron Oxide or Boron Halides by Metals

Electropositive metals, for example, Al, Mg, or an alkali metal, are used as reduction agents. The following reaction illustrates the process:

$$CaO + 3B_2O_3 + 10Mg \longrightarrow CaB_6 + 10MgO \quad (3)$$

The process is used in industrial production.

3.5 Fused-salt Electrolysis

Electrolysis is carried out at 1000 to 1300 K of a mixture of alkali halide, metal oxide, and a borate. This is a process of industrial interest. However, high-purity and single-phase products are not easily obtained.

3.6 Preparation of Coatings by Chemical Vapor Deposition (CVD)

In Chemical Vapor Deposition (CVD), the gaseous reactants are carried over a heated substrate, where the chemical reactions or thermal decomposition occur.[35] If the process parameters are correctly selected an adherent solid coating is obtained with attractive mechanical or electrical properties. Overall reactions can be of the type already mentioned in Section 3.2.

3.7 Crystal Growth

Crystal growth of boride phases can be carried out by most of the methods known. However, the high melting points and the great reactivity of, in particular, boron-rich compounds limits the techniques applicable and calls for special equipment. The low-temperature, gas-phase methods (1300–1600 K), including CVD and chemical vapor transport, have been used for crystal growth of diborides, especially TiB_2, ZrB_2, and TaB_2 with melting points around 3300 K. Liquid phase methods (crystal pulling, floating zone melting, and flame fusion) are used to produce diboride, hexaboride, and REB_{66} single crystals.[35,36]

An attractive method to produce single crystals (in the dimension range from μm to several mm) is the high-temperature solution (flux) method, because of its simplicity and the low temperature required.[37] The elements are dissolved in the solvent metal (often Al) and subsequently the solution is slowly cooled to room temperature. A prerequisite is, of course, that the solubility of the used solvent in the desired boride is insignificant. The solubility of Al in most boron-rich binary borides has been found to be extremely small. Crystals prepared in this manner are suitable for measurement of physical properties, for instance, microhardness, electrical resistivity, and so on.

3.8 Other Methods

Precipitation from aqueous solution has been reported in a few cases. Amorphous Ni_2B was, for instance, obtained from nickel acetate and a solution of tetrahydroborate at room temperature.

Many borides can be synthesized by novel synthetic methods, including shock-induced chemical reactions, mechanical alloying by ball milling, and self-propagating high-temperature synthesis. In these methods, intimately mixed elemental powders are brought to react by a rapid pressure increase, mechanical deformation including local

temperature increase and triggered self-sustaining reaction (exothermic), respectively.

4 BAND STRUCTURE AND BONDING

The nature of the chemical bonding in borides was in early work described by simplified models emphasizing the role of M–M, M–B, and B–B bonding. The question of magnitude and direction of charge transfer has been much debated. There is complete agreement that the bonding in borides involves simultaneous contributions of metallic, covalent, and ionic bonding to the cohesive energy. The proportions, however, depend on the nature of the metallic component and the boron/metal ratio. In recent years, the growth of more powerful experimental methods and greatly improved calculation facilities have contributed immensely to our knowledge of band structure and bonding in borides.

Several band structure calculations (*see* ***Electronic Structure of Solids***) for diborides have been carried out.[38,39] The density of state versus energy for ZrB_2 from a self-consistent calculation is shown in Figure 10. The Figure demonstrates a Fermi level (E_F) at the minimum of the DOS curve between bonding states (left) and antibonding states (right). It is difficult to draw conclusions from the corresponding band structure (not reproduced here), although the authors suggest covalent bonds within the boron layers and some covalency (perhaps also metallic bonding) along the Zr–B directions. At the Fermi level the states are nearly completely of Zr-4*d* character. These calculations are in qualitative, and in some cases in very good quantitative, agreement with experimental data for ZrB_2 from X-ray photoemission spectroscopy, measurements of optical properties, Hall effect, dc resistivity, and specific heat. Experimental and theoretical studies indicate a relatively small transfer of electrons from metal to boron.[40] Band structure calculations of the new medium-T_c superconductor MgB_2 (T_c 39 K) and related diborides have been published.[41] It was early suggested to use a 'rigid band' model for the electronic structure of the diborides and only one DOS curve, which was then filled up with the number of electrons available in the boride. This method has often proved to be a very crude approximation.

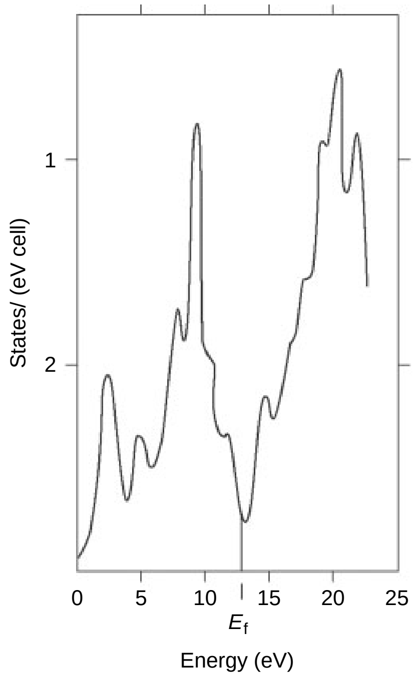

Figure 10 Calculated density of states for ZrB_2 (zero energy at the bottom of the conduction band)[38]

In early studies of hexaborides, the conclusion was reached that there is a finite energy gap between the conduction and valence bands and that the valence band contains 20 electrons. The six boron atoms provide 18 electrons and, if the metal is divalent (Ca, Br, Ba), the hexaboride is anticipated to be insulating (semiconducting), while a higher valence, occurring among the rare-earth elements, is anticipated to lead to metallic conductivity. This is in agreement with experiments. The simple picture involves a charge transfer to the boron network and thus a significant ionicity in the bond. A self-consistent symmetrized APW calculation of the energy band structure of LaB_6[42] has revealed many more details. The calculated density of states for the valence bands agrees well with X-ray photoelectron measurements. The La–B bonding originates in the strong hybridization of La-d states and d-like B-sp states of the six octahedral boron atoms.

A simple treatment of the stability requirements of a boron icosahedron in a solid was presented early.[1] An icosahedral boron cluster was shown to require two external electrons. The icosahedron is linked to its neighbors via normal covalent bonds. This description leads to a simple understanding of the stability of the B_6O and B_6P structures.

The electronic structure of quaternary borides of the type RETBC was presented and discussed recently in a review-type paper.[43] Theoretical calculations, predictions, and syntheses of were also presented for BN analogues of fullerenes (fulborenes) and BN nanotubes.[44]

5 PROPERTIES AND APPLICATIONS

Characteristic properties of borides are high chemical inertness, high thermal stability, and great hardness. Magnetic and electrical properties vary strongly within the boride group of compounds. This is apparent from the compilation of Samsonov and Vinitskii,[45] which contains a large number of values for chemical reactivity of borides (toward acids and bases), thermodynamic and thermal properties, as well as electrical, magnetic, and optical properties. In addition

the handbook contains values of mechanical and refractory properties. More recent fundamental data can be found in the proceedings from the boron symposia,[12–16] and specialized textbooks.[46] Values for some physical properties of a few borides are collected in Table 4.

Table 4 displays a broad range of resistivities beginning with the insulator h-BN, continuing with the semiconductors CaB_6, B_4C, and YB_{66}, and ending with the metallic phases Fe_2B, TiB_2, and LaB_6. The resistivity of TiB_2 is remarkably low, being only one-fifth of that for metallic titanium. The band gap of the three semiconductors mentioned are 0.20, 1.6, and 1.36 eV, respectively (*see* ***Semiconductors***).

Superconductors of the RET_4B_4 system are interesting for the study of the interplay between superconducting and magnetic order (*see* ***Superconductivity***). The RET_4B_4 compounds represent a great variety of correlated electron phenomena, consisting of ferromagnetism, antiferromagnetism, superconductivity, valence fluctuation, or Kondo lattice anomalies, and effects which arise from their interplay in the structure.[47] Another very interesting group of superconducting, boron-containing materials are borocarbides of the composition RET_2B_2C (T = Ni, Pd, Pt). The compounds of this group show a relatively high T_c if the rare-earth ions are large, that is, (La, Pr).[43] It was discovered recently (2001), that MgB_2 (known since the 1950s) is a superconductor at as high a temperature as 39 K. This surprising discovery initiated a large number of investigations of *iso*-structural binary and ternary compounds to reveal its basic properties and to search for other related compounds with even higher T_c:s.[48]

The excellent permanent magnetic properties of materials based on $Nd_2Fe_{14}B$ were discovered in 1983.[49] Very soon afterwards strong, small permanent magnets were available commercially with a Curie temperature of 850 K and a very high energy product $(BH)_{max}$. This quantity for $Nd_2Fe_{14}B$ is ~64 MGOe, which is more than twice than that of the very strong $SmCo_5$ magnets.

Most borides are chemically inert in bulk form, which has led to industrial applications as engineering materials, principally at high temperature. The transition metal borides display a considerable resistance to oxidation in air. A few examples of applications are given here. Titanium and zirconium diborides, alone or in admixture with chromium diboride, can endure temperatures of 1500 to 1700 K without extensive attack. In this case, a surface layer of the parent oxides is formed at a relatively low temperature, which prevents further oxidation up to temperatures where the volatility of boron oxide becomes appreciable. In other cases the oxidation is retarded by the formation of some other type of protective layer, for instance, a chromium borate. This behavior is favorable and in contrast to that of the refractory carbides and nitrides, which form gaseous products (carbon oxides and nitrogen) in air at high temperatures. Boron carbide is less resistant to oxidation than the metallic borides.

Borides, especially those of group IV transition metals, exhibit a high resistance to attack by molten metals and nonbasic slags and salts. These properties make them attractive as materials for vaporization boats (TiB_2, hex. BN), for crucibles and containers for liquid metals, for example, Al, and for protective tubes of thermocouples.[50] Composites of TiB_2 and BN are frequently also used as boats for vacuum metallizing of capacitor foils and car mirrors. Titanium diboride is also utilized for collector bars in the aluminum reduction process owing to its low resistivity and great inertness toward liquid aluminum.[50] A major part of the boride production is used for chemical and metallurgical applications. Calcium hexaboride is, for instance, used as a deoxidation agent in copper production, which results in higher conductivity than conventionally phosphorus-deoxidized copper owing to the low solubility of

Table 4 Typical properties of some borides

Phase	Melting temperature (K)	Microhardness (GPa)	ΔH_f (kJ·mole^{-1})	Resistivity (ohm·m·10^8)	T_c (K)
MgB_2	1100[a]	11	−92	16	39
TiB_2	3500	33	−280	7–15

[a]Decomposes.

boron in copper. Large amounts of Al–Ti–B alloys, containing TiB_2, are used as grain refiners in the aluminum industry.

The most attractive properties of boron-containing materials, in particular diborides and boron carbide, are the high melting point, the high hardness (see Table 4), the excellent wear resistance, and the favorable chemical inertness. However, they are brittle, so special precautions must be taken in their exploitation. They can be used as coatings, either as thick films obtained by packboronizing of structural parts in B_4C powder at high temperature, or as thin films obtained by chemical vapor deposition or physical vapor deposition (*see Chemical Vapor Deposition*) techniques. Hexaboride coatings are even attractive to be used as decorative coatings on consumer products.[51] In these cases advantage is derived from the combination of a ductile core and a wear-resistant adhesive coating. Another solution to the brittleness problem is to produce a composite with a ductile binder, that is, a boride cermet or a 'cemented boride', in analogy to the cemented carbides. This has led to the presently active research interest in cemented borides utilizing TiB_2 as hard substance and iron, iron-based or nickel-based binders. The results indicate that dense sintered parts with good chemical stability and attractive mechanical properties can be obtained.[52] Promising results have also been obtained from studies of the cermet Mo_2FeB_2 with an iron-based binder phase.[53]

The utilization of the outstanding mechanical and wear properties of cubic BN and related superhard materials has been demonstrated, although further process improvements are necessary before a more general use can be expected. Superhard cubic BN exhibits superb inertness to hot steel surfaces under conditions in which diamond would be severely attacked. Other tetrahedral structures, for instance, BCN and B_2O, are anticipated to display similar attractive properties. The high-pressure phase B_2O is a semiconductor with a band gap of $\sim$0.25 eV and a hardness between that of boron carbide and diamond.

Boron carbide is a relatively inexpensive hard material, which is used for its mechanical properties of strength and extreme hardness in armor-plates for body protection, in sandblast nozzles, and as an abrasive for grinding and cutoff wheels.[54] In nuclear plants, boron carbide is used as the neutron absorbing material of the control rods.

Intense research has in recent years been devoted to noncrystalline materials. It was discovered also that the majority of semiconducting boron-rich borides display several properties that resemble those of the noncrystalline solids.[55] Among the 'amorphous' properties are the temperature and field dependencies of electrical conductivity at low temperature, the temperature dependence of thermal conductivity at high temperatures, and the temperature dependence of the magnetic susceptibility. In addition, the boron-rich semiconductors display 'crystalline' properties, for example, the temperature dependence of the thermal conductivity at low temperatures, the lattice absorption spectra and the possibility to change the properties by doping. The boron-rich borides, which display charge carriers with extremely low mobility, are thus intermediate between crystalline and noncrystalline solids as regards certain properties, which probably can be ascribed to their complex and defect-rich structures. Optical studies of boron and boron-rich borides have led to invaluable information on the electronic and vibrational structure of the compounds.[56]

Recently, semiconducting refractory boron compounds have been suggested for high-temperature thermoelectric energy conversion.[57] For such an application, the corresponding figure of merit requires high values of the Seebeck coefficient and the electric conductivity, and a low value of the heat conductivity of the material even at high temperatures. The thermoelectric properties, high melting points, and chemical inertness of boron carbide and related boron compounds make them of special interest in such a context. Another recent application, where the electrical properties are decisive, is the use of LaB_6 and CeB_6 as thermionic emitter materials in applications where very high brightness is required.[58] The materials mentioned are used in electron microscopes and electron beam lithography systems. The borides are preferred to the conventional tungsten emitters owing to their higher brightness and longer service life, although they are more expensive.

The structurally complex semiconducting boride, YB_{66}, with a cubic unit cell axis of 23.44 Å, has been found to be an excellent monochromating material for synchrotron radiation.[36] In this application the attractive properties are high vacuum and thermal stability, good mechanical strength, and radiation-damage resistance and low thermal expansion coefficient. It is also essential that large, high-quality single crystals can be grown, which has been demonstrated successfully.

1 INTRODUCTION

Boranes are mixed hydrides of boron and hydrogen.[1] The unusual properties of these compounds arise from the fact that in forming compounds, boron can furnish four orbitals (s, p_x, p_y, p_z) but only three electrons for bonding. Since the number of orbitals exceeds the number of electrons, the boranes are sometimes referred to as 'electron-deficient' compounds. The consequence of this imbalance can be seen in comparing the two simple hydrides of carbon and boron, that is, ethane (C_2H_6) and diborane (B_2H_6), using valence bond formalism. Their Lewis diagrams are shown in Figure 1. The structure of ethane can be understood in terms of seven two-electron-two-center bonds (*2e–2c*) formed between adjacent atoms. However, such a description is not possible for diborane, since there are not enough electrons. The bonding description that is depicted in Figure 1 shows the molecule as consisting of two BH_2 units, in which the two hydrogens (the terminal hydrogens) are attached by *2e–2c* bonds, with the BH_2 units joined by two B–H–B *3c–2e* bridged bonds. Although the bonding can better be understood using molecular orbital theory, the above description does introduce some common descriptive terms, that is, multicentered bonds and bridged and terminal hydrogens. Figure 2 shows the structures of diborane and some higher boranes.

The structures are drawn as polyhedra composed of fused triangular faces (deltahedra), in which boron atoms, bonded to at least one terminal hydrogen, occupy the vertices; bridge hydrogens are shown for the *nido*-complexes.[1] For example, B_5H_9 (pentaborane(9)) has five boron atoms at the vertices of a square pyramidal cage, each one of which is bonded to an *exo*-polyhedral hydrogen (a terminal hydrogen). In addition, there are four hydrogens bridging adjacent borons

on the rectangular open face. Note that the lines drawn in the structures show connectivity and do not necessarily indicate *2c–2e* bonds.

A useful molecular orbital description can be developed by considering each boron atom to be *sp* hybridized with one *sp* hybrid pointed toward the center of the cage (radially oriented) and the other pointed directly toward its terminal hydrogen, with the two p orbitals oriented tangentially to the cage.[2,3] The outwardly oriented orbital could overlap with a hydrogen s orbital to form a *2c–2e* bond, using one electron from the boron and one from the hydrogen. The radially directed and the two tangentially directed orbitals on each boron can be combined to give the cage molecular orbitals. These molecular orbitals (MO) will be filled by the two electrons left on each boron, those from charges, plus one additional electron from each bridging hydrogen. For example $[B_6H_6]^{2-}$, which has a closed (*closo*-) octahedral structure, will have 18 boron based orbitals (AO) for cage bonding and 14 ($2 \times 6 + 2$) cage electrons. The 18 AOs will yield 18 MOs, 7 of which are bonding and 11 antibonding. The 14-cage electrons are enough to fill the bonding MOs for a stable structure. In general, a closed polyhedral cage, composed of fused deltahedra, with n vertices will have $3n$ AOs for cage bonding that give rise to $n + 1$ bonding MOs and $2n - 1$ antibonding MOs.[2–4] Therefore, such structures should be stabilized by $2n + 2$ cage electrons. Inspection of Figure 2 shows this to be the case. Analysis also shows that the addition of two electrons to *closo*-$[B_6H_6]^{2-}$ causes the cage to open, giving the pentagonal pyramidal *nido*-$[B_6H_6]^{4-}$ cage (which can pick up four bridge hydrogens). Considering only the fate of the cages, the $[B_6H_6]^{4-}$ has 16 cage electrons that fill 8 ($n + 2$) bonding MOs. Note that one could obtain this pentagonal pyramidal cage by removing a single vertex from a seven vertex *closo*-cage (the *closo*-$[B_7H_7]^{2-}$ shown in Figure 2). This brings up a very important relationship: removal of one or more vertices from a *closo*-cage does not change the number of bonding MOs.[4] This forms the basis of the polyhedral electron-counting rules (Wades rules). Table 1 summarizes these rules and Figure 3 shows the progression of several important structural types from *closo* (closed) to *nido* (nest-like) to *arachno* (spiderweb-type).[5] Further removal would lead to more open structures (*hypo, fisco, reticulo*).

Other hybridization schemes could be used; as long as they result in one radially directed and two tangential orbitals

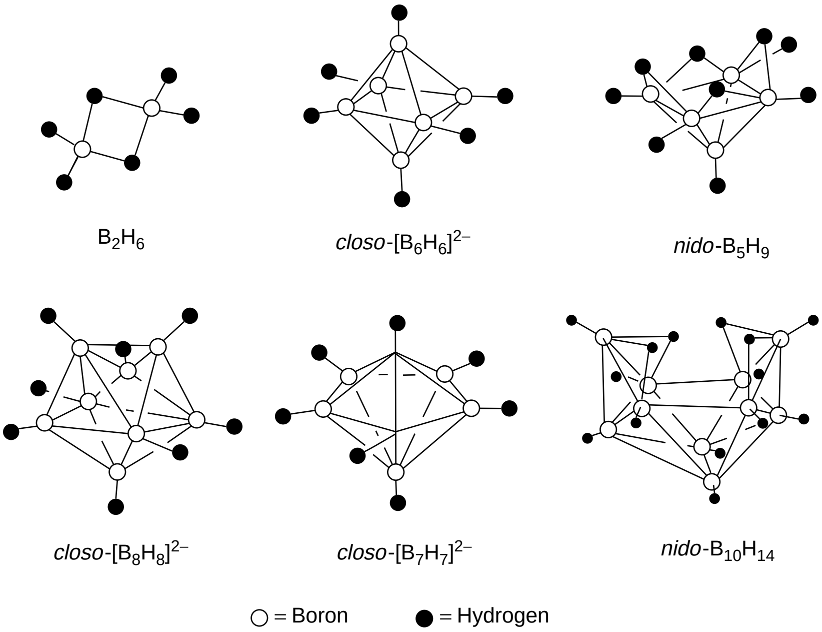

Figure 2 Borane structures

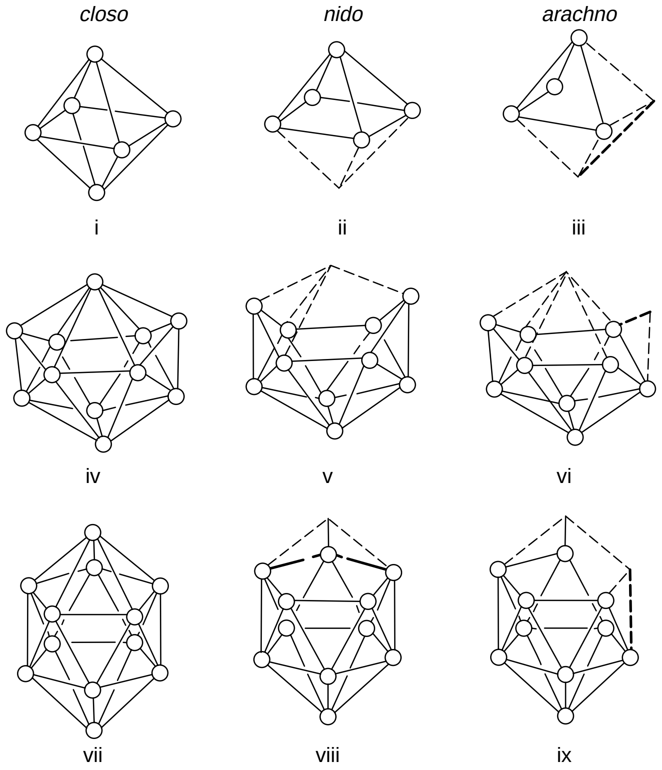

Figure 3 Cage structures

for cage bonding, they would give the same result. The utility of these rules can be extended by noting that the terminal hydrogens could be replaced by any atom or group that forms a single bond (halogen, CH_3, NH_2, etc.) without changing any structural particulars. Also, the replacement of a BH vertex by any group that can furnish a radially directed and two tangentially directed orbitals for cage bonding (i.e. is isolobal with BH), and contribute two electrons, should not substantially change cage geometry. The same would be true when a BH^- is replaced by a three-orbital, three electron group. This leads to a series of mixed atom cages, called *heteroboranes*.[2] When the hetero-atom is a metal, the term metallaborane is used. One of the most important such heteroboranes are those in which two CH groups replace BH^- vertices in a *closo*-$[B_nH_n]^{2-}$ cage to give a neutral *closo*-$[C_2B_{n-2}H_n]$ cage. Since the neutral dicarbaboranes (carboranes) are more stable and easier to work with than are their borane analogues, more studies have been conducted on carboranes than on the parent boranes.[6,7] In general, all the main group elements, with the appropriate substituents, can be thought of as being isolobal with boron. Therefore, the electron-counting rules can be applied to other main group elements by using a formalism in which the particular cage element, X, brings to cage bonding its valence electrons (v), plus those from other ligands attached to it (x), less the two associated with *exo*-polyhedral interactions or $(v + x - 2)$ electrons, as listed in Table 2. A number of heteroboranes, and carboranes incorporating other main group elements have been characterized.[7] Electron-counting rules can be extended to transition metal substitution by assuming that the metal group will have 12 of its $v + x$ electrons not involved in cage bonding; Table 3 gives the electron contributions for the groups 6 through 10 metals.[8,9] Using these numbers and the rules from Table 1, the

structures of a number of different heteroboranes can be rationalized. Examples of some heteroboranes are given in Figure 4.

2 NOMENCLATURE

The IUPAC nomenclature of the heteroboranes takes the name of the unsubstituted borane as the parent, with the number of hydrogens given in parentheses, that is, B_5H_9 is pentaborane(9).[10] The cage geometry is specified using the prefixes *closo* for a closed polyhedron, *nido* when one vertex is missing, *arachno*- when two vertices are removed, and so on, and the prefix *conjuncto*- when two cages are joined by one or more B–B bonds. The cage numbering begins with the apex atom of the polyhedron as '1' and the successive belts of atoms are numbered in a clockwise fashion.[10,11] When possible, preference is given to the nonboron atoms by assigning them the lowest numbers. When there is no unique apical atom, the atom with the lowest coordination number is assigned the position '1'. This numbering system, along with the standard replacement nomenclature rules taken from organic chemistry, are used in naming the heteroboranes. This can lead to names that are as impressive as the formulas. For example, in Figure 4, *closo*-2,3-(CH_3)-1,2,3-$SnC_2B_9H_9$ is 2,3-dimethyl-1-stanna-2,3-dicarba-*closo*-dodecaborane(12), *closo*-1-(CH_3)-1,2,3-$GaC_2B_4H_6$ is 1-methyl-1-galla-2,3-dicarba-*closo*-heptaborane(7), while *arachno*-$[B_9H_{13}]^{2-}$ is tridecahydro-*arachno*-nonaborate(2−). More times than not, formal names are avoided in preference to formulas.

3 SYNTHESES

The heteroboranes are derived ultimately from boranes, which, in turn, can be built up from lower molecular weight boron hydrides, the simplest of which is diborane, B_2H_6. There are a number of industrial processes described for the synthesis of diborane, most involving the reduction of boron trihalides with metal hydrides, as shown in equation (1). Other methods involve the reduction of trihaloboranes with group 1

$$2BF_3(g) + 6NaH(s) \xrightarrow{180^\circ} B_2H_6(g) + 6NaCl(s) \quad (1)$$

hydroborates or the reduction of alkylborate esters with alkali metal hydrides.[12] Small amounts of diborane can be obtained by the reaction of alkali metal borohydrides with I_2 (equation 2) or an

$$2NaBH_4 + I_2 \xrightarrow{\text{diglyme}} B_2H_6 + 2NaI + H_2 \quad (2)$$

$$2KBH_4(s) + 2H_3PO_4(l) \longrightarrow B_2H_6(g) + 2NaH_2PO_4(s) + 2H_2(g) \quad (3)$$

$$2M[BH_4] + 2BX_3 \longrightarrow B_2H_6 + 2M[HBX_3] \quad (4)$$

anhydrous acid (equation 3).[13] Hydride abstraction from $[BH_4]^-$ by BX_3 (equation (4)) has also been described. It should be stressed that diborane is an extremely toxic, flammable, and explosively reactive gas that should be handled with extreme care. The controlled pyrolysis of B_2H_6 yields higher boranes plus H_2, culminating in decaborane(14) ($B_{10}H_{14}$), which is quite stable. Hydride ion abstraction reactions of lower molecular mass hydroborates by BX_3 has also produced a number of neutral boranes in good yields.[14] Other methods that target specific boranes, such as B_5H_9 and $B_{10}H_{14}$, have also been described.[15]

4 REACTIONS

The syntheses of the heteroboranes often involves the addition of heteromolecules to *nido*-boranes, in so called cage expansion reactions.[7,16,17] Two of the most used borane precursors are pentaborane(9) (*nido*-B_5H_9) and decaborane(14) (*nido*-$B_{10}H_{14}$); both of which are shown in Figure 2. These boranes react with acetylenes (RC≡CR′) to give, respectively, *nido*-2-R-3-R′-2,3-$C_2B_4H_6$ and *closo*-1-R-2-R′-1,2-$C_2B_{10}H_{10}$.[18] The *closo*-C_2B_{10} carboranes can be degraded to give *nido*-7-R-8-R′-7,8-$C_2B_9H_{11}$ cages or reduced directly to give the corresponding *nido*-7-R-8-R′-7,8-$C_2B_{10}H_{12}$. These *nido*-carboranes have two bridged hydrogens that can be removed to give the more reactive dianions that undergo metallation reactions and are used as ligands that closely resemble cyclopentadienide ($[C_5H_5]^-$) in their bonding interactions. A number of main group,[7,17] transition metal[6] and rare earth[19] metallacarboranes of these and other carboranes have been reported and studied.

In the last 50 years, there has been a wealth of fascinating chemistry published on the boranes and heteroboranes.[1] Their unique structures have forced us to rethink our ideas on bonding and they have proven to be invaluable reagents in other areas of chemistry.[20]

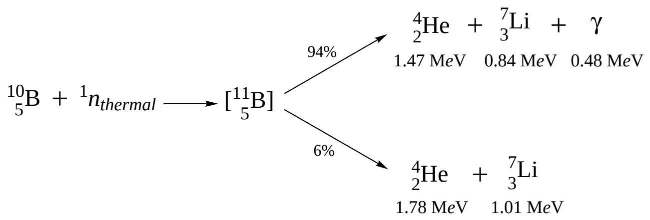
1 INTRODUCTION

The fifth element in the periodic table, boron, is usually grouped with the nonmetallic elements but has some metallic properties and is sometimes labeled a metalloid. Unlike the other group 13 elements, it is a semiconductor rather than a metallic conductor. Boron is unique among the elements and is notable for exhibiting unusual chemistry in all of its compounds. Although distinctive, the chemistry of boron is more similar to that of silicon and carbon than to the metallic group 13 elements. The electronic structure of boron, $1s^2 2s^2 2p^1$, suggests that it should form univalent compounds, but this is rarely the case and such compounds are difficult to prepare and isolate. Rather, boron utilizes all three of its valence electrons to form compounds having sp^2 hybridized boron of the type BR_3, where R can be halogen, alkyl, alkoxy, and so on, or compounds containing electron deficient multicenter bonds, as found in the boron hydrides. The formation of three covalent bonds provides more than enough energy to offset the cost of converting to the sp^2 hybrid state. Compounds of the BR_3 type are trigonal planar six electron molecules having an empty or partially occupied $2p_z$ orbital. Thus, they exhibit a tendency to react with electron donor species to form tetrahedral complexes complying with the octet rule. For this reason, boron is often called electron deficient.

The Lewis acid character of many boron compounds and the ability of boron to participate in multicenter bonds lead to a vast and complex chemistry. Boron exclusively forms covalent bonds in an immense variety of compounds, often participating in rings, cages, clusters, and networks. It forms strong covalent bonds with electronegative elements, most notably with oxygen; only fluorine forms a stronger bond to boron. Much of boron chemistry can be considered to be iono-covalent in that boron is found covalently bound in many complex anions that in turn form salts with cationic species.

Naturally occurring boron is widely distributed in the environment. With the exception of a few rare boron fluoride minerals, only boron–oxygen compounds are found in nature. Boron has also been identified in space and in the sun and other stars. At a concentration of only 0.001% of the earth's crust, boron is a relatively uncommon element. However, in the form of borate minerals, the element is found universally in rocks and soils, and also occurs at measurable levels in nearly all natural waters. Boron is typically found in rocks and soils at levels of a few $\mu g\,g^{-1}$, although concentrations vary widely. Ocean waters contain approximately $4.6\,\mu g\,g^{-1}$; freshwater lakes and rivers usually have much lower concentration, near $0.1\,\mu g\,g^{-1}$, but can contain significantly higher levels in regions of higher boron geologies.[1] Although boron is widely distributed in the earth's crust, borate ore deposits of sufficient concentration for profitable mining are relatively rare. These deposits are mainly found in arid regions of the world having a history of volcanism and hydrothermal activity.[2]

Boron has been recognized as an essential element for plants since the 1920s.[3] All plants contain measurable levels of boron, and boron deficiency is considered to be one of the most prevalent agricultural micronutrient deficiency problems in the world.[4] In areas of low soil concentrations of boron, it is standard agricultural practice to correct this deficiency by adding boron to the soil, typically using borates mixed with other required fertilizers. Considerable progress has been made in recent years in understanding the biological role of boron in plants. In particular, boron was shown to play an essential role in plant cell wall functions through ester crosslinking with complex carbohydrates (see Section 6.4).[5] Boron concentrations in plants and plant-derived foodstuff typically fall in the $0.1–64\,\mu g\,g^{-1}$ range.[6,7] There is now considerable evidence indicating that boron is also essential to animals and humans.[8,9] Consumption of plants by herbivorous animals introduces boron into the overall food chain, and animals and humans inevitably contain low concentrations of boron. For example, human blood contains boron concentrations of approximately $0.01–0.17\,\mu g\,mL^{-1}$ and urine contains $0.15–2.98\,\mu g\,mL^{-1}$.[7] Body tissues have boron concentrations comparable to those in blood, and bone may contain somewhat higher levels. Essentially, all boron ingested is excreted in the urine within about 24 h. It has been estimated that an adult in the United States consumes approximately 1 mg boron per day. Boron consumption by healthy populations in other parts of the world may be considerably higher depending on regional diets.[10]



Scheme 1

Boron has an atomic weight of 10.81, representing a mixture of about 20% of the ^{10}B isotope and 80% of the ^{11}B isotope. The observed isotope ratio, and thus the average atomic weight, varies slightly from these values depending on the geographical source of the boron. Data on this subject are summarized.[11] Other boron isotopes such as ^{8}B, ^{12}B, and ^{13}B are unstable with half-lives of less than a second. The ^{10}B isotope is unique among the light nuclides in having an unusually high-capture cross-section for low-energy thermal neutrons (3.8×10^{-25} m^2, 0.02–0.05 *e*V neutron). This reaction yields recoiling α particles and ^{7}Li nuclei with a total energy release of 2.28 M*e*V, as shown in Scheme 1. The primary reaction pathway also yields a 0.48 M*e*V γ-ray, which is exploited in the analytical method for boron determination known as prompt gamma activation analysis. The nuclear chemistry of ^{10}B provides the basis for the experimental treatment for cancers and other diseases known as boron neutron capture therapy, or BNCT.[12] This method involves localizing ^{10}B-enriched compounds at tumor cells followed by irradiation with a relatively nondestructive thermal neutron beam. The resulting α particles and ^{7}Li nuclei travel only about one cell diameter but have a high lethality for cells they enter. The BNCT concept has led to extensive research on the design of chemistries for the selective delivery of ^{10}B-containing compounds to tumor and other diseased cells.[12] By far, the largest application for the boron neutron capture reaction involves the use by the nuclear industry of unenriched boron compounds, typically boric acid, in neutron radiation shielding.

This article covers only a part of the chemistry of boron. Boron–carbon compounds are covered in other articles in this volume (*see* ***Boron: Organoboranes***; ***Boron: Metallacarbaboranes***, and ***Boron: Polyhedral Carboranes***). The main subject of the latter two articles, and the separate one on ***Boron Hydrides*** is the extensive chemistry of the multicenter bonded boron-hydride systems. This area has been a major focus of boron research for the past 60 years. There is some direct overlap between the two articles ***Borides: Solid-state Chemistry*** and ***Borates: Solid-state Chemistry***, and this more general one covering the inorganic chemistry of boron. ***Boron–Nitrogen Compounds*** are also covered separately. These articles should be consulted for more detailed discussions of the structure, bonding, and properties of borides, solid-state borates, and boron–nitrogen compounds. Several general reference volumes cover, in differing amounts of detail, most of the subjects included in this article.[13–21] Each section contains additional, more specific references.

2 ELEMENTAL BORON AND REFRACTORY BORON COMPOUNDS

2.1 Introduction

Elemental boron is a refractory material that is usually isolated either as a shiny black crystalline solid or a softer, browner, more impure amorphous solid. Reduction of readily available boron compounds containing boron–oxygen bonds to elemental boron is energy intensive and costly. This has limited the extent of commercial use of this material. Many related refractory boron compounds have been prepared and characterized including metal borides, boron carbides, boron nitrides, and various boron–metal alloys. These refractory materials and elemental boron are also discussed in some detail in the article ***Borides: Solid-state Chemistry***. Other general references are available on elemental boron and other refractory boron compounds.[21–24]

2.2 Elemental Boron

A preliminary description of the preparation of impure elemental boron was presented by Humphrey Davy, who stated in an address to the Royal Society in the fall of 1807 that reduction of moist boric acid with an electric current produced a 'dark colored combustible matter.'[25] Further accounts of the isolation of impure elemental boron, by both electrolysis and reduction with potassium, were made the following year by Guy-Lussac and Thénard and also independently by Davy. A convenient preparation of higher purity boron was not described until 1892, when Moissan reported the preparation of 90–95% amorphous boron by reaction of magnesium with boric oxide. This process is still used in the commercial production of moderate quantities of the amorphous boron. Boron purer than 99% was subsequently obtained by remelting and recrystallizing amorphous boron and by thermal decomposition of boron trichloride in a hydrogen atmosphere. A crystalline product of approximately 95% purity can also be obtained by heating 90% amorphous boron with mixed fluorides at 950–1000 °C followed by heating in a vacuum to near-fusion temperatures. Further upgrading to 99.7–99.9% can be accomplished by recrystallization under vacuum. Thermal decomposition of boron hydrides can produce high-purity crystalline boron.

The principal commercial methods in use for production of elemental boron are the Moissan reduction of boric oxide with magnesium for 90% amorphous boron and thermal decomposition of boron trichloride in hydrogen for crystalline

boron filaments. There are numerous small to moderate volume uses for elemental boron. Perhaps the most prominent is the use of boron filaments deposited on tungsten wire as reinforcements in plastics, such as epoxy resins, and metal composites, such as aluminum and titanium. These boron fiber-reinforced composites have an exceptional compressive strength and are used in aerospace applications and in sporting goods, including golf club shafts, tennis racket frames, and fishing rods. Elemental boron has also been used as a fuse to initiate release of nitrogen gas in automobile air bags by its rapid reaction with sodium azide.

Many forms of elemental boron have been reported in the literature. The presence of trace impurities can have major effects on the structure and properties of boron, in some cases leading to false identification of unique forms. Crystalline boron exists in at least three allotropic forms depending on the preparative method used. The structures of the α-rhombohedral, β-rhombohedral, and β-tetragonal allotropes have been defined by X-ray diffraction studies and shown to each incorporate B_{12} icosahedra in their structures. Similar icosahedral structures exist in boron carbide, boron phosphide, $B_{12}P_2$, and boron arsenide, $B_{12}As_2$, discussed below. Details of the structures of these allotropes can be found in ***Borides: Solid-state Chemistry***. The β-tetragonal allotrope, originally thought to consist of B_{12} icosahedra linked by B_2 units, now appears to be an impure boron phase with B_{12} icosahedra linked by C_2 or N_2 units.

Amorphous boron (>90%) melts at 2300 °C, sublimes at approximately 2550 °C, and has a density of 2.35 g mL^{-1}. Crystalline α-rhombohedral boron melts at temperatures in the range 2180–2190 °C, sublimes at 3650–3660 °C, and has a density of 2.45 g mL^{-1}. The crystalline forms are hard refractory materials with Moh's hardnesses in the range of 9–11, compared to 15 for diamond.

In general, both crystalline and amorphous boron are relatively inert materials with the amorphous form tending to react more readily with chemical reagents. Finely divided micron-sized amorphous boron can react violently with hydrogen, oxygen, and chlorine at elevated temperatures and with water above 100 °C. Crystalline boron can be dissolved in a hot 2:1 mixture of sulfuric and nitric acids, but is nearly inert toward oxygen, water, nitric acid, and sodium hydroxide.

2.3 Metal Borides

A large number of binary metal borides have been prepared and characterized. Their stoichiometries vary from M_5B to MB_{100}, but the most common are M_2B, MB, MB_2, MB_4, MB_6, and MB_{12}. The structures of metal borides vary from isolated boron atoms in borides from M_4B to M_2B, to chains of boron atoms in MB and M_3B_4, to two-dimensional networks of boron atoms in MB_2 and M_2B_5, to complex three-dimensional arrays of boron atoms in MB_4, MB_6, and MB_{12}. In general, metal borides exhibit characteristics of typical metals, for example, high electrical and thermal conductivity. Most of them have high melting points, high hardnesses, and good resistance to chemical attacks. The boron-rich metal borides, having compositions ranging from MB_6 to MB_{60} or greater, are among the hardest known substances.

Most borides are inert toward nonoxidizing acids, although Be_2B and MgB_2 react with aqueous acids to form boron hydrides. Oxidizing acids such as nitric or hot sulfuric dissolve most borides. Hot alkaline salt melts and fused alkali peroxides also dissolve borides to form the more stable borates. Borides are generally resistant to oxidation in dry air due to the formation of a protective oxide layer. Many borides do not oxidize in air below 1000–1400 °C.

More than one boride phase can be formed with most metals, and in many cases a continuous series of solid solutions may be formed. Several methods have been used for the relatively large-scale preparation of metal borides. One that is commonly used is carbon reduction of boric oxide and the appropriate metal oxide at temperatures up to 2000 °C. Fused salt electrolysis of borax or boric oxide and a metal oxide at 700–1000 °C have also been used. Small-scale methods available include direct reaction of the elements at temperatures above 1000 °C and the reaction of elemental boron with metal oxides at temperatures approaching 2000 °C. One commercial use of borides is in titanium boride–aluminum nitride crucibles or boats for evaporation of aluminum by resistance heating in the aluminizing process, and for rare earth hexaborides as electronic cathodes. Borides have also been used in sliding electrical contacts and as cathodes in Hall cells for aluminum processing.

The discovery that magnesium diboride, MgB_2, is a superconductor with a transition temperature of 39 K was first announced in 2001.[26] Although 39 K does not qualify magnesium diboride for the status of a high-temperature superconductor, it is a record high transition temperature for a relatively simple and inexpensive material. Magnesium diboride was well known for decades prior to this discovery, but prevailing theories of superconductivity did not predict this high transition temperature. Thus, this discovery resulted in a resurgence of interest in superconductivity and the possibility of developing a new class of low-cost high-performance superconductor materials.[27]

Magnesium diboride is a metallic compound having a structure in which boron atoms form hexagonal layers with magnesium atoms located between the layers above and below the centers of the boron hexagons. The unusual properties of this material are thought to result from strong interactions between lattice vibrations (phonons) and the electronic structure of the boron layers. It is proposed that the anomalous superconducting properties of magnesium diboride can be explained by the presence of two, rather than the usual one, superconducting energy gaps in this material.[28] These gaps correspond to transition temperatures of 15 K and 45 K, and combine to give an overall transition temperature of 39 K.

The tertiary alloy of composition $AlMgB_{14}$, referred to as 'BAM', has a hardness similar to industrial diamond. Since its discovery was reported in 1999, BAM has been the subject of intense research interest.[29] It is reported to be an excellent material for use in cutting tools. One unique property of this ultrahard substance is its ability to cut hot materials without becoming hot itself. It is also less reactive with steel than diamond is, and so can be used to cut both masonry and steel. Although still produced on a laboratory scale, current efforts are focused on developing methods for its manufacture on industrial scale. This has required development of improved methods for the preparation of high-purity low-oxygen content elemental boron, since oxygen impurity lowers the hardness of BAM by forming spinel, Al_2MgO_4. The use of BAM may eventually reduce energy consumption and other wear-related costs in industrial cutting and grinding operations.[30]

Another important application of metal borides is in permanent magnets. Metal–boron alloys such as neodymium iron boron, having a base composition of $Nd_2Fe_{14}B$, exhibit the highest energy product of any readily available magnetic material. Produced commercially since the early 1980s, rare earth magnets are used extensively in the manufacture of hard disc drives, high-performance electric motors, speakers, and instruments. These magnets are typically manufactured using a metallurgical process in which a powder of the appropriate alloy composition is first produced and then sintered into the desired shape for a given application.[31] A coating of protective material, such as nickel, is often applied to Nd–Fe–B magnets because they tend to be susceptible to oxidation.

2.4 Boron Carbide

Boron carbide is usually obtained in a form written empirically as B_4C to indicate the ratio of boron to carbon atoms. However, the actual stoichiometry can vary from this ratio of 20 atom % carbon in B_4C to $B_{10.4}C$ with only 8.8 atom % carbon. Boron carbide belongs to a family of solid solution compounds, including B_4Si, $B_{12}P_2$, $B_{12}As_2$, $B_{12}O_2$, $B_{12}S$, based on α-rhombohedral boron-containing various interstitial elements.[21–24] Boron carbide with B_4C stoichiometry was originally thought to exist as a rhombohedral structure consisting of B_{12} icosahedra joined by C_3 chains. Therefore, $B_{12}C_3$ would be a more descriptive formula. In this structure, which is similar to the rhombohedral crystalline forms of elemental boron, each polyhedral boron atom is bonded to five others in the same icosahedron, and to either a boron atom in an adjacent icosahedron, or to a carbon atom in one of the chains. However, studies indicate that this relatively simple structure is incorrect, and that the three chain positions and some of the icosahedral positions can be filled by boron or carbon atoms. X-ray, Raman, and electrical and thermal transport studies support a disordered structure for $B_{12}C_3$. These data indicate that boron carbides exist as single-phase materials from approximately 9–20 atom % carbon. At 20 atom % carbon, or $B_{12}C_3$, the structure is composed of $B_{11}C$ icosahedra linked by C–B–C chains. With decreasing carbon content from 20 to 13%, the C–B–C chains are progressively replaced by C–B–B chains, and below 13%, the $B_{11}C$ icosahedra are replaced by B_{12} icosahedra.

The properties of boron carbide are similar to elemental boron. It has a theoretical density of 2.52 g mL^{-1} and a melting point of approximately 2400 °C. Boron carbide has a high compressive strength, but its tensile strength is limited. Boron carbide is prepared commercially by the reduction of boric oxide with carbon in a hydrogen atmosphere in an electric furnace at 1400–2300 °C (equation 1). In a related reaction, magnesium is added to boric oxide in the presence of carbon black at 1400–1800 °C (equation 2), and magnesium-containing by-products are removed by acid treatment. Usually, boron carbide is converted to a granular form that can be molded or bonded into useful shapes. In order to achieve high strengths and high densities, boron carbide is hot pressed at 1800–2400 °C in graphite molds. Although it is brittle and sensitive to thermal shock, the exceptional hardness of boron carbide, with a Moh's hardness of approximately 10 compared to 15 for diamond, has resulted in moderate commercial usage in its hot-pressed form in ceramic armor plates, sandblasting nozzles, wear parts, and in dressing grinding wheels. Because of its radiation stability, chemical inertness, and the ability of boron to capture neutrons, boron carbide has also found use in radiation shielding and control devices in nuclear reactors.

$$2B_2O_3 + 7C \longrightarrow B_4C + 6CO \quad (1)$$

$$2B_2O_3 + 6Mg + C \longrightarrow B_4C + 6MgO \quad (2)$$

2.5 Boron Nitride

A review of boron nitride chemistry is available.[32] Boron nitride, BN, is a so-called III–V compound. It is isoelectronic with the carbon allotropes, diamond and graphite, and has several forms that, like these two forms of carbon, display very different properties. Hexagonal boron nitride (h-BN) has a graphite-like structure consisting of layers of fused six-membered $(BN)_3$ planar rings. Alternate sheets are located such that boron atoms are directly over nitrogen atoms. This structure results in planes that readily slide relative to each other, similar to those in graphite. As a result, hexagonal boron nitride, sometimes called 'white graphite,' has good lubricant properties. The rhombohedral form is similar to the hexagonal form, except with sheets stacked in groups of three rather than two. Two dense forms have also been described. The one usually referred to as 'cubic' boron nitride (c-BN) has a zinc blende lattice and the other has a wurtzite lattice. Both forms are unstable at atmospheric pressure, but transfer rates to hexagonal boron nitride are so slow as to be inconsequential for practical purposes.

Hexagonal boron nitride melts at approximately 3000 °C under nitrogen pressure and sublimes at 2500 °C at

atmospheric pressure. Its theoretical density is 2.27 g mL^{-1}. In contrast to graphite, hexagonal boron nitride is a good electrical insulator. Cubic boron nitride has a theoretical density of 3.49 g mL^{-1}, a structure resembling diamond, and a Moh's hardness near the maximum of 15 for diamond. Cubic boron nitride is widely regarded as the second hardest substance known after diamond.

Hexagonal boron nitride can be prepared by a variety of reactions starting with boric oxide, boric acid, or borate salts. These include heating boric oxide or boric acid with ammonia, and heating boric oxide, boric acid, or borate salts with ammonium chloride, alkali metal cyanides, or calcium cyanamide. High-purity hexagonal boron nitride can be prepared by reaction of ammonia with boron trichloride or boron trifluoride. The rhombohedral form of boron nitride is prepared by rapid heating of a mixture of sodium borohydride and ammonium chloride to 750–1000 °C in the presence of added sodium chloride. Both hexagonal and rhombohedral boron nitride can be converted to the cubic zinc blende form by heating at 1400–1700 °C and 4–6 GPa pressure. This conversion is accelerated by the presence of additives including lithium and alkaline earth nitrides and amides. The wurtzite form is obtained in the absence of additives at higher pressures.

The various forms of boron nitride are all relatively inert to chemical attack under normal conditions. For example, hexagonal boron nitride does not react with oxygen, chlorine, or steam up to 700 °C. Reaction with steam begins at 900 °C. Rapid reactions are observed with hot alkali or fused alkali carbonate, but reactions are slow with most acids and alcohols, and boron nitride is not wetted by most molten metals and glasses. The cubic forms have similar reactivity but rates are slower because of their dense structures.

Both hexagonal and cubic boron nitride are important commercial products, and consumption of both forms has gradually increased in recent years. Hexagonal boron nitride is used as a lubricant and release agent in engineering polymer and molten metal extruding and forming operations. Hexagonal boron nitride is a good electrical insulator and a thermal conductor, a combination of properties that leads to applications in the electronics industry. In this application, h-BN is blended into elastomeric or thermoplastic parts used to transfer heat away from electronic components while maintaining electrical insulation. Hexagonal boron nitride powder is often hot-pressed at temperatures up to 2000 °C and pressures up to 14 Mpa to form articles of various shapes, such as high-temperature vessels. Its low coefficient of thermal expansion, excellent thermal shock resistance, and resistance to chemical attack makes such vessels useful for many high-temperature processes. Hexagonal boron nitride is often combined with other nonoxide ceramic materials and intermetallic composites to improve their physical properties. Hexagonal boron nitride is sold as powders and hot-pressed articles, as well as paste and liquid dispersions in water or organic solvents for use as coatings and aerosol sprays.

Another commercial form is known as pyrolytic boron nitride, p-BN. This form is a variation of standard h-BN and is manufactured by pyrolyzing boron trihalides in the presence of ammonia at about 2000 °C and allowing the pyrolysis products to deposit on a graphite substrate. This process results in boron nitride having a high degree of crystal orientation, with hexagonal layers running parallel to the substrate surface. This gives anisotropic characteristics valuable in the fabrication of articles, such as high-temperature crucibles. Pyrolytic boron nitride has exceptional thermal properties, high tensile strength that increases with temperature, and the highest dielectric properties of any readily available material. It is also extremely resistant to attack by most chemical reagents even at high temperatures.

Crystalline cubic boron nitride is mainly used as an extremely hard abrasive, similar to how industrial diamond is used. As 1–500 µm particles, it is sold as an abrasive material with trade names including Borazon and Amborite. This material is used in cutting tools and as grit for grinding and polishing wheels. Cubic boron nitride is bonded into cutting tools used to shape hard ferrous- and nickel-based alloys, which tend to react with diamond cutting tools, and also to cut masonry and glass.

Subsequent to the much acclaimed discovery of carbon nanotubes, techniques were developed to prepare boron nitride nanotubes.[33] These bear a similar isostructural relationship to carbon nanotubes as diamond and cubic boron nitride, and can be prepared as multiwall tubes.[34] Boron nitride nanotubes have been prepared by electric arc-discharge in the gas phase and by depositing boron and nitrogen ions on a hot, electrically biased tungsten surface. Boron nitride nanotubes have some potential advantages over carbon nanotubes in being more resistant to oxidation and thus suited for high-temperature applications. In addition, BN nanotubes are expected to be semiconducting with conductivities less dependent on the specific nanotube geometry.

2.6 Boron Phosphides

Two boron phosphides have been isolated, BP and $B_{12}P_2$. Heating elemental boron and red phosphorus at 900–1100 °C yields BP as refractory brown crystals having a cubic zinc blende structure similar to cubic boron nitride. This material can also be prepared by a number of other methods including the pyrolysis of $Cl_3P{\cdot}BCl_3$, reaction of boron or boron trichloride with zinc phosphide or phosphine, and hydrogen reduction of $Cl_3P{\cdot}BC1_3$.

Cubic boron phosphide is a III–V semiconductor with a large band gap. It is stable to 2500 °C at high pressure but decomposes at 1100 °C under vacuum with elimination of volatile white phosphorus, and formation of gray $B_{12}P_2$, which can be recrystallized from molten iron or aluminum to give black crystals. X-ray studies indicate that this material contains B_{12} icosahedra linked by P_2 moieties. The related boron

arsenide, $B_{12}As_2$, has a similar structure with the icosahedra joined by As_2 moieties.

3 BORIC OXIDES, BORIC ACIDS, AND METAL BORATES

3.1 Introduction

Boric oxides, boric acids, and metal borates are of primary importance in any discussion of boron chemistry since these include essentially all boron minerals and the vast majority of boron compounds produced and used worldwide on a weight basis. Reviews of this chemistry and the commercial aspects of this general subject are available.[2,18]

3.2 Boric Oxides

Reviews of boron oxide chemistry are available.[13,35] The fundamental material B_2O_3 is referred to in the literature as boric oxide, boron trioxide, and diboron trioxide. In the commercial context it is called boric oxide, anhydrous boric acid, boric anhydride, and boric acid anhydride. This material, the only significant commercial form of boric oxide, is usually isolated as a vitreous solid at room temperature. It is prepared in large quantities by fusing refined boric acid in a furnace. The resulting molten glass is drawn out of the furnace, cooled on chill rolls, crushed, and screened. Two crystalline forms of B_2O_3 have been prepared in laboratory quantities. The α form, or B_2O_3-I, is prepared as hexagonal crystals by seeding with this form or with boron phosphate at 250 °C. The more exotic β form has only been obtained by heating vitreous boric oxide at 400 °C and 22 000 atmospheres. Some physical properties of the vitreous and crystalline forms are shown in Table 1.

Structural features of vitreous and molten boric oxide have been subject to debate. It appears that only trigonal boron is present in the solid glass, in a branched network containing $(BO)_3$ boroxin rings. The percentage of boron in B_2O_3 glass participating in boroxin rings has been controversial. Spectroscopic data indicate that 60–70 mol percent of boron in this material is present in boroxin ring structures; however theoretical calculations have predicted only 15–20%.[36] As the glass melts, boroxin ring structures break down, and above 800 °C, the strong boroxin line in the Raman spectrum disappears. Above 800 °C, the melt apparently consists of strongly associated discrete small molecules. The large discrepancy between spectroscopic observations and calculations may be related to the inability of computations to accurately simulate realistic cooling rates. Structures of the crystalline forms of B_2O_3 have been determined. The B_2O_3-I crystalline phase is hexagonal with trigonal boron-geometry. The crystal lattice of monoclinic B_2O_3-II consists of a compact network of BO_4^- tetrahedra with the four apical oxygens that are shared by two or three boron atoms. The Lewis acid character usually associated with trigonal BO_3 groups is absent in this crystalline form, and reactions with water and fluoride ion, as examples, are sluggish. Reaction of vitreous boric oxide with water is exothermic and gives boric acid (equation 3). Vitreous boric oxide is mildly hygroscopic at room temperature, and commercial samples usually contain approximately 1% water as a surface layer of boric acid. Molten boric oxide reacts readily with water above 1000 °C to form metaboric acid vapor (equation 4).

Table 1 Some physical properties of boric oxides

Property	Vitreous form	Crystalline forms: B_2O_3-I	Crystalline forms: B_2O_3-II
Mp (°C)	Softens 300–325	455–475	510
Bp (°C)	2316 (extrap.)	–	–
Density ($g\,mL^{-1}$)	1.84	2.46	2.95
B-O geometry	trigonal	trigonal	tetrahedral

$$B_2O_3 + 3H_2O \longrightarrow 2B(OH)_3 \quad (3)$$

$$B_2O_3(\text{molten}) + H_2O(g) \longrightarrow 2HBO_2(g) \quad (4)$$

Values for the physical properties of boric oxide are somewhat confused in the literature due to the tendency of this substance to react readily with water. Many physical properties of boric oxide are sensitive to water content, and the water content of samples used for measurements was not always carefully controlled. For example, at 0.28% water, the density of vitreous boric oxide is 1.853 $g\,mL^{-1}$ and the softening point 240–275 °C. Reducing the water concentration to 20 $\mu g\,g^{-1}$ reduced the density to 1.829 $g\,mL^{-1}$ and raised the softening point to 300–325 °C.[37] Other properties, such as thermal expansion, viscosity, and refractive index, are also significantly affected by moisture content. Water concentrations can be reduced to as low as 10 $\mu g\,g^{-1}$ by prolonged heating in vacuum.

In addition to its reactivity toward water, the Lewis acidity of boric oxide leads to coordination with even relatively weak bases to form tetrahedral boron species. Molten boric oxide dissolves most metal oxides at high temperatures (>1000 °C), and is therefore corrosive to metals in the presence of oxygen. Boric oxide reacts readily with alcohols to form boric acid esters and boroxins, and with P_2O_5 to give boron phosphate. Because of its fluxing action, boric oxide is used as a solvent for metal reductions, for growing crystals at high temperatures, and in the preparation of metal salts such as lead titanate and calcium zirconate from the oxides. The general fluxing action of boric oxide is important in preparing many types of glasses, glazes, frits, ceramic coatings, and porcelain enamels, and this property is also utilized in soldering and welding fluxes. Boric oxide is a chemical intermediate in the production of a variety of other boron compounds, including esters, carbides, nitrides, and metal borides.

3.3 Boron Suboxides

Boron suboxides have boron:oxygen mole ratios equal to or greater than one. These compounds range from molecular species to refractory solid-state materials. Monomeric vapor-phase BO and B_2O_2 have been studied by spectroscopic techniques. In addition to these rather unstable high-temperature species, several forms of solid noncrystalline boron suboxides have been reported. A water-soluble low-temperature form is obtained by the vacuum dehydration of tetrahydroxydiborane at 220 °C (equation 5). At 500 °C, this form converts to a light brown modification that has also been obtained by reactions of boric oxide with elemental boron, boron carbide, or carbon at high temperatures (>1250 °C).

$$nB_2(OH)_4 \longrightarrow (BO)_{2n} + 2nH_2O \quad (5)$$

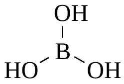
Refractory suboxides with boron:oxygen ratios significantly greater than one have been isolated as by-products from elemental boron production or by reactions of boron with boric oxide at high temperatures. These are related materials represented as B_6O, B_7O, and $B_{13}O_2$. The suboxide B_6O was prepared by reaction of elemental boron with zinc oxide at 1350 °C in argon, and has a structure based on an α-rhombohedral boron with interstitial oxygen atoms. This structure is similar to an α-rhombohedral boron carbide with each B_{12} icosahedron connected through oxygen atoms to adjacent icosahedra. Single crystals of boron suboxide prepared by dissolving elemental boron in molten B_2O_3 at >2000 °C and >5000 Mpa were recently reported to be close in hardness to cubic boron nitride (see Section 2.5) and to have greater fracture toughness.[37] In theory, boron suboxide can be prepared at lower pressures than c-BN, making this an attractive material for larger-scale industrial use.

A special case of molecular boron suboxides is found in the hydroxylated polyhedral boranes (*see* ***Boron Hydrides***). For example, the icosahedral anion *closo*-$[B_{12}H_{12}]^{2-}$ and related compounds can be completely hydroxylated to form discrete molecular boron suboxides, including *closo*-$[B_{12}(OH)_{12}]^{2-}$.[38] These can be regarded as members of a class of formally hydrated suboxides related to compounds such as tetrahydroxydiborane, $B_2(HO)_4$ ($BO{\cdot}H_2O$). The terminal hydroxyl groups of these compounds can be functionalized as esters or ethers to produce a variety of large molecule derivatives.

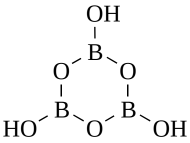
3.4 Boric Acids

3.4.1 Introduction

Boric acid, $B(OH)_3$, or H_3BO_3, is the only boric acid of commercial significance. It is also referred to as orthoboric acid, but usually only when context requires specifying this particular form. It can also be written as $B_2O_3{\cdot}3H_2O$, emphasizing the relationship with its acid anhydride B_2O_3. The formula $B(OH)_3$ denotes the correct structure (**1**) and is preferred to H_3BO_3, which gives the misleading impression that boric acid is a tribasic Brønsted acid such as H_3PO_4. Boric acid occurs as the relatively rare mineral sassolite that at one time was extracted commercially from hot springs in Italy. Metaboric acid, HBO_2 or $B_2O_3{\cdot}H_2O$, has been isolated in three crystalline modifications (see Section 3.4.3), including the boroxin or orthorhombic form (**2**). Summaries of boric acid chemistry are available.[13,39,40]



(**1**)



(**2**)

Properties. Boric acid is a white solid that crystallizes from aqueous solutions as triclinic waxy plates. The crystal structure of boric acid consists of planar sheets of planar trigonal $B(OH)_3$ molecules (**1**) linked by hydrogen bonds. This produces a graphite-like structure, accounting for the slippery feel of boric acid and the ease with which crystals cleave into flakes. This tribological property, or lubricity, has led to uses of boric acid as a lubricant.[41]

Preparation and Uses. Boric acid can be prepared in the laboratory by acid hydrolysis of a variety of boron compounds, including halides, esters, salts, and hydrides. It is produced commercially by reactions of sulfuric acid with sodium borates in the United States, and with sodium and calcium borates in Turkey. In South America, boric acid is produced by reaction of sulfuric acid with ulexite, a mixed sodium-calcium borate. Boric acid is also produced in Russia from the borosilicate mineral datolite.

Boric acid has many uses. Several hundred thousand tons are consumed annually in the manufacture of industrial and consumer products. Its most significant use is as a source of B_2O_3 in glasses and other vitreous products, including textile fiberglass, heat-resistant borosilicate glasses, ceramic glazes, porcelain enamels, and sealing and optical glasses. Boric acid is a versatile synthetic reagent and serves as a starting material in the production of many other commercial boron chemicals and reagents. In addition to potassium, ammonium, and zinc borates, boric acid is used in the manufacture of borate esters, boron hydrides, fluoroborates, refractory boron compounds, such as boron carbide and boron nitride, and amorphous metals and metal alloys, including ferroboron and permanent magnets. Other applications include preservatives for natural products such as wood and natural fibers. Boric acid acts as a mild antiseptic in a wide variety of consumer products and is frequently used in eye wash formulations. It is effective in the control of cockroaches and wood-boring insects. Boric acid is used to reduce the flammability and smoke production of cellulosic materials such as wood, cellulose insulation, and

cotton batting for mattresses and furniture. Boric acid is also used in nuclear reactors because of the high neutron-absorbing cross section of the ^{10}B isotope. It is also used as an additive in the air oxidation of hydrocarbons, and related reactions, where its presence hinders unwanted oxidation side reactions.

Although the melting point of boric acid is given as 170.9 °C, some water loss occurs at temperatures as low as 100 °C when boric acid is heated slowly. Below 160 °C, the vapor phase includes water and gaseous boric acid. Boric acid is volatile in steam, and loss of boric acid from boiling aqueous solutions can be a problem in some industrial operations. At higher temperatures (600–1000 °C), gaseous metaboric acid is the principal compound formed by equilibration of water vapor and molten boric oxide.[42]

3.4.2 Metaboric Acid

Metaboric acid, HBO_2, has been offered commercially in the past, but no significant market has developed. Three crystalline forms can be prepared by the controlled dehydration of boric acid. Some of their physical properties are included in Table 2. The α form, or HBO_2-III, forms as orthorhombic crystals at approximately 130 °C when boric acid is heated slowly. This compound, of structural formula $(HOBO)_3$ (**2**), has a layered structure having B_3O_3 rings joined by hydrogen bonding between the hydroxyl groups on boron. On further heating, the α form gradually converts to the monoclinic β form or HBO_2-II. The boron atoms in this form are in BO_4 tetrahedra as well as in chains of trigonal B_2O_5 groups. Above 150 °C, dehydration continues beyond the metaborate composition. The third modification, the χ-form or HBO_2-I, is the most stable crystalline form and is prepared as cubic crystals by melting a mixture of boric acid and HBO_2-III in a vacuum at 180 °C for several weeks. Some physical properties of the boric acids are given in Table 2.

3.4.3 Aqueous Chemistry of Boric Acid and its Salts: Polyborates and pH Effects

Boric acid is moderately soluble in water and has a large negative heat of solution. The aqueous solubility of boric acid therefore increases greatly with increasing temperature (Table 3). In dilute aqueous solution, boric acid exists almost exclusively as the undissociated monomers $B(OH)_3$ and $B(OH)_4^-$. It is a weak monobasic acid primarily due to its Lewis acid or base acceptor character. Brønsted acidity, or the tendency to donate protons, plays little or no role in the aqueous chemistry of boric acid. The calculated equilibrium constant for the reaction shown in equation (6) is 5.80×10^{-10} at 25 °C.

$$B(OH)_3 + H_2O \longrightarrow B(OH)_4^- + H^+ \qquad (6)$$

Boric acid is a relatively weak acid compared to other common acids, as illustrated by the acid equilibrium constants given in Table 4. Boric acid has a similar acid strength to silicic acid. Calculated pH values based on the boric acid equilibrium constant are significantly higher than those observed experimentally. This anomaly has been attributed to secondary equilibria between $B(OH)_3$, $B(OH)_4^-$, and polyborate species. Interestingly, the aqueous solubility of boric acid can be increased by the addition of salts such as potassium chloride and sodium sulfate, but decreased by the addition of others salts, such as the chlorides of lithium and sodium. Basic anions and other nucleophiles such as fluorides and borates significantly increase boric acid solubility.

Although $B(OH)_3$ and $B(OH)_4^-$ are monomeric in dilute solutions, at concentrations above about 0.1 mol L^{-1}, condensed borate species that are often referred to as polyborates form. Titration of a boric acid solution with one molar equivalent of a strong base leads to formation of the tetrahydroxyborate anion, $B(OH)_4^-$, as the principal species in solution. Mixtures of boric acid and its conjugate base, the tetrahydroxyborate anion, form what appears to be a classical buffer system where the pH is determined primarily by the acid:salt ratio with $[H^+] = K[B(OH)_3]/[B(OH)_4^-]$. This relationship is approximately correct for sodium and potassium borates with a sodium:boron ratio of 1:2. Here the $B(OH)_3$:$B(OH)_4^-$ ratio equals one, and the solution pH remains near 9 over a wide range. However, for borate solutions with pH values significantly above or below 9,

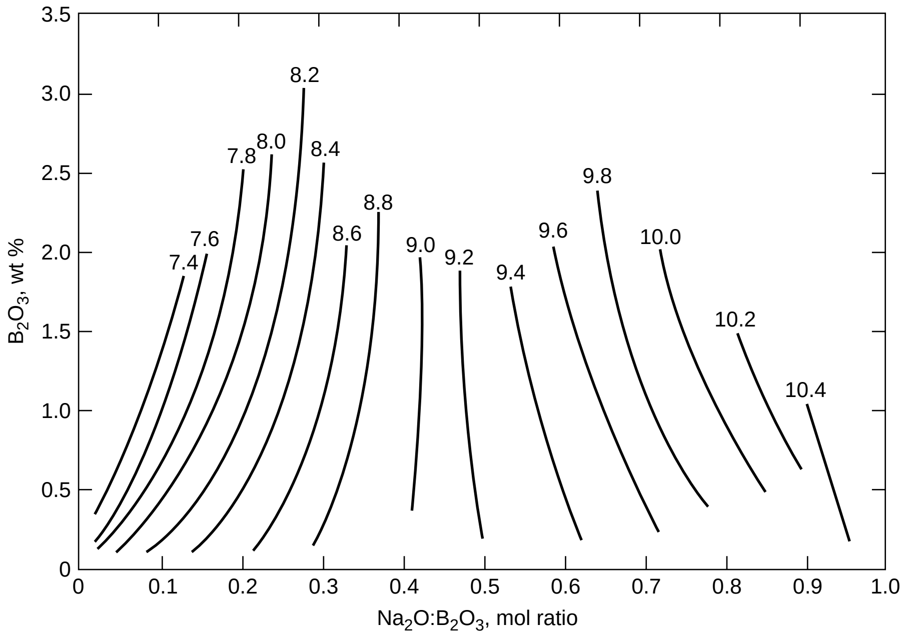

Figure 1 pH values of the Na_2O-B_2O_3-H_2O system at 25 °C

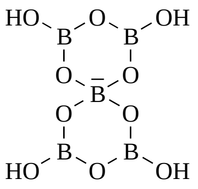
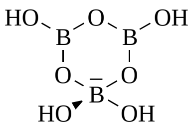
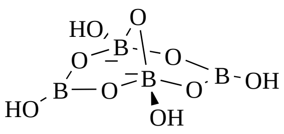
the solution pH becomes sensitive to concentration change, as shown in Figure 1.[43] This anomalous behavior results from the formation of the polyborate anions (**3–6**), which dissociate



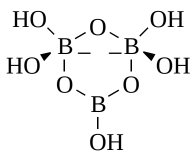
(**3**)



(**4**)



(**5**)



(**6**)

into the monomeric species $B(OH)_3$ and $B(OH)_4{}^-$ when the solutions are diluted. Below pH 9, the pH increases on dilution. Above 9, the pH decreases with dilution. This is probably due to shifts in the equilibria between monomeric and polymeric species and their relative acidities. At a sodium:boron molar ratio of 0.41, the pH of 8.91 is independent of concentration. This ratio and the pH attained have been referred to as the isohydric point. The isohydric point for potassium solutions is slightly different from sodium solutions: pH 9.0 at a potassium:boron ratio of 0.405.

The addition of metal salts, particularly alkaline earth cations and/or halides, can result in significant shifts in the monoborate-polyborate equilibria. Equilibrium constants have been calculated for the equilibria between $B(OH)_3$ and $B(OH)_4{}^-$ and several polyborates: the pentaborate monoanion (**3**), the triborate monoanion (**4**), the tetraborate dianion (**5**), and triborate dianion (**6**).[44] Figure 2 illustrates the relative populations of borate species as a function of pH for a B_2O_3 concentration of 13.93 g L^{-1}. The formation of polyanions is particularly significant in the intermediate pH range. These polyborate anions form successively in the order (**3**) to (**6**) with increasing pH and have been identified in solution by their colligative properties and by Raman and ^{11}B NMR spectroscopy. These anions are also found in crystalline, synthetic, and minerals borates. Alkali metal borate glasses probably contain similar structures.[45]

In addition to pH effects resulting from formation of polyanions in solution, significant enhancements in the solubilities of boric acid and alkali metal borates are also observed at certain mole ratios. For example, soluble borate salts can be dissolved in saturated boric acid solutions to produce solutions having significantly higher B_2O_3 concentrations. The formation of polyborate anions decreases the concentrations of $B(OH)_3$ and $B(OH)_4{}^-$ in equilibrium with undissolved borate salts, thereby permitting more borate salts to dissolve. In the case of alkali metal borates, maximum solubility is achieved at a metal:boron ratio of approximately 1:4. This provides the basis for the commercial product $Na_2B_8O_{13}4H_2O$ (see Section 4.4), which dissolves readily in water with little temperature change to form concentrated borate solutions.

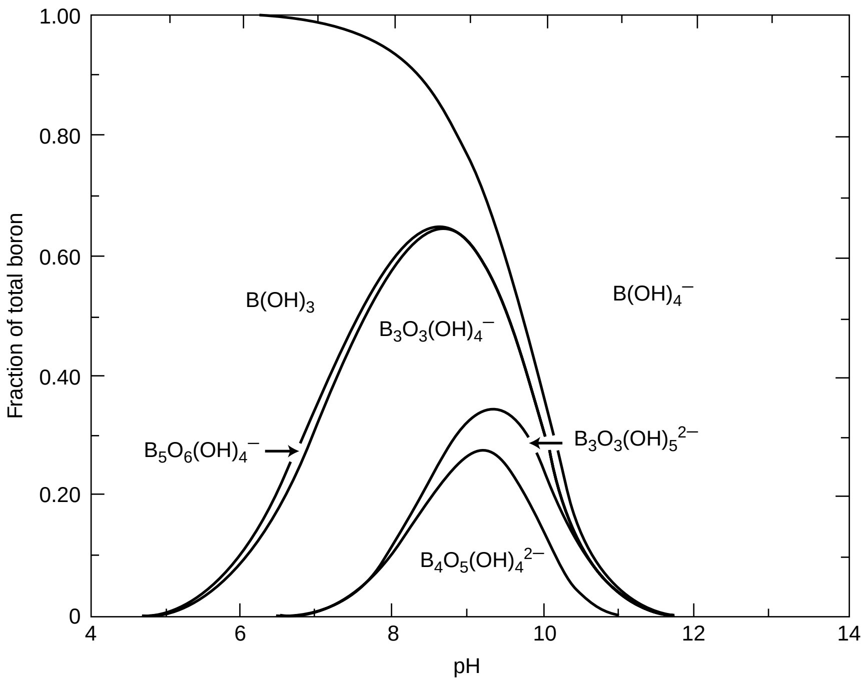


Figure 2 Estimated population distribution of borate species in aqueous solution as a function of pH

It is important to note that the presence of polyborate anions, as shown in Figure 2, is only significant in relatively concentrated solutions. This is relevant to the environmental and biological aspects of boron chemistry, since boron is present in both natural waters and biological systems at low concentrations. Under these conditions, only $B(OH)_3$ and $B(OH)_4^-$ are significant species; and at near neutral pH, the concentration of the $B(OH)_4^-$ anion is minor. Ocean waters contain an average boron concentration of about 4.6 g µg g^{-1}, which is almost entirely present in the form of naturally occurring boric acid. Boron in plants and animals is also present mainly as boric acid, even if the dietary source of boron is a borate salt.

4 METAL BORATES

4.1 Introduction

Metal borates can be divided into two broad classes: hydrated and anhydrous. So-called hydrated borates, which have the general formula $aM_xO{\cdot}bB_2O_3{\cdot}CH_2O$, contain B-OH groups, sometimes interstitial OH^-, and may also contain interstitial water. Anhydrous borates do not contain water, OH^-, or B-OH groups, and have the general formula $aM_xO{\cdot}bB_2O_3$. As crystalline compounds, hydrated borates typically crystallize from aqueous solutions under relatively mild conditions. Anhydrous borates nearly always form at high temperatures, often crystallizing from molten inorganic systems. It is unusual to obtain anhydrous borates from aqueous solutions except occasionally under hydrothermal conditions. In terms of tonnage, the vast majority of synthetic industrial borates are hydrated, and most mineral borates also fall into this category. However, crystalline anhydrous borates have received considerable attention in the scientific literature because of their potential for use in smaller-scale advanced technology applications, such as optoelectronic devices. The structural chemistry of anhydrous metal borates has been reviewed.[46]

Metal borates have been prepared in hydrated or anhydrous forms from most metals in the periodic table and have many small to medium scale applications. The general method used to prepare hydrated metal borates involves mixing an aqueous solution of boric acid or an alkali metal borate with aqueous solutions or suspensions of metal oxides, halides, or sulfates. The resulting precipitates of metal borates may be either crystalline or amorphous solids of slight to moderate solubility. Most metals can produce several different crystalline borates. In the case of crystalline hydrated borates, the specific crystalline form obtained generally depends on the relative concentrations of starting materials and the temperature. Salts of metals that produce highly insoluble hydroxides frequently produce complex hydroxide gels upon reaction with soluble borate salts rather than metal borate compounds. These gels, which may contain significant amounts of adsorbed borate, have often been incorrectly described as true metal borate compounds, particularly in the older literature. Anhydrous metal borates are either prepared by dehydration of the

appropriate hydrate at 300–1000 °C, or by direct fusion of metal oxides with boric acid or boric oxide, with the crystalline form produced governed by temperature and reactant ratios.

Both hydrated and anhydrous metal borates have numerous industrial uses. Some of the major uses of hydrated metal borates are the manufacture of glasses, ceramics, and industrial fluids, and as micronutrient fertilizers, fire retardants, and biostats. Anhydrous borates find use as heterogeneous catalysts, scintillation hosts, and in the fabrication of optoelectronic devices. Anhydrous aluminum borates are used as additives in oxide ceramics to promote the formation of desirable phases. Also, aluminum borate whiskers are used as reinforcing additives in composite materials. Specific uses of sodium, calcium, zinc, and barium borates are discussed in sections below.

Two fundamental problems are encountered when discussing metal borates. One is nomenclature, and the other is the chemical formulation or notation of chemical structures. To illustrate this dilemma, consider the common mineral and commercial product, borax. It is usually referred to as sodium tetraborate decahydrate and written as $Na_2B_4O_7{\cdot}10H_2O$. Alternatively, it is often written in the oxide formula, $Na_2O{\cdot}2B_2O_3{\cdot}10H_2O$ and named sodium(1:2)borate decahydrate. Finally, the structural formula $Na_2[B_4O_5(OH)_4]{\cdot}8H_2O$, or sodium tetraborate octahydrate, is used on the basis of the actual structure of this compound, which contains the tetraborate anion (**5**).

The sodium tetraborate decahydrate system is used almost exclusively in commerce, the oxide system in classical mineralogy, and the more correct structural designation in chemical discussions. The *Chemical Abstract Service* (CAS) has devised another more computer-compatible system for inorganic borates based on hypothetical acid salts. The CAS system is not used except in indexing by that reference source. The metal salt names are used commonly for refined products, for example, sodium tetraborate decahydrate for borax. The problem with this nomenclature is that it is based on the fictitious $[B_4O_7]^{2-}$ ion, gives an incorrect count for waters of hydration, and does not recognize the presence of hydroxyl groups. This is also true of the oxide formulas, which are often used for mineral and glass compositions. The structural designation $Na_2[B_4O_5(OH)_4]{\cdot}8H_2O$ correctly identifies the tetraborate ion (**5**) in the crystalline compound and correctly defines the hydroxyl groups and waters of hydration.

4.2 Borate Minerals

Most boron-containing minerals are alkali metal and alkaline earth borate salts. These compounds are the subject of earlier reviews.[2,15,47,48] More than 230 naturally occurring borate minerals have been identified.[2] The most abundant of these is the tourmaline group of aluminoborosilicate minerals, $(Na,Ca)(Mg,Li,Al,Fe^{2+})_3Al_6B_3Si_6(OH)_4$, which may contain roughly 10% boron by weight but have not been found in sufficient grades for economic mining. Concentrated, commercially exploitable borate deposits are found mainly in arid parts of the world. By far, the most extensive deposits have been located in Turkey and western United States. Other important deposits are located in Russia, China, Chile, and Argentina. Table 5 identifies the principal minerals that serve as sources of industrial borates. Over 80% of the world's borate production is divided between Turkey and the United States. In some cases, minerals, particularly colemanite and ulexite, are sold directly as commercial products after minimal refining steps that might include crushing, grinding, and blending. Major uses for these beneficiated minerals are in the manufacture of fiberglass and ceramics, and as raw materials for the production of boric acid and other boron-containing products. Table 6 lists the quantities of the principal minerals being mined worldwide.[49]

4.3 Sodium Tetraborates

Four sodium tetraborates are important as boron minerals and/or large tonnage items of commerce. Borax, or sodium tetraborate decahydrate, is extracted from large open-pit mines in Turkey and the United States. Turkish beneficiated native borax, also referred to by the mineral name tincal, is used directly in glass making and other applications. Refined borax is used widely in consumer products and as

Table 5 Commercially significant borate minerals

Mineral	Oxide formula	Structural formula	B_2O_3 (wt%)
Ascharite (szaibelyite)	$2MgO{\cdot}B_2O_3{\cdot}H_2O$	$Mg_2(OH)[B_2O_4(OH)]$	41.4
Colemanite	$2CaO{\cdot}3B_2O_3{\cdot}5H_2O$	$Ca[B_3O_4(OH)_3]{\cdot}H_2O$	50.8

Tincal (borax)	$Na_2O{\cdot}2B_2O_3{\cdot}10H_2O$	$Na_2[B_4O_5(OH)_4]{\cdot}8H_2O$	36.5
Ulexite	$Na_2O{\cdot}2CaO{\cdot}5B_2O_3{\cdot}16H_2O$	$NaCaB_5SiO_6(OH)_6{\cdot}5H_2O$	43.0

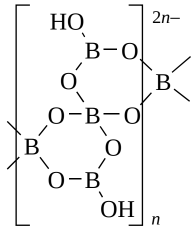
Table 6 Worldwide production of boron minerals in 2002[49]

Country	Metric tons (×1000)	Minerals
Turkey	1500	tincal, colemanite, ulexite
United States	1200	tincal, kernite, borate brines
Russia	1000	ascharite, datolite, inderite, hydroboracite
Argentina	500	tincal, ulexite, colemanite, hydroboracite
Chile	330	ulexite
China	150	ascharite, tincal, meyerhofferite, kernite
Bolivia	35	ulexite
Peru	30	ulexite

a starting material for the manufacture of other chemicals. Sodium tetraborate pentahydrate, also known as the mineral tincalconite, is produced by recrystallization of borax above approximately 60.8 °C, and is the boron compound sold in the largest quantities worldwide. Sometimes referred to as borax pentahydrate, this is the borate product produced in the largest tonnage worldwide. Its largest use is in the manufacture of insulation fiberglass. The crystal structures of sodium tetraborate pentahydrate and decahydrates are both based on the tetraborate ion (**5**), with three and eight molecules of water of hydration respectively. A single-crystal X-ray analysis shows that the pentahydrate contains only 4.67 equivalent waters of hydration because two of the three hydration sites in its structure are only partially occupied.[50] The structural formula of the 'pentahydrate' is therefore $Na_2[B_4O_5(OH)_4]\cdot 2.67H_2O$, and the common and the oxide formulas are $Na_2B_4O_7\cdot 4.67H_2O$ and $Na_2O\cdot 2B_2O_3\cdot 4.67H_2O$ respectively.

The oxide formula of the mineral kernite, $Na_2B_4O_7\cdot 4H_2O$, gives the impression that it contains the same tetraborate structure as sodium tetraborate penta- and decahydrates, but its actual structure is quite different. Kernite has the structural formula $Na_2[B_4O_6(OH)_2]\cdot 3H_2O$ and contains an anionic borate structural unit consisting of infinite parallel chains of composition $[B_4O_6(OH)_2]_n^{2n-}$ (**7**), made up of triborate rings linked through shared tetrahedral boron atoms.[51] The relatively slow dissolving and crystallization rates of kernite are consistent with this polymeric structure. Kernite is mined in the United States and converted to boric acid. Kernite can also be hydrated to borax decahydrate and refined into borax pentahydrate.

Anhydrous sodium tetraborate can exist in several crystal forms but it most commonly occurs as a glassy amorphous product that is used in fused glasses and related products. The commercial compound is prepared by fusing sodium tetraborate hydrates in a furnace. The resulting melt is pressed between chilled rollers to produce sheets of glassy product that is ground, screened to appropriate sized granules, and packaged for sale.



(**7**)

Aqueous solubilities of these sodium borates, as well as other borate salts of commercial interest, are listed in Table 7. Kernite, because of its polymeric structure, is the least soluble of the sodium borates.

4.4 Other Sodium Borates

Four additional sodium borates are produced commercially in smaller quantities. So-called 'disodium octaborate tetrahydrate' is a commercial product having the hypothetical formula $Na_2B_8O_{13}\cdot 4H_2O$. This is not a discrete crystalline compound but rather an amorphous spray-dried material having an approximate composition in agreement with this chemical formula. It has a little crystalline character and dissolves rapidly in water without the temperature decrease that normally occurs when crystalline sodium borates are dissolved. It also readily forms supersaturated solutions in hot water. The ratio of sodium to boron in this material is such that maximum solubility is achieved. Table 8 illustrates the increased solubility of disodium octaborate tetrahydrate compared to borax or sodium borate decahydrate and the magnitude of the supersaturation observed. Disodium octaborate tetrahydrate is marketed under various trade names depending on intended use. Major uses of this product are as a boron source in agriculture, a diffusible wood preservative, a flame retardant for cellulosic materials, and for the control of insect pests.

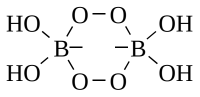
0	2.4	1.6	0.7
20	9.5	6.3	1.7
50	32.0	21.2	6.5
94	45.3	30.0	21.0

A sodium pentaborate having the oxide formula $Na_2O{\cdot}5B_2O_3{\cdot}10H_2O$ is a minor commercial product. It exists in nature as the relatively rare mineral sborgite, and can be prepared synthetically by crystallization from a solution having a Na_2O to B_2O_3 molar ratio of 0.2. It is sometimes referred to in the literature as sodium pentaborate pentahydrate based on the formula written as $NaB_5O_8{\cdot}5H_2O$. Its structural formula is $Na[B_5O_6(OH)_4]{\cdot}3H_2O$, containing the pentaborate anion (**3**). This borate occurs as monoclinic crystals with a specific gravity of 1.713. It melts at 54 °C and is stable in air to approximately 75 °C. Above 75 °C, the interstitial water begins to be released.

There are two sodium metaborates of commercial significance. These have oxide formulas $Na_2O{\cdot}B_2O_3{\cdot}4H_2O$ and $Na_2O{\cdot}B_2O_3{\cdot}8H_2O$. Here again, there is considerable confusion in the nomenclature applied to these borates. As articles of commerce, these are referred to as 'sodium metaborate 4 Mol' and 'sodium metaborate 8 Mol', according to the oxide formulas. However, these are often referred to in the literature as sodium metaborate dihydrate and sodium metaborate tetrahydrate based on their formulas written as $NaBO_2{\cdot}2H_2O$ and $NaBO_2{\cdot}4H_2O$. These compounds have the structural formulas $Na[B(OH)_4]$ and $Na[B(OH)_4]{\cdot}2H_2O$, respectively, and contain the tetrahedral $B(OH)_4^-$ anion with either no or one interstitial water molecule. The $Na[B(OH)_4]{\cdot}2H_2O$ compound is obtained as monoclinic crystals, sp gr 1.743, by cooling a borax solution containing slightly more than the theoretical amount of sodium hydroxide. This is the stable phase in contact with its saturated solution at 11.5–53.6 °C. Above 53.6 °C, $Na[B(OH)_4]$ becomes the stable solid in contact with its solution. This compound is obtained as triclinic crystals, sp gr 1.909, by heating a slurry of the tetrahydrate above 53.6 °C, by crystallization from metaborate solution at 53.6–80 °C, or by vacuum dehydration of the tetrahydrate. The higher hydrate loses water slowly on standing at room temperature and melts at 90–95 °C. The metaborates are currently produced in relatively small quantities for use in industrial applications, such as photographic solutions. It can be seen from Table 7 that the sodium metaborates are among the most soluble of the sodium borates. They dissolve in water to give solutions having a pH of about 11 and can be considered as the endpoint products of the titration of boric acid with strong base.

4.5 Sodium Perborates

Perborates, or peroxoborates, are usually written as if the perborate anion were BO_3^-. The three known sodium perborates are therefore commonly referred to as the mono-, tri-, and tetrahydrates, $NaBO_3{\cdot}nH_2O$, where $n = 1$, 3, and 4. However, these actually contain the cyclic dianion (**8**). On the basis of this structure, these compounds are more correctly referred to as anhydrous, tetrahydrate, and hexahydrate.



(**8**)

Using the established nomenclature, the so-called mono- and tetrahydrates, which are also referred to as PBS-1 and PBS-4 respectively, are important commercial products. Both have been used extensively as bleaching agents in home laundry detergent formulations. These are crystalline powders that decompose in water with formation of peroxoborate species, including $(HO)_2BOOH$, $[(HO)_3BOOH]^-$, and $[(HO)_2B(OOH)_2]^-$, and ultimately liberate hydrogen peroxide. Thus, they provide a convenient means of handling latent hydrogen peroxide in a dry powder form. There is considerable evidence that peroxoborates provide greater selectivity in oxidation reactions than H_2O_2 alone. The tetrahydrate is manufactured in large tonnages by reaction of hydrogen peroxide with a metaborate solution prepared from sodium hydroxide and sodium tetraborate pentahydrate. The monohydrate is produced by the reversible dehydration of the tetrahydrate. The tetrahydrate contains 10.4 wt% active oxygen, and its decomposition in water is accelerated by metal and transition metal catalysts and temperature. Unless a stabilizer is added, solutions will slowly lose active oxygen at room temperature. It melts in its own water of hydration at 63 °C. On heating to 250 °C, it decomposes rapidly to oxygen and sodium metaborate. Water solubilities of the tetrahydrate are 2.5 wt% at 20 °C and 3.6 wt% at 29 °C. Sodium perborate monohydrate, $NaBO_3{\cdot}H_2O$, has a higher active oxygen content of 16.0% and is prepared commercially by dehydration of the tetrahydrate. The monohydrate also exhibits a much faster rate of solubility in water than the tetrahydrate. Sodium perborate trihydrate, $NaBO_3{\cdot}3H_2O$, is not a commercial product but can be prepared as a triclinic solid containing 11.8 wt% active oxygen by the controlled dehydration of the tetrahydrate, or by seeding a hydrogen peroxide-sodium metaborate solution. Sodium perborates can be used as convenient and versatile oxidizing agents for organic syntheses.[52] Perborates salts of other metals are also know, for example, magnesium perborate.

4.6 Other Alkali Metal Borates

Although potassium and lithium borates are produced commercially, their usage is small compared to sodium and calcium borates. Potassium tetraborate, $K_2[B_4O_5(OH)_4]\cdot 2H_2O$ ($K_2B_4O_7\cdot 4H_2O$), and pentaborate, $K[B_5O_6(OH)_4]\cdot 4H_2O$ ($KB_5O_8\cdot 4H_2O$), have the same borate anions as found in the corresponding crystalline sodium borates (**5** and **3**, respectively). When the tetraborate is heated, reversible water loss begins between 85 and 111 °C. Thermogravimetric analysis shows that two moles of water are lost by 140 °C, one more at 200–230 °C, and the last one at 250–290 °C. Potassium pentaborate tetrahydrate is stable in a vacuum to 105 °C and up to 170 °C in an atmosphere saturated with water at 90 °C. Lithium tetraborate, $Li_2[B_4O_5(OH)_4\cdot H_2O]$ ($Li_2B_4O_7\cdot 3H_2O$), and lithium metaborate, $Li[B(OH)_4]$ ($LiBO_2\cdot 2H_2O$), are manufactured in relatively small quantities.

Single crystals of anhydrous lithium borates are grown from high-temperature molten salt for use in optoelectronic devices. Crystalline anhydrous lithium triborate, LiB_3O_5, is used commercially as a nonlinear optical material to convert light from high-powered lasers from higher to lower frequencies. Its attributes in this application include a wide transparency range and high-damage threshold. Crystalline anhydrous lithium tetraborate, $Li_2B_4O_7$, is used as a piezoelectric material in mobile communications devices such as cellular phones and pagers.

4.7 Calcium Borates

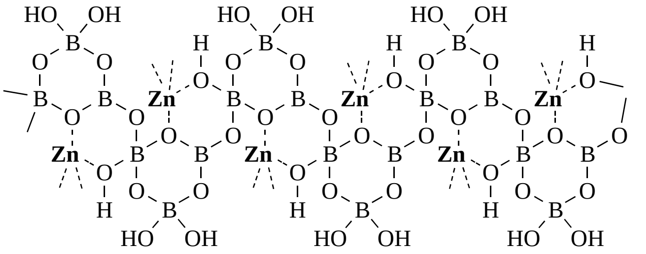
A number of crystalline calcium borates are known that occur as either minerals or synthetic compounds. The most important calcium borate mineral is colemanite, $2CaO\cdot 3B_2O_3\cdot 5H_2O$. This mineral exists in nature as monoclinic crystals having a specific gravity of 2.42. Colemanite contains polymeric chains of the triborate anion $[B_3O_4(OH)_3]_n^{2n-}$.[53] At 480 °C, colemanite decrepitates violently, losing all of its water and forming a low-bulk density powder. The water solubility of colemanite is relatively low for a borate, 0.1 wt% at 25 °C and 0.38 wt% at 100 °C.

A second important calcium borate is the mineral ulexite, $NaCaB_5O_9\cdot 8H_2O$ or $Na_2O\cdot 2CaO\cdot 5B_2O_3\cdot 16H_2O$. It can also be prepared synthetically by seeding an aqueous solution of calcium metaborate, boric acid, borax, and probertite, $NaCaB_5O_9\cdot 5H_2O$. Ulexite crystals are triclinic with a specific gravity of 1.95. When ulexite is heated, four moles of water are lost at 80–100 °C, 8.5 more at 175 °C, and the remaining 3.5 moles at 450 °C. Ulexite has the structural formula $NaCa[B_5O_6(OH)_6]\cdot 5H_2O$ and contains the pentaborate trianion.[54] This anion is similar to (**3**) with two additional hydroxyl groups bound to two of the trigonal borons making them tetrahedral. An unusual property of some ulexite crystals is their ability to behave as fiber optic material and project images through the crystals in one direction. Ulexite has a relatively low water solubility, 0.5 wt% as NaB_5O_9 at 25 °C. The related mineral probertite, $NaCaB_5O_9\cdot 5H_2O$ or $Na_2O\cdot 2CaO\cdot 5B_2O_3\cdot 10H_2O$, is less common than ulexite. Its crystals are monoclinic and have a specific gravity of 2.1. It has the structural formula, $NaCa[B_5O_6(OH)_4]\cdot 3H_2O$ based on a polymeric pentaborate anionic structural unit.[55] Both colemanite and ulexite are mined in large tonnages in Turkey and sold as impure concentrates for use worldwide in the manufacture of textile and insulation fiberglass. Colemanite is also used in the manufacture of ceramic glazes. Ulexite ores are also produced in South America and used as a raw material for the production of boric acid.

4.8 Zinc Borates

The industrial importance of the zinc borates has increased in recent years. Several unique crystalline hydrated zinc borates are known, exhibiting a range of structure types illustrative of the diversity of borate chemistry. Well substantiated crystalline zinc borates have the compositions $4ZnO\cdot B_2O_3\cdot H_2O$,[56–59] $ZnO\cdot B_2O_3\cdot 1.12H_2O$,[60] $ZnO\cdot B_2O_3\cdot 2H_2O$ (or $2ZnO\cdot 2B_2O_3\cdot 3H_2O$), $6ZnO\cdot 5B_2O_3\cdot 3H_2O$,[61] $2ZnO\cdot 3B_2O_3\cdot 7H_2O$,[62] $2ZnO\cdot 3B_2O_3\cdot 3H_2O$,[57] $2ZnO\cdot 3B_2O_3\cdot 9H_2O$ (or $3ZnO\cdot 5B_2O_3\cdot 14H_2O$), and $ZnO\cdot 5B_2O_3\cdot 4.5H_2O$,[61] spanning a range of B_2O_3:ZnO mole ratios from 0.25 to 5. Each of these compounds can be prepared selectively by aqueous reactions of zinc oxide with boric acid, or by reactions of zinc and borate salts, with the specific compound obtained determined by reactant concentrations and temperature. Only $4ZnO\cdot B_2O_3\cdot H_2O$, $ZnO\cdot B_2O_3\cdot 1.12H_2O$, $2ZnO\cdot 3B_2O_3\cdot 7H_2O$, and $2ZnO\cdot 3B_2O_3\cdot 3H_2O$ have been structurally characterized, and compositions of the remaining four should be considered approximate until their structures are elucidated. The compound $4ZnO\cdot B_2O_3\cdot H_2O$ has the structural formula $Zn_2(BO_3)OH$ and consists of corrugated sheets of oxygen-sharing ZnO_3OH tetrahedra interconnected by BO_3 triangles into an infinite network.[58,59] This structure is noncentrosymmetric as first shown some years after this compound had become a commercial product, by the structure determination of the closely related OH/F disordered compound $Zn_2(BO_3)(OH)_{0.75}F_{0.25}$, which gives essentially the same X-ray pattern.[59] The compound $ZnO\cdot B_2O_3\cdot 1.12H_2O$ consists of a complex extended network of unusual, large $B_{12}O_{24}{}^{12-}$ polycyclic borate units interconnected by cationic Zn_3O_3 clusters into an infinite network.[60] This results in an open framework solid containing one water molecule coordinated to each zinc atom as well as some additional interstitial water. The compound $2ZnO\cdot 3B_2O_3\cdot 7H_2O$ has the structural formula $Zn[B_3O_3(OH)_5]\cdot H_2O$, and contains isolated $[B_3O_3(OH)_5]^{2-}$ anions.[62] The compound $2ZnO\cdot 3B_2O_3\cdot 3H_2O$ has the structural formula $Zn[B_3O_3(OH)_5]\cdot H_2O$, and contains infinite chains of triborate rings similar to those found in the calcium borate mineral colemanite, interconnected by coordination with zinc (**9**).[57]

A few zinc borates are currently manufactured in significant tonnages. Most of the zinc borates listed above have



(**9**)

limited usefulness because of their low dehydration on-set temperatures, ruling out uses requiring processing at elevated temperatures. The most important commercial zinc borate in use today is $2ZnO{\cdot}3B_2O_3{\cdot}3H_2O$, which has worldwide annual production greater than 10 000 metric tons. This zinc borate is mainly used as a polymer additive and as a preservative for wood composites and other engineered wood products. As a polymer additive, it serves as a fire retardant synergist, char promoter, antidrip agent, smoke and afterglow suppressant, and modifier of electrical and optical properties.[63] It has also been used as an adhesion promoter in steel-belted tires. Addition to ceramic bodies can also improve green strength and reduce firing times and temperatures. Added to coatings, it functions as a corrosion inhibitor, fire retardant, preservative, mildewstat, and tannin stain blocker.[64] Important properties of $2ZnO{\cdot}3B_2O_3{\cdot}3H_2O$ include a relatively low water solubility of about 0.28 wt% and a relatively high dehydration on-set temperature, $>290\,°C$. The latter property permits processing in a wide range of polymer systems and construction products. Also, its low refractive index (1.58) permits the manufacture of transparent or translucent articles. As an article of commerce, $2ZnO{\cdot}3B_2O_3{\cdot}3H_2O$ is generally referred to as $2ZnO{\cdot}3B_2O_3{\cdot}3.5H_2O$ or $4ZnO{\cdot}6B_2O_3{\cdot}7H_2O$. These slightly incorrect formulas result from an original error in characterization.[57]

In addition to $2ZnO{\cdot}3B_2O_3{\cdot}3H_2O$, the zinc borates $2ZnO{\cdot}3B_2O_3{\cdot}7H_2O$, $2ZnO{\cdot}3B_2O_3{\cdot}9H_2O$, $ZnO{\cdot}B_2O_3{\cdot}2H_2O$, and $4ZnO{\cdot}B_2O_3{\cdot}H_2O$ have all been produced commercially on multiton scale. The first two exhibit low thermal stability, limiting their commercial applicability, and $ZnO{\cdot}B_2O_3{\cdot}2H_2O$ is stable to about 200 °C. The compound $4ZnO{\cdot}B_2O_3{\cdot}H_2O$ or $Zn_2(BO_3)OH$ has the highest thermal stability of the commercially manufactured hydrated zinc borates, with a dehydration on-set temperature of 410–415 °C.[56] This high dehydration temperature allows the use of this zinc borate in engineering thermoplastics processed at high temperatures. More than a decade after this compound was in commercial production on a multiton scale, it was rediscovered by the materials science community and reported to have interesting photoluminescent and photovoltaic properties.[58]

4.9 Barium Borates

Both hydrated and anhydrous barium borates find significant commercial use. Barium metaborate monohydrate, $BaO{\cdot}B_2O_3{\cdot}H_2O$, is used as a corrosion inhibitor in industrial paints and primers, a biocide in paints and plastics, and to a lesser extent as a fire retardant additive. It is generally manufactured by reacting barium sulfate with a sodium tetraborate hydrate in water. Several other crystalline hydrated barium borates are also known but have less industrial importance.

Crystalline anhydrous beta barium borate, β-$BaO{\cdot}B_2O_3$ or β-BaB_2O_4, has technological importance as a nonlinear optical material. Its attributes in this application include transparency over a wide range of frequencies and phase matching ranges, a large nonlinear coefficient, high-damage threshold, and good optical homogeneity well in the UV region.[65]

5 NONMETAL BORATES

5.1 Introduction

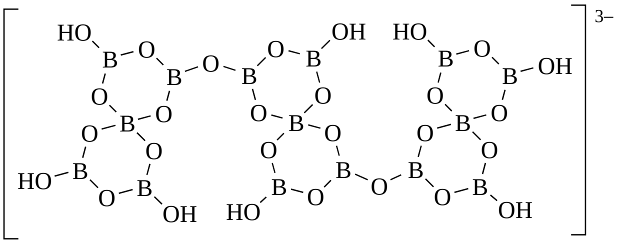
Ammonia, alkylamines, and other proton acceptor species can react with boric acid in aqueous or alcoholic solutions to form a wide range of crystalline nonmetal borate salts.[66] Borate salts of aprotic nonmetal cations, such as quaternary ammonium cations, have also been characterized.[67,68] The ammonium borates are significant commercial products, and the recognition that both protic and aprotic nonmetal cations can stabilize unusual borate anions has led to increased interest in the study of this area.

5.2 Ammonium Borates

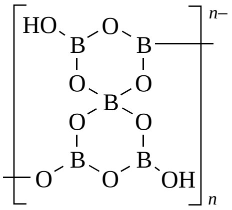
The ammonium cation represents one of the simplest examples of a nonmetal cation. This cation is only slightly less acidic than boric acid itself and cannot form salts with borate anions more basic than tetraborate (**5**), and even this salt has marginal stability. Thus, the hypothetical ammonium metaborate, NH_4^+ $[B(OH)_4]^-$, does not exist as a stable solid. Of the nonmetal borates, only ammonium pentaborate, $NH_4[B_5O_6(OH)_4]{\cdot}2H_2O$ or $(NH_4)_2O{\cdot}5B_2O_3{\cdot}8H_2O$, and ammonium tetraborate, $NH_4[B_4O_7(OH)_4]{\cdot}4H_2O$ or $(NH_4)_2O{\cdot}2B_2O_3{\cdot}4H_2O$, are manufactured in significant commercial quantities. Ammonium pentaborate is more stable than the tetraborate, which exhibits a significant vapor pressure of ammonia under atmospheric conditions. When the pentaborate is heated from 100 to 230 °C, it loses 75% of its water content but less than 1% of its ammonia. The pentaborate crystallizes in two forms, orthorhombic and monoclinic. The orthorhombic form crystallizes as the kinetic product, which is sold commercially. Solubilities of ammonium borates are given in Table 7.

Prolonged reflux of an aqueous slurry of ammonium pentaborate results in quantitative conversion to $[NH_4]_3[B_{15}O_{20}(OH)_8]{\cdot}4H_2O$, also known as the mineral

ammonioborite. This compound contains the unusual 15-boron anion, $[B_{15}O_{20}(OH)_8]^{3-}$ (**10**), produced by the formal condensation of three pentaborate anions (**3**). Another ammonium borate mineral, larderellite, $[NH_4][B_5O_7(OH)_2]\cdot H_2O$, contains an anionic structural unit composed of an infinite chain of condensed pentaborate anions (**11**). Both the isolated trianion (**10**) in ammonioborite and the chain polyanions (**11**) in larderellite are so far known to occur only with the ammonium cation.



(**10**)



(**11**)

5.3 Other Nonmetal Borates

Most nonmetal borates reported in the literature are ammonium and substituted ammonium salts. In general, boric acid forms salts with alkyl- or aryl-amines that are roughly as or more basic than pyridine. Depending on the reaction conditions, a number of different crystalline borates might be isolated from a given amine. However, the chemistry of substituted amine borates is dominated by the occurrence of pentaborates, and relatively few compounds in this class have been reported containing more basic borates anions.

Nonmetal cations can stabilize other unusual borate structures. For example, the tetraethylammonium cation can be used to crystallize the compound $[NEt_4]_2[BO(OH)_2]_2\cdot B(OH)_3\cdot 5H_2O$, which contains a rare example in a crystal structure of the Arrhenius conjugate base of boric acid, the $[BO(OH)_2]^-$ anion.[67] This anion is also found in the related urea inclusion compound $[NMe_4]_2[BO(OH)_2]\cdot 2(NH_2)_2CO\cdot H_2O$, containing the tetramethylammonium cation.[68] Another unusual borate species found only with nonmetal cations is the nona-borate trianion, $[B_9O_{12}(OH)_6]^{3-}$. This isolated anion is found in the imidazolium and guanidinium borates, $[C_3H_5N_2]_3[B_9O_{12}(OH)_6]$ and $[C(NH_2)_3]_3[B_9O_{12}(OH)_6]$, which form readily upon reaction of boric acid with imidazole or guanidinium carbonate, respectively, in hot water.[69]

6 BORIC ACID ESTERS

6.1 Introduction

Ebelman and Bouquet prepared the first examples of boric acid esters in 1846 from boron trichloride and alcohols.[70] Literature reviews of this subject are available.[71,72] The general class of boric acid esters includes the more common orthoboric acid based trialkoxy- and triaryloxyboranes, $B(OR)_3$ (**1**), and also the cyclic boroxins, $(ROBO)_3$, which are based on metaboric acid (**2**). The boranes can be simple trialkoxyboranes, cyclic diol derivatives, or more complex trigonal and tetrahedral derivatives of polyhydric alcohols. Nomenclature is confusing in boric acid ester chemistry. Many trialkoxy- and triaryloxyboranes such as methyl, ethyl, and phenyl are commonly referred to simply as methyl, ethyl, and phenyl borates. The IUPAC boron nomenclature committee has recommended the use of trialkoxy- and triaryloxyboranes for these compounds, but they are referred to in the literature as boric acid esters, trialkoxy and triaryloxy borates, trialkyl and triaryl borates or orthoborates, and boron alkoxides and aryloxides. The IUPAC nomenclature will be used in this review except for relatively common compounds such as methyl borate. Boroxins are also referred to as metaborates and more commonly as boroxines. Boroxin is preferred by the IUPAC nomenclature committee and will be used in this review.

6.2 Trialkoxy- and Triaryloxyboranes

6.2.1 Properties

Trialkoxy- and triaryloxyboranes are more systematic names for $B(OR)_3$ and $B(OAr)_3$ compounds. These are more commonly referred to simply as alkyl and aryl borates, for example, methyl borate for $B(OCH_3)_3$ and phenyl borate for $B(OC_6H_5)_3$. This class contains compounds ranging from low-boiling liquids to high-melting solids. Some physical properties of selected members of this class are included in Table 9. These compounds contain sp^2 hybridized trigonal planar boron atoms. As with other trivalent boron compounds, the vacant $2p_z$ orbital imparts a Lewis acid character, and many of their reactions involve a tendency to accept unshared electrons from donor species. Trialkoxy- and triaryloxyboranes are generally monomeric and soluble in most organic solvents. They also dissolve in water with reactions as discussed below.

6.2.2 Preparation and Uses

Trialkoxy- and triaryloxyboranes can be prepared by a variety of methods. The original procedure from boron trichloride and alcohols (equation 7) is not practical on a commercial scale but can be used to prepare laboratory

Table 9 Some properties of boric acid esters

Compound	Formula	Mp (°C)	Bp (°C)	d_4^t
Methyl borate	$B(OMe)_3$	−29	68.0–68.5	0.920
Methyl borate azeotrope	$B(OMe)_3{\cdot}MeOH$	–	54.3	0.880
Ethyl borate	$B(OEt)_3$	−84.8	117–119	0.859
Ethyl borate azeotrope	$B(OEt)_3{\cdot}7.75EtOH$	–	76.6	–
n-Propyl borate	$B(O\text{-}n\text{-}Pr)_3$	–	176–179	0.856
Isopropyl borate	$B(O\text{-}i\text{-}Pr)_3$	–	139–140	0.815
n-Butyl borate	$B(O\text{-}n\text{-}Bu)_3$	–	227	0.856
2,2′-Oxybis(4,4,6-trimethyl-1,3,2-dioxaborinane) (**12**)	$C_{12}H_{24}B_2O_5$	–	114–115 at 0.27 kPa	1.013
2,2′-[(l-Methyl-1,3-propanediyl)-bis(oxy)1-bis(4-methyl-1,3,2-dioxaborinane)] (**13**)	$C_{12}H_{24}B_2O_6$	–	207–213	1.071
Phenyl borate	$B(OPh)_3$	80–90	360–370	–
Triethanolamine borate (**15**)	$B(OCH_2CH_2)_3N$	–	235–237	–
Methylboroxin	$(OBOMe)_3$	–	dec.	1.2286
n-Propylboroxin	$(OBO\text{-}n\text{-}Pr)_3$	52–54	235–239 dec.	–

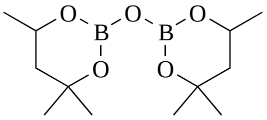
quantities of esters. For larger quantities, boric acid or boric oxide is generally reacted with alcohols or phenols (equations 8 and 9). The equilibria in these reactions, which lie far to the left, must be shifted to the right by removal of product water. This is usually accomplished by isotropic distillation with excess alcohol or phenol or by adding a suitable azeotroping solvent. The preparations of methyl and ethyl borates are further complicated because these borates form azeotropes with their respective alcohols. In these cases, the azeotrope must be isolated and the pure ester separated in a second step. Improved yields of trialkoxy- and triaryloxyboranes and boroxins can be achieved by removing product water with anhydrous calcium hydride.[73] Derivatives of slow reacting, sterically hindered alcohols can be successfully prepared by this method.

$$BX_3 + 3ROH \longrightarrow B(OR)_3 + 3HX \quad (7)$$

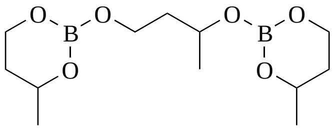
$$B(OH)_3 + 3ROH \longrightarrow B(OR)_3 + 3H_2O \quad (8)$$

$$B_2O_3 + 6ROH \longrightarrow 2B(OR)_3 + 3H_2O \quad (9)$$

The largest volume uses of boric acid esters are in the captive production of methyl borate as an intermediate in the production of sodium borohydride and isopropylborate as an intermediate in the production of triphenylboron for use as a cocatalyst in polyamide production. Also significant, are uses of boric acid esters as fuel additives, wood preservatives, and as components in many different kinds of industrial fluids, including lubricants, hydraulic fluids, metal cutting fluids, and so forth. A mixture of the two dioxaborinanes (**12**) and (**13**) is sold as the microbiocide that is used as an additive for control of slime and sediment-producing microorganisms in hydrocarbon jet and diesel fuels. Methyl borate azeotrope is used as a gaseous flux in welding and brazing. Borate esters may also be used as polymer additives and epoxy resin curing agents.



(**12**)



(**13**)

Another convenient method, for the preparation of higher-boiling trialkoxy- and triaryloxyboranes, in particular, is the transesterification of lower-boiling boranes (equation 10). The lower boiling alcohol is removed continuously by distillation.

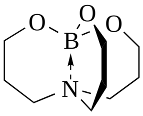
$$B(OR)_3 + 3R'OH \longrightarrow B(OR')_3 + 3ROH \quad (10)$$

The conversion of boron compounds to trialkoxyboranes is the basis for a widely used historic prospecting procedure for identification of borate minerals. By adding a mineral acid and methanol to a ground mineral sample and then igniting the mixture, one can observe whether it burns with the green flame of volatile methyl borate.

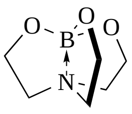
6.2.3 *Reactions*

Most trialkoxy- and triaryloxyboranes react readily with water, hydrolyzing to boric acid and alcohol (reverse of equation 8). This susceptibility to hydrolysis, even with atmospheric moisture, has limited their usefulness in commercial applications. Partially hydrolyzed intermediates such as $(RO)_2BOH$, are usually isolated only with compounds containing large substituent groups, but hydrolysis usually proceeds completely to boric acid. Hydrolysis rates observed with esters derived from short-chain primary aliphatic alcohols and unhindered phenols are very fast, but significant rate decreases are observed as the substituent groups become large and bulky. This probably results from

the demanding steric requirements of the sp^3 hybridized transition state formed when the boron center undergoes a nucleophilic attack by water. Compounds that have internal coordination to boron, for example, the transannular bond from the electron pair on nitrogen to boron in compounds such as tripropanolamine borate (**14**) and triethanolamine borane (**15**), exhibit good hydrolytic stability. Owing to lower ring strain, tripropanolamine borate is more resistant to hydrolysis than triethanolamine borate. Some comparative hydrolysis rates in homogeneous water-dioxane are shown in Table 10.[74] Reactions were run either at 21 °C in 60% dioxane or at 55 °C in 91% dioxane, and the relative rates adjusted to comparable values are shown in the table.



(**14**)



(**15**)

Transesterification with other alcohols and phenols (equation 10), particularly if they are high boiling, is another typical reaction of trialkoxy- and triaryloxyboranes. Similar reactions with amines proceed very slowly, and preparation of triaminoboranes by displacement of alcohols from trialkoxyboranes is not a practical synthetic route.

6.3 Boroxin

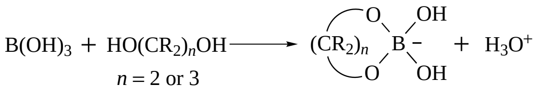
Boroxins have properties and reactivities similar to orthoborate esters. The six-membered boroxin ring structure (**2**) is approximately planar, generally exhibiting a small out-of-plane envelope deformation. The trigonal boron atoms in trialkoxyboroxins generally exhibit a stronger Lewis acid character than comparable borons in trialkoxyboranes because there is only one electron-donating alkoxy group per boron. Preparative methods are essentially the same as those noted for trialkoxyboranes except that the stoichiometry is changed. The calcium hydride method is particularly efficient for preparation of boroxins, which are difficult to prepare using azeotropic distillation. Although some boroxins have been offered commercially, no significant applications for them have been developed.

Table 10 Relative hydrolysis rates of boric acid esters in aqueous dioxane

R in $B(OR)_3$	Relative rates
Methyl, ethyl, propyl, isopropyl, *n*-butyl, isobutyl, phenyl, *o*-cresyl, *o*-phenylphenyl, *o*-cyclohexylphenyl	$>5.87 \times 10^5$
n-Pentyl	5.87×10^5
n-Hexyl	2.02×10^5
sec-Butyl	1.68×10^5
n-Octyl	3.67×10^4
Oleyl	3.53×10^4
n-Dodecyl	2.77×10^4
Stearyl	2.71×10^4
2-Octyl	4.33×10^3
2-Ethylhexyl	2.77×10^3
tert-Butyl	1.37×10^3
tert-Pentyl	4.49×10^2
3-Heptyl	4.15×10^2
Diisobutylmethyl	5.9
2-Cyclohexylcyclohexyl	3.7
Dicyclohexylmethyl	1

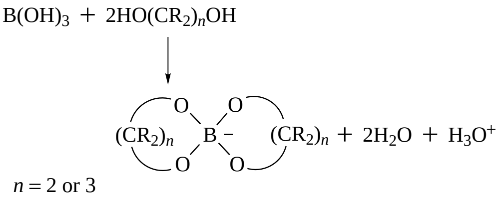
6.4 Esters of Polyhydroxy Compounds

Boric acid esters are generally hydrolytically unstable and decompose to boric acid and alcohol rapidly when exposed to moisture. However, reaction of boric acid with 1,2- and 1,3-diols having the appropriate configurations results in the formation of five- and six-membered cyclic esters (equation 11).[75] Although still hydrolytically labile, these cyclic esters have sufficiently enhanced kinetic stability to shift the reaction equilibrium significantly to the right in aqueous media. Since this reaction produces a proton, reaction of boric acid with appropriate polyols can result in strongly acidic complexes. This reaction is commonly used in procedures for determination of boric acid and other boron compounds. In this method, a sugar, such as mannitol or sorbitol, is added to boric acid and the resulting strong acid is titrated with base, where a distinct endpoint characteristic of strong acids is observed.



(11)

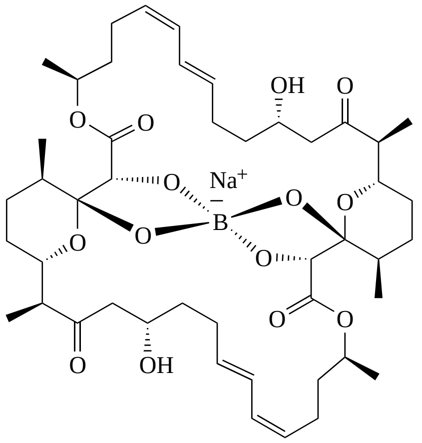
Boric acid reacts with two equivalents of diol to form spiro ester complexes as shown in equation (12). In the case where the diol is part of a polymer chain, this reaction leads to crosslinking. Addition of borates to aqueous solutions of appropriate polyhydroxylated polymers, for example, polyvinyl alcohols, guar gums, and starches, can have a dramatic effect on rheology, often resulting in gel formation. Borate crosslinking of polymers is utilized commercially in the manufacture of starch adhesives for corrugated boxes and in the formation of polyvinyl alcohol gel films to protect metal surfaces and for other applications. Reactions of this type are also exploited in boron-specific exchange resins and adsorbents to remove borates from aqueous solutions.



(12)

The interaction of borates with carbohydrates and other polyhydroxy compounds, including perhaps proteins and glycoproteins, provides a basis for the biological role of boron. It has been shown that at least one essential role of boron in plants involves ester crosslinking of the complex carbohydrate rhamnogalacturonan II (RG II) as part of an intricate control mechanism vital to the maintenance of proper plant cell wall function.[7]

Once thought rare, boron-containing natural products are now known to be widespread. Traditional methods for the isolation of organic natural product compounds involve procedures that typically result in the hydrolytic loss of boron. Thus, only in recent years have significant numbers of boron-containing natural products become recognized. Among the first boron-containing natural products characterized were macrolide antibiotics, including boromycin (**16**),[76] aplasmomycin,[77] and tartrolon B,[78] derived from streptomycetes, myxobacteria, and cyanobacteria. Studies of the metabolic roles of boron in higher plants have now revealed numerous other boron-containing natural products. For example, plants utilize borate ester of sugars to transport boron.[79] A protein specifically responsible for the active transport of boron has been identified in plants.[80]



Tartrolon B
(**16**)

The presence of adequate supplies of boron has been shown to be essential for the proper development of frogs and fish, and considerable evidence indicates that boron plays a vital role in other animals and humans.[4] Although precise biochemical mechanisms are yet to be revealed for animals, it appears likely that boron interacts through reversible ester formation in significant and necessary ways with membrane components and enzymes in animal cells.

7 BORON–SULFUR COMPOUNDS

7.1 Introduction

The detailed chemistry of boron–sulfur and related boron–selenium compounds has emerged only slowly because of a lack of suitable experimental techniques to handle these highly reactive compounds until recently. The B–S bond energy has been estimated at 100 kcal mol^{-1} in B_2S_3 compared to 164 kcal mol^{-1} for the average B–O bond in B_2O_3, and this difference is reflected in the relative reactivities of the two classes of compounds. Only in the past decade and a half have sufficient advances been made in preparative methods to allow the isolation and characterization of many compounds in this class, revealing a number of unusual compounds. Although some parallel features are shared with the more common boron–oxygen derivatives, boron exhibits a considerably different structural chemistry when combined with the heavier chalcogenides. Boron–oxygen structural chemistry is dominated by the B_3O_3 boroxin ring, whereas in boron-sulfur chemistry we see many compounds containing four- and five-membered boron–sulfur rings, leading to even greater complexity. The chemistry of boron–sulfur and boron–selenium compounds has been the subject of a review.[81] To date there are no significant commercial uses of these compounds.

7.2 Binary Boron–sulfur Compounds

A number of binary boron–sulfur compounds has been reported. Of these, B_2S_3, $(BS_2)_n$, and B_8S_{16} are probably best characterized. Diboron trisulfide, B_2S_3, can be prepared by the high-temperature reactions of elemental boron, boron hydrides, or metal borides with sulfur or other sulfur-containing compounds. It is generally obtained as a white amorphous sublimate that reacts with water and atmospheric moisture. It has been described as pale yellow, probably because of the presence of impurities. It softens at approximately 320 °C. Its reactivity leads to its use as a starting material for the preparation of a variety of organoboron compounds. Reactions with alcohols lead to borate esters, $B(OR)_3$, and with amines to triaminoboranes, $(R_2N)_3B$.

Crystalline B_2S_3 has a layered structure with sheets of interconnected six-membered B_3S_3 and four-membered B_2S_2 rings, linked by shared sulfur atoms, extending throughout the crystal. Boron disulfide, $(BS_2)_n$, has a layered structure consisting of five-membered 1,2,4-trithia-3,5-diborolane rings connected into zigzag chains by shared sulfur atoms. These chains run parallel within planes and run antiparallel to chains in adjacent layers. An analogous $(BSe_2)_n$ has been characterized. The compound B_8S_{16} contains the same trithiadiborolane rings as found in $(BS_2)_n$ except, instead of forming infinite chains, sets of four rings are linked by shared sulfur atoms into planar porphin-like macrocycles. These tetramers stack to form parallel columns.

Other reported binary boron sulfides include subvalent $B_{12}S$, a black crystalline material prepared by a high-temperature reaction of amorphous boron with elemental sulfur, and BS, which has been studied spectroscopically in an electric discharge. A vapor-phase dimer, $(BS)_2$, was identified, and a refractory condensed form of BS was reported from the reaction of elemental boron with sulfur at 1850 °C and a pressure of 94 500 atmospheres. Boron disulfide, BS_2, has been identified in the gas phase and appears to be the primary compound present in the vapor phase over diboron trisulfide or elemental boron and sulfur.

7.3 Ternary Thioborates

A few dozen metal thioborate compounds have been structurally characterized. These include $TlBS_2$, M_3BS_3 (M = Li, Tl), $Cs_2B_2S_4$, $K_2B_2S_7$, $M_3B_3S_6$ (M = Na, K, Rb), $Tl_3B_3S_{10}$, $M_6B_{10}S_{18}$ (M = Li, Ag), $Li_5B_7S_{13}$, $Li_9B_{19}S_{33}$, MB_2S_4 (M = Ba, Sr), $M_3[BS_3]_2$ (M = Ba, Sr), $Sr_3[B_3S_6]_2$, among others. These contain thioborate anions such as the trigonal planar $[BS_3]^{3-}$ and the four-, five-, and six-membered cyclic anions, $[B_3S_6]^{3-}$, $[B_2S_4]^{2-}$, and $[B_2S_5]^{2-}$, all having terminal B–S groups. A few related selenoborates have also been characterized, including Tl_3BSe_3, and the unusual selenoborate $Cs_8[B_{12}(BSe_3)_6]$, which contains a central B_{12} icosahedron, in which each boron atom is bound to a selenium atom of a bichelating BSe_3 moiety to form the $[B_{12}(BSe_3)_6]^{8-}$ anion, which has six terminal B–Se group projecting radially. The central B_{12} polyhedron possesses $2n + 2$ skeletal electrons (for n vertices), in agreement with Wade's rules, with six excess negative charges located on the terminal selenium atoms. Considerable interest has been focused on lithium and silver thioborates containing rigid anionic frameworks, since these are good candidates for superionic conducting materials.

7.4 Trialkyl- and Triarylthioboranes

Many compounds with B-S-R groups have been synthesized, including thioborates or trialkyl- and tiaryl-thioborates, $B(SR)_3$, the sulfur analogs of trialkoxy- and triaryloxyboranes, and trialkyl- and triarylborathiins, $(SBR)_3$, the sulfur analogs of boroxins. Simple thioborates are usually prepared by reactions of boron halides with thiols (equation 13).

$$BX_3 + 3RSH \longrightarrow B(SR)_3 + 3HX_3 \qquad (13)$$

These reactions usually proceed more slowly than the reactions of the corresponding alcohols or phenols with boron halides. In some cases, where direct reaction is too slow, the lead or mercury derivatives of thiols are used. Attempts to use the reactions of thiols with diboron trisulfide to prepare trialkylthioboranes have usually been unsuccessful, although analogous reactions with oxygen compounds are commonly used to prepare trialkoxyboranes. Formation of B–S bonds is more difficult than the corresponding B–O bonds, and nucleophilic displacement of RS groups proceeds more readily than with RO groups upon attack by nucleophiles such as water, alcohols, and amines. Exchange reactions with thiols also proceed readily, and these reactions can be used to prepare thioborates of higher boiling thiols (equation 14). Although a sulfur analog of boric acid has not been reported, the cyclic metaboric acid (**1**) analog, $(HSBS)_3$, has been characterized. The dimer $(HSBS)_2$ was also isolated and shown to readily convert to the trimer on heating.

$$B(SR)_3 + 3HSR' \longrightarrow B(SR')_3 + 3RSH \qquad (14)$$

8 BORON–PHOSPHORUS COMPOUNDS

The chemistry of boron–phosphorus compounds has been reviewed.[82,83] Numerous boron–phosphorus derivatives have been reported, but relatively few boron–arsenic or boron–antimony compounds have been described. Boron-phosphorus compounds are similar in many ways to boron–nitrogen derivatives, but the tendency to share bonding electrons in covalent tetrahedral compounds is much more evident with phosphorus than with nitrogen. In fact, most boron–phosphorus chemistry involves tetrahedral boron. They are typically either phosphine–borane complexes, such as $R_3P{\cdot}BR'_3$, or phosphinoboranes $(R_2PBR'_2)_n$, cyclic or polymeric derivatives of the hypothetical $H_3P{\cdot}BH_3$. The chemistry of these compounds and that of boron phosphate and thiophosphate is described below. Boron phosphides are discussed in Section 2.6.

Many phosphine-borane complexes $Y_3P{\cdot}BZ_3$ have been characterized. They include compounds where Y = alkoxy, alkyl, amino, halide, and hydride groups, and Z = alkyl, halide, and hydride. The stabilities of these complexes vary widely depending on the Lewis acidity and basicity of the boron and phosphorus moieties, respectively. The relative stabilities of Lewis acid-base complexes with BH_3 are $R_3P > R_3N > R_3As > R_3Sb$, but with BF_3 the order is $R_3N > R_3P > R_3As > R_3Sb$. The stabilities of the boron halide complexes of phosphines follow the same order as the amine complexes: $BI_3 > BBr_3 > BCl_3 > BF_3$.

The pyrolysis of phosphine-borane complexes was reported in the 1950s to give a series of cyclic and polymeric products.[84] A relatively stable monomer, H_2PBMe_2, which slowly polymerized, was isolated from the reaction of phosphine with $BrBMe_2$ in the presence of triethylamine. Pyrolysis of $Me_2PH{\cdot}BH_3$, however, yielded not the monomeric phosphinoborane but a trimer, $(Me_2PBH_2)_3$, a tetramer, $(Me_2PBH_2)_4$, and a polymeric residue with the approximate composition $(Me_2PBH_2)_n$. Since these early studies were made, a large number of phosphinoboranes has been prepared. Most of them are cyclic trimers plus a few tetramers and dimers. Although most monomers tend to cyclize or polymerize,

some stable derivatives of the type $R_2PBR'_2$, where R and R′ are bulky groups, have been isolated. The six-membered rings in phosphinoborane trimers and eight-membered rings in tetramers consist of alternating boron and phosphorus atoms with some out-of-plane puckering of the rings. These cyclic compounds are colorless crystalline solids having thermal stability. The *P*-hexamethyl trimer, for example, is stable to 250 °C in vacuum. However, decomposition is rapid in the presence of air. The boron–hydrogen bonds in these compounds are unexpectedly resistant to hydrolysis. The hypothetical compound $(HPBH)_3$, the phosphorus analog of the common boron–nitrogen trimer borazine, has not been isolated. However, derivatives of this compound containing the six-membered $(PB)_3$ moiety can be stabilized using bulky substituents on the boron and phosphorus atoms, as in $(2,4,6\text{-}Me_3C_6H_2BPC_6H_{11})_3$.[85]

Boron phosphate, BPO_4, is prepared by the dehydration of a mixture of boric acid and phosphoric acid at temperatures of 1000–1200 °C. Although BPO_4 begins to form in these mixtures at much lower temperatures, complete dehydration requires temperatures above 1000 °C. Boron phosphate is a white infusible solid that slowly vaporizes above 1450 °C without decomposition. The structure of boron phosphate prepared under atmospheric conditions consists of tetragonal bipyramids analogous to the high cristobalite forms of silica. Both boron and phosphorous atoms are tetrahedrally coordinated by oxygen. Heating the common form of boron phosphate to 500 °C at 5 GPa (50 000 atm) yields a quartz-like form. A number of hydrates of boron phosphate have been prepared: $BPO_4 \cdot nH_2O$ where $n = 3, 4, 5$, or 6. All the hydrates decompose in water to give the parent acids; anhydrous boron phosphate hydrolyzes similarly. The anhydride is used as a heterogeneous catalyst. The related compound, boron thiophosphate, BPS, is prepared by reaction of the elements or from diboron trisulfide, phosphorus, and sulfur.

9 BORON-HALOGEN COMPOUNDS

9.1 Introduction

Boron-halogen compounds, or boron halides, can be divided into three major categories that are defined by the ratios of halogens to borons. The boron trihalides (halogen:boron ratio = 3) were discovered and characterized first and represent the most common and thoroughly investigated boron halide category. Haloborates, with a halogen:boron ratio of 4, are important because of the relatively widespread commercial usage of fluoroborates. The third category, boron subhalides, with halogen:boron ratios <3, represents a theoretically interesting class of compounds that have been prepared only in relatively small quantities.

9.2 Boron Trihalides

9.2.1 *Properties*

A chronology of the discovery and characterization of the four boron trihalides is interesting since the scientists involved were some of the most prominent chemists of the 19th century:

1809	boron trifluoride	Davy, Gay-Lussac, Thénard
1824	boron trichloride	Berzelius
1846	boron tribromide	Poggiale
1891	boron triiodide	Moissan

Boron trihalides were studied extensively in subsequent years, and their chemistry has been summarized in several reviews.[86–88] They are also referred to as trihaloboranes, but boron trihalide is used more frequently. Boron trihalides are trigonal molecules with bond angles of the expected 120°. This sp^2 hybridized state leaves a vacant $2p_z$ orbital on boron, a characteristic that, as with other boron compounds, provides the basis for much of the chemistry of boron halides. The measured bond lengths in boron trihalides are shorter than calculated, and their Lewis acidities ($BI_3 > BBr_3 > BC1_3 > BF_3$) are reversed from the order expected from a consideration of the relative electronegativities of the halogens. For example, boron trifluoride is the weakest acceptor with electron donors such as amines even though fluorine is the most electronegative of the halogen substituents. These observations are usually rationalized by assuming back-bonding in which nonbonding halogen electrons interact with the vacant p orbital on boron. If this does occur to a significant extent, fluoride would be the most effective back-bonding halogen and iodide the least, thereby rationalizing the observed order of Lewis acidity and the unexpectedly short bond lengths observed in all the trihalides. This presumed bonding order was confirmed experimentally in investigations of gas-phase photolysis spectra of boron trihalides.[89]

Table 11 outlines some physical properties of the trihalides including bond lengths and bond energies. Each property tends to vary continuously from gaseous boron trifluoride to the relatively high-boiling boron triiodide. All of the pure compounds are colorless, although the bromide and iodide become colored when exposed to light, apparently as the result of photolytic liberation of the free halogens.

Table 11 Physical properties of boron trihalides

Property	BF_3	BCl_3	BBr_3	BI_3
Mp (°C)	−127.1	−107	−46	−49.9
Bp (°C)	−99.9	12.5	91.3	210
B-X Bond length, Å	1.30	1.75	1.87	2.10
B-X Bond Energy, kJ mol^{-1}	646	444	368	267

Note: X = halogen.

9.2.2 *Preparation and Uses*

Boron Trifluoride. Boron trifluoride is prepared commercially by the reaction of fluorosulfonic acid (HSO_3F) with boric acid in sulfuric acid followed by purification using fractional distillation. It can also be prepared by the reaction of fluorspar (CaF_2) with boric acid or its equivalent, borax ($Na_2B_4O_7{\cdot}10H_2O$) and sulfuric acid, or by the two-step reaction of borax with hydrofluoric acid and sulfuric acid. Various other methods have been reported for laboratory-scale synthesis or preparation of high-purity boron trifluoride. One example of a procedure for preparation of high-purity material is thermal decomposition of benzenediazonium fluoroborate. Boron trifluoride is used in significant quantities as a Lewis acid catalyst in the large-scale production of organic compounds, particularly in Friedel-Craft reactions, and as an epoxy resin curing agent. In this application, boron trifluoride is either used directly, as one of its coordination compounds, or mixed with a promoter. Distillation of the dimethyl etherate of boron trifluoride is used commercially for the separation of ^{10}B and ^{11}B isotopes and the subsequent production of isotopically enriched boron compounds.

Boron Trichloride. Boron trichloride is prepared commercially by the chlorination of boron carbide (equation 15). Direct chlorination of boric acid or a sodium borate in the presence of carbon is an alternative method. Most of the boron trichloride produced is converted to filaments of elemental boron by chemical vapor deposition (CVD) on tungsten wire in a hydrogen atmosphere. Numerous laboratory preparations of boron trichloride have been reported. One of the most convenient is the halogen exchange reaction of aluminum chloride with boron trifluoride or a metal fluoroborate.

$$B_4C + 6Cl_2 \qquad 4BCl_3 + C \tag{15}$$

Boron Tribromide and Boron Triiodide. Boron tribromide is prepared commercially in relatively small quantities by the bromination of boron carbide, and its commercial use is limited. No commercial use for boron triiodide has been reported. Laboratory quantities of boron tribromide can be prepared by the reaction of aluminum bromide with boron trifluoride or a metal fluoroborate. Boron triiodide can be prepared in small quantities by the reaction of boron or a metal tetrahydroborate with iodine.

9.2.3 *Reactions*

The four boron trihalides are quite reactive and undergo similar reactions with a variety of other chemicals. Most of these reactions are based on the strong Lewis acidity of the halides. The boron trihalides form complexes with ethers (equation 16) and other Lewis bases based on N, S, P, and As atoms.

$$BX_3 + OR_2 \longrightarrow R_2O{\cdot}BX_3 \tag{16}$$

If the donor molecule contains reactive hydrogen, as H_2O, NH_3, PH_3, AsH_3, R_2NH, RNH_2, and lower alcohols, hydrogen halides are produced (equations 17–19). In these reactions the initial adducts formed with boron trifluoride are much more stable to protonolysis than with the other trihalides, and these reactions proceed slowly or not at all.

$$BX_3 + H_2O \longrightarrow B(OH)_3 + 3HX \tag{17}$$

$$BX_3 + R_2NH \longrightarrow (R_2N)_3B + 3HX \tag{18}$$

$$BX_3 + 3ROH \longrightarrow (RO)_3B + 3HX \tag{19}$$

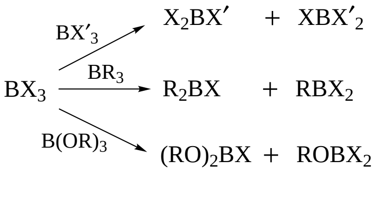
Some of these reactions, particularly with the strongest Lewis acids, are rapid or even violent at room temperature. In general, boron trifluoride is significantly less reactive than the other halides. For example, it forms two distinct hydrates that are stable to 20 °C. This resistance to hydrolysis and strong Lewis acid character has led to the relatively wide use of boron trifluoride as a reaction catalyst in a number of organic reactions.

Exchange reactions are common between boron halides and alkyl or aryl substituents, other halides, alkoxy and aryloxy groups, and diborane. Some examples are shown in Scheme 2.

Reduction of boron trihalides to elemental boron can be accomplished by heating with alkali metals, alkaline earth metals, or hydrogen. Under the proper conditions, reductions of this type can also yield diborane and, under selected conditions, boron subhalides (see below). Metal hydrides also react with boron trihalides to give diborane. Boron nitride and boron carbide have been prepared by the high-temperature reductions of boron trihalides with ammonia and methane, respectively, and deposited on metal substrates by CVD.

9.3 Fluoroborates

These compounds are also referred to as tetrafluoroborates, but the tetra-prefix is usually dropped. Fluoroborates and fluoroboric acid have been studied extensively because of their commercial uses as fluxes and in metal-plating baths.[90] Fluoroboric acid, HBF_4, does not exist as such but can be stabilized as a solvated ion pair in aqueous solution. Commercially available solutions contain approximately 48% HBF_4 as $H_3O^+\ BF_4^-{\cdot}4H_2O$. Other names used less frequently for this reagent are hydrofluoroboric acid, hydroborofluoric acid, and tetrafluoroboric acid. The boron atom in fluoroboric acid is nearly tetrahedral, with almost equidistant B–F bonds,



Scheme 2

and F–B–F angles close to the theoretical 109°. It is a strong acid in water with a pK of −4.9 compared to −4.3 for nitric acid.

Fluoroboric acid is produced commercially by the reaction of 70% hydrofluoric acid with boric acid. Fluoroborate solutions must be treated like hydrofluoric acid and handled in corrosion resistant equipment consisting of polyethylene, polypropylene, or neoprene-type rubber. The major use of fluoroboric acid is as an intermediate in the preparation of fluoroborate salts. It is also used in electroplating aluminum and in metal cleaning operations.

Metal fluoroborates are produced either from fluoroboric acid and metal salts or by reactions of boric acid and hydrofluoric acid with metal salts. Fluoroborates of alkali metals and ammonium ions tend to crystallize as hydrates and are water soluble except for those of potassium, rubidium, and cesium. The major use for these compounds is as a high-temperature flux. Transition metal and other heavy metal fluoroborates are not as well known and well characterized. They are usually prepared from fluoroboric acid and an appropriate salt and are sold as 40–50% water solutions. Some fluoroborates from metals such as tin, lead, copper, and nickel are prepared by electrolysis of fluoroboric acid. The transition and other heavy metal fluoroborate solutions are used primarily as plating solutions and catalysts.

9.4 Boron Subhalides

A review of the boron subhalides (halogen:boron ratios <3) is available.[91] The simplest monohalides such as BCl, BBr, and BI are unstable and highly reactive. Unstable boron dihalide radicals (BX_2) have been studied spectroscopically. Diboron tetrahalides B_2X_4 are known for fluorine, chloride, bromine, and iodine. Research on these compounds has been limited by difficulties in preparing suitable quantities for investigations. The fluoride and bromide derivatives are usually prepared from the tetrachloride, which is obtained in the laboratory by passing BCl_3 through an electric discharge, or more efficiently, by using a radio frequency discharge in the presence of mercury. Methods have been devised to convert B_2Cl_2 into B_2F_4 or B_2Br_4. The corresponding iodide has been prepared by the radio frequency discharge reaction of BI_3. Diboron tetrachloride, a yellow solid having a melting point of 94 °C, has been studied in the greatest detail.

Diboron tetrachlorides undergo a variety of reactions, including facile additions to alkenes similar to hydroboration (equation 20). The reactions of boron subhalides, particularly B_2Cl_4, with organic and organometallic compounds, have been studied in some detail.
